has repeated them is generally admired, the following homot has been applied to him: *Excess Arabum melius Latinitatis conditid.*

Gen. Ch. *Cal. PERIANTHUM superior, of four equal teeth. Cor. of one petal, funnel-shaped; tube the length of the calyx; limb fringed, in four equal broad segments. Stam. Filaments four, very short, inserted into the top of the tube; anthers erect, oblong, hollow, half as long as the limb, at length recurved. Pet. German inferior, globular; style thread-shaped, the length of the flower; stigma obtuse. Peric. Berry crowned with the calyx, of two cells, the partitions not reaching quite across, but their central part is (according to Jullien) supplied by a receptacle bearing the seeds. Seeds numerous.

Eff. Ch. *Corolla of one petal, funnel-shaped, superior. Anthers nearly sessile, in the mouth of the corolla. Berry of two cells, with many seeds.*

Obi. *This genus differs from Catechus in its short filaments and the place of their insertion. How far it is distinct from Ranitis, (now made a Gardenia,) except in number, which is of small or no importance, may admit of much doubt. Jullien gives their fruit to be similarly constructed.* We merely notice it here for future consideration.

Two species are described.

1. F. lanceolata. Lamarch, Encycl. v. 2. 432. Illust. 287. "Segments of the corolla obtuse. Berry globose." A much-branched shrub or tree, found in the island of Mauritius, where it is called *Bois de Buits,* or *Faux Buis,* Fass Box, from the resemblance of its leaves to common Box. It has no thorns. The flowers are whitish, axillary, two or three together, on short, simple, silky flanks, with a bell-shaped, toothed bract, like a second calyx to each. Corolla scarcely half an inch long. Berry the size of a black currant. Lamarch reckons two varieties; but those appear to us merely the same plant, gathered at two different seasons of the year, that in fruit having larger leaves.

2. F. olivacea. Lamarch, Illust. 287. t. 67. f. 1. "Segments of the corolla acute. Berry oval." Native of the same country, according to Lamarch, from whom alone we have any knowledge of this species. What he has associated with it in his plate, is an altered copy of *Petisia Liguliflorum* from Brown's *Jamaica,* t. 3:5; but has let this right in his letter-prepar.

**FERNERA,** in Geography, a town of Germany, in the principality of Culmbach; 12 miles S.W. of Culmbach.

**FERNES,** a cape, and also a bay on the W. coast of Edea, one of the Orkney Islands. N. lat. 59° 2'. W. long. 2° 43'.

**FERNY,** a small, regular, well built town, pleasantly situated near the lake of Geneva, with a handsome seat, celebrated for being the residence of Voltaire, at the intersection of two high ways, the one leading from Switzerland to Lyons, and the other from the Franche-Comte to Geneva.

**FERNITE,** a town of the duchy of Savoy; eight miles S.E. of Gratz.

**FERNS,** a small port town in the county of Wexford, Ireland, which is a bishop's see, united to Leighlin. For an account of the united bishoprics, see Leighlin. The bishop's residence is a handsome and convenient palace lately erected in Ferns. This town is 54 miles south from Dublin. Beaufort's Memoir.

**FEROE, or FAROE, Islands,** are situated in the North Sea, between N. lat. 61° 15' and 62° 21'; and with regard to longitude, the town of Thorshavn lies 19° 15' 15" W. from Copenhagen, and 9° 47' 45" E. from Tenerife. They are eighty-four miles distant from the coast of Norway on the eastern side, and forty-five miles from the Shetland isles towards the south-west. It is not improbable, that the free-booters, who at one time infested most of the northern seas, first discovered the way to these islands, where they introduced sheep, in order to supply them with provisions in their frequent cruises. In the time of Harald Harfager, king of Norway, that is, in the ninth century, these islands were inhabited by some discontented Norwegians, who for a long time supported themselves by piracy and occasional incursions into their original country, Norway. These people, it is reasonably supposed, were first subjected to the Norwegian dominion by king Hagen Adelheem, but they soon threw off the yoke, and maintained their freedom, till they were again reduced to obedience by king Magnus the Good; after which period these islands belonged to Norway, till they became a part of Denmark by the union of the two crowns. Christianity was introduced into these islands soon after its establishment in Denmark, A. D. 1007; and they were thought worthy of a particular bishop, who was appointed to reside in the island of Streome. The Norwegians are supposed to have given them the name of Feroe, from the number of sheep which they found in them; *far* in Danish signifies sheep, and an island; others, however, conceive, that the name is derived from *fer,* feathers, an article with which they were always abundantly supplied, or from *far,* or *fjor,* far distant. These islands are in number twenty-two, seventeen of which are inhabited. They occupy in a direction from N. to S. fifteen miles; extend in breadth from E. to W. ten miles; and contain altogether nearly 23 4 square miles. They consist of a group of steep hills or rocks, rising from the sea, chiefly of a conical form, and placed for the most part close to each other, none of which proceed with an even declivity to the shore; but the greater part of these declivities has two, or three, or more sloping terraces, formed by projecting rocks, and covered with a thin stratum of earth, which produces grass. Close to the sea, however, the land in general consists of perpendicular rocks, from two to three hundred fathoms in height. The highest of these hills is Shalinnin, in the southern part of Nordfornore, being two thousand two hundred and forty English feet high. The hills lie so close to each other, that they are separated merely by a brook or rivulet; and between them there are no valleys of any extent. In the higher ground, however, between their summits, are a few dales, covered with wretched grass. The rocks in general consist of trap, much intermixed with feldspar, glimmer and small grains of zeolites. No certain traces of any crater or signs of volcanic eruptions are found here; nor does there seem to be any pumice-flone or lava, unless basaltites, of which there are several columns, belongs to that kind of production. The Feroe islands contain a great many streams and rivulets, which are generally fordable and furnishing trout. Trout is also caught in some fresh water lakes between the hills. After rain these hills present a number of water-falls, the most remarkable of which is Fofia, between Qualvig and Haldersvig, in Nordfornore. These islands abound also in springs, which are of two kinds, cold and warm; of the latter, the most remarkable is Vernakilde in Oilarpe. The Feroe islands which are inhabited are seventeen, and form seven parishes; their names are

Fugle,
Fugloe, Swineo, Videiro, Bordo, Kinooe, Kalfoe, Otarve, Stromoe, Kolder, Hattoe, Nolfoe, Vaagee, Myggenes, Sandoe, Skuwe, the greater Dimon, and Suderoe. Bordo is separated by a narrow channel from Videiro, and is little more than 23 miles long, and at its greatest breadth 1 1/2 mile. It has seven villages. For the other islands, see their respective articles.

In these islands there is no want of good harbours and anchoring places; but there is some difficulty in obtaining pilots. The currents round and between the islands are rapid and strong, especially three days before and three days after new and full moons. There are several whirlpools at some distance from the shores. The turf which prevails round these islands is very remarkable, and in winter and the early part of spring it exhibits a wonderful and awful spectacle. As the Feroe islands lie in the latitude of 62° north, the sun, during the three summer months, is scarcely four hours beneath the horizon, so at that time there is no night; at least there is light sufficient for enabling a person to read and write. But in winter the days are so much shorter, and would be exceedingly dark, if the deficiency of light were not in some measure supplied by the morning and evening twilight. The heat, notwithstanding the high latitude, is more temperate in summer, and the cold less severe in winter than in the more southern provinces of Denmark; the sea round the coast never freezes; and the climate of this mildness of the winter is the vicinity of the sea. The weather in Feroe is never uniform, and the barometer is exceedingly variable. These islands have been under the imputation of being foggy and unhealthy; but though the first charge may be true, the second is not so well founded. The winds and hurricanes in the Feroe islands are so violent among the hills and rocks, as to inspire the traveller with terror. Thunder is not so common as in Denmark; but the northern lights are often seen, particularly in the winter.

Thee islands are at present almost entirely destitute of wood, but this does not appear to have been formerly the case. Attempts have been made at different times to introduce wood, by planting bushes and trees of various kinds, but they have been for the most part attended with little success. The black cattle here are small, and little or no trade is carried on in this article. The cows are much neglected and ill fed; and of course yield little milk. The Feroe heifers are small, with thick drooping heads; they are generally of a fox colour, and some few are almost black. Little attention is paid to them. Sheep, of which there is plenty, sometimes two or three hundred, are the principal riches of these islands; their flei affords them food; their wool clothing; and of the remainder, after their own wants are supplied, they manufacture articles of commerce. The sheep remain out summer and winter, without ever being housed; and on this account many of them are lost. Domestic cats are common, some of which become wild; and dogs are very useful to the peasants, as they affiliate them in the care of their sheep. It would extend this detail too much to enumerate the variety of their fowl and fish. Geese were formerly more abundant than they are now; but these islands have various kinds of ducks, the most remarkable of which, on account of its valuable production, is the eider duck. See Feroe.

One great source of subsistence to these islands is fish. A fowl which abound on the coast, and which are caught either by dragging them out of their holes, or by another method, for which a bird-pole, with a peculiar apparatus, is employed. The operation is regularly adventurous, and attended with danger, among the high and steep rocks, which the bird-takers climb, or from which they are supported by ropes. The catching of seals is also of great importance to the inhabitants of these islands. The fishery at Feroe, however, is much declined; at one time fish was an important article of food and of commerce; but these have now almost entirely deserted the coast. The kinds of fish caught in salt water are the torkil, halibut, and cod. The whale fishery is periodical, and does not now take place so often as formerly; but where it is carried on it produces great advantage to these islands. Small whales come to Feroe in flocks of from one hundred to one thousand; and when it is considered that each fish in general yields one cask of train oil, which falls for nine rix dollars, the value of one fishing will amount to from nine hundred to one thousand rix dollars, besides the benefit which the natives derive from the fish itself, which, if not employed for making oil, affords agreeable and wholesome food. See Whale-Fishery.

In Feroe there are no frogs, toads, lizards, snakes, or serpents, and no amphibious animal of any kind.

The natives of Feroe are, in general, handsome and well-made. In the colour of their hair there is considerable variety. Their complexion exhibits a healthful mixture of red and white, acquiring a brownish cast in hot summers, whilst they are employed in procuring turf. Their features are never disfigured by the small-pox, for this disease has not yet become endemic in these islands. The natives of the Southern islands, though their whole extent be only 15 miles, are of less stature, have round faces, speak precociously, and appear to be much livelier in their actions; whereas the natives of the Northern islands in general taller, have more lengthened countenances, speak flowier, and are much graver in their whole deportment. The women are, for the most part, exceedingly pretty and well-proportioned; many of the people are inclined to be phlegmatic; but they poise their great sensibility. They are of a religious disposition; and when, on a Sunday, they cannot have the benefit of a clergyman's services, they meet in church, sing psalms, hear the service read by one among themselves, and also a sermon. They are peaceable among themselves; affable and friendly in their disposition; and also, according to their means, hospitable, kind and benevolent. They are also kind in all their dealings with one another, and humane and compassionate towards strangers. The language of Feroe consists, in great part, of old Danish, or rather Norwegian words; which, by a corrupted pronunciation, has assumed a foreign appearance. However much of the inhabitants of these islands understand the Danish language, in which the Christian religion is taught. This account of the Feroe islands we have extracted from an anonymous writer who made copies extracts from the communications of a Danish clergyman who resided in them several years, and who had the best opportunity of acquiring himself with their situation, manners, and customs, as well as with their productions, and the manners and customs of the inhabitants.

PEROESIS, MARSIA, in Natural History, a race given by some authors, to marry with, found principally in the Pillars and coasts of Rhoen, and called by the generality of later naturalists, a curious mineral, and the basis by the ancients, terra, or terra fenestra. See Pericope.

PEROKABAD, in Georgia, a town of 11,000 inhabitants, on the coast of Othman; 13 miles N. of Castrum.

PEROM, a few port and good harbours, on the coast of the Rhoen Ocean, in the tropics; fast to the 70th parallel. 50 miles S.S.W. of Travullu, S. lat. 9° W. long.

flowers are unknown to botanists. The fruit is a compressed, roundish, rugged, bordered drupe, not very fleshy, with a compressed nut of two cells, with one seed in each, but it often happens that only one cell perfect its seed. The trunk is 40 or 50 feet high, bearing numerous branches at the top, the ultimate ones very slender. Leaves two inches long, alternate, on short stalks, elliptic-lanceolate, pointed, entire. Fruit in terminal bunches. The bark of the tree is smooth and ash-colored, milky when wounded. The heart of the wood is a kind of fattin wood, hard and heavy, red variegated with yellow, taking a fine polish. It is found growing in the woods called bois de Férodes, from a name of a former governor of Cayenne, who first introduced it as an article of commerce. Joffrin suspects this tree may be generically allied to the Pariniri of Aublet, t. 254-256. Petacryla of Schreber. They agree in the drupa of two cells, and are not dissimilar in habit.

**Ferulli**, in Geography, cape or point, a cape on the W. coast of Newfoundland, N. of St. John's bay. N. lat. 51°2' W. long. 74°52'.

**Feronia**, in Mythology, derived from fero, to bring relief, or from the town Feronia, near mount Soraceto, was, according to Servius, the patroness of the enfanchised slaves, to whom were prefixed many offerings; this goddess being in high veneration through all Italy. Servius supposes her to be the fame with the virgo Juno, and this supposition is confirmed by an ancient inscription quoted by Fabretti, and expressed in this terms: "Juno feronorum." The Romans appropriated to this goddess the care of the woods and orchards. She had a temple at the foot of mount Soraceto, where an annual sacrifice was offered to her; and it has been said that those who were fully inspired by this goddess walked bare-footed upon coals without being burnt, or suffering any harm. Hierocles in one of his passages (I. 1. fat. 5.) mentions the homage that was paid to this divinity, in walking the face and hands, according to custom, in the face of a mountain which flowed near her temple.

Gen. Ch Cal. Perianth inferior, of one leaf, small, flat, in five deep segments, deciduous. Cor. Petals five, oblong, acute, spreading, much longer than the calyx. Stamin. Filaments ten, inserted into the receptacle, awl-shaped, erect, shorter than the petals, broad and compressed, as well as very hairy, at the base: anthers erect, ovate. Phil. German superior, nearly ovate, style short, conical; stigma blunted, notched. Pfr. Berry of five cells, globular, with a tough roughish coat. Seeds very numerous, in simple rows, attached to the central receptacle.

The only known species is

F. elephantum. Roxb. Coromandel. v. 2. 21. t. 141. Elephant apple. A native of mott woods and mountainous parts of India, flowering, according to Dr. Roxburgh, during both the hot and cold seasons, and ripening fruit in hot and rainy weather. It forms a large tree, with a deeply cracked bark, from which, when wounded, issues a beautiful transparent gum, excellent for water-colours. The wood is white, hard and durable, but splits in the sun. Pulpy part of the fruit universally eaten by the inhabitants of the coast of Coromandel. The branches are thorny. Leaves pinnate, of about seven cleft, entire, smooth, opposite leaflets. Flowers in terminal and axillary clusters, white tinged with purple. Fruit the size of an orange, greenish. Some flowers have an abortive pilil.

**Ferosepoire**, in Geography, a town of Hindooftan, in Moultan, on the Setledge; 48 miles S. of Lahore. N. lat. 31°5'. E. long. 73°59'.

**Ferrácino, Bartholomew**, in Biography, was born at Baffano in Vicentin, in 1692, of parents too humble, that in early life he was engaged in fawing wood as the means of a livelihood. Having a natural genius for mechanics, he soon invented a fan to be worked by the wind, he rendered it so perfect, as to perform his work with expedition and accuracy, without much manual exertion. Success in one invention soon led him to make experiments in other branches of business, in which he likewise succeeded; he made clocks in iron; and invented some useful hydraulic machines; of these, one was formed on the principle of Archimedes' screw, which raises water to a considerable height. His chief work was the noble bridge over the river Brenta, at Baffano, which is greatly admired for boldness of conception, and solidity of construction. Ferracino died soon after he had completed this undertaking. His life was published in 1764, by M. P. Mem, in quarto, who has entered largely into his labours and inventions Now. Dict. Hist.

**Ferrand, Lewis**, was born at Toulon in 1645, where he received the elements of a learned education, but he finished his studies at Lyons. He was originally intended for the law, but he gave early proofs of attachment to Biblical literature and theology, by publishing, when he was but nineteen years of age, "A paraphrase on the fewest penitentiary Psalms." In the following year he went to Menevia, with a view of employing all his powers in a new translation of the Bible from the Hebr. His zeal being now checked by the want of encouragement, he returned to France, applied himself to the law, took his degrees at Orleans, and was admitted an advocate of the parliament of Paris. In 1670 he published a work, consisting of a plan of annals of the kings of France and the Ottoman emperors: in 1679 he published "Reflections on the Christian Religion, containing Explanations of the Prophecies of Jacob and Daniel relating to the advent of the Messiah," in two vols. abounding in much curious chronological and historical matter. For this work, on the account of his high merit, he obtained a pension of 800 livres. M. Ferrand died in 1699, having published many other works besides those which have been referred to, almost entirely on theology. The labour in which he was engaged was entitled "A Collection of Dissertations, &c. on the Bible, in the Latin language," only one volume of which was published during his life. He left behind him a great mass of MSS. on various topics of thee, one was committed to the press entitled "Of the knowledge of God." He was esteemed by his contemporaries a very able and very learned man; and he was unanimously most indefatigable in whatever he undertook. Morei.

**Ferrandus, surnamed Fulgentius**, who flourished in the 6th century, was an African by birth, and a disciple of St. Fulgentius. When that prelate was banished by the Arians to Sardinia, Ferrandus accompanied him; but on his return he was chosen deacon of the church of Carthage, when he entered with much zeal into the question which was the subject of warm discussion at that day, "whether it could be said that one of the persons of the Trinity suffered on the cross." Ferrandus died about the year 537, leaving behind him many works that were highly thought of by his contemporaries. The most considerable was "A Collection of Ecclesiastical Canons," for reforming discipline in the churches of Africa. This is one of the most ancient collections
collections of canons among the Latins. It consists of between two and three hundred abridged from the councils of Africa, Ancyra, Laodicea, Nect, Antioch, &c. A life of Fulgentius has also been ascribed to Ferrandus, but by some authors it has been ascribed to another of the prelate's pupils. Moreri.

FERRAR, Robert, was an eminent divine, born at Halifax, in the county of York, at which place he received the rudiments of his education; for its completion he was sent to Cambridge, and afterwards was admitted as a candidate into the university of Oxford. Having early embraced the doctrines of the Reformers, and in their defence displayed a considerable portion both of learning and zeal; he was patronized by archbishop Cranmer, who appointed him one of his chaplains, and subsequently procured for him the bishopric of St. David's. During the regency of Edward VI. he fell into disgrace at court, on fulmination of his entertaining heretical opinions, and was put in confinement on charges falsely preferred against him, as was subsequently proved; for in the reign of Mary he so far distinguished himself in the Protestant cause, as to excite the vengeance of the intantate persecutors of truth, bishop Gardiner; by whom Ferrar was immured to recant his errors, and, perfiling in his refusal to comply, was condemned as an heretic, and burnt at the stake in the town of Cambridge, South Wales; where an inhumed monument still records the magnanimity of that计量, and delineates the spot on which the pious prelate suffered martyrdom in the year 1555. Fox's Acts and Monuments.

FERRARA, in Geography, a city of Italy, and capital of the exarchate of the Lower Po, situated on a branch of the Po, on the frontiers of the Venetian states. Fortified by Sinagoras, exarch of Ravenna in 575, it was erected into a bishopric by pope Vitalian in the year 657, and in 735 it was made an archbishopric. It was afterwards enlarged, and became celebrated under the princes of the house of Este; but having lost its dukedom it declined in magnificence and wealth. It is about four miles in circumference, and defended by a citadel, strong walls, and bastions. The streets are handsome, and it has many magnificent palaces and churches. They reckon, besides the cathedral, which is ancient, 109 churches, 38 convents, and about 14,000 inhabitants. The air in its environs is unhealthy, owing to the account of the marshes that encompass it; Ariosto's buried in the Benedictine convent, and in the hospital of St. Ann Taio was confined as an idiot. Its university was founded in 1392 by Albert, marquis of Ferrara; 4 miles S.E. of Mantua. N. lat. 41° 51'. E. long. 13° 35'.

FERRARESE, late a province of Italy, in the state of the church, is bounded on the N. by the Po, on the E. by the gulf of Venice, on the S. by the Romagna and Bologna, and on the W. by the Mantuan and Modenese. The whole country is fertile, but low and marshy, being often overflowed by the waters of the Po. After passing from the house of Este, to which it was granted by the emperor Frederic II., to the state of the church, it now constitutes the department of the Lower Po, being ceded by the pope in 1797. It has few towns, being wholly cultivated, and thinly inhabited. The chief places are Ferrara and Comacchio.

FERRARI, John Matthew, in Biography, known by the surname of De Gradibus, or De Graudis, from the villa in which he was born, in the Milanese, was one of the most expert physicians of his time. He professed medicine at Milan, whence he was invited to Pavia, to occupy the medical chair in that university, an appointment which he fulfilled with great applause. He was also physician to Maria Bianchi Visconti, duchess of Milan. He died in 1480. He has left three large works, which have been frequently reprinted. The first is "A Commentary on rhases;" the second is entitled "Expositiones super vicesimam secundam Penit.," "Canonis Avicennae;' and the third also "A Collection of the Opinions of Avicenna, and Rabbi Moses."

FERRARI, Odonavio, was born at Milan in 1518, and having pursued a regular course of studies, he was made professor of moral philosophy and politics in the Casalbano college, a post which he occupied eighteen years. He was afterwards professor at Padua, or Pavia, but returned to Milan, where he died in 1586. He was intimate with the most eminent scholars of his time; and published an introduction to the Aristotelian philosophy, entitled "De efficientia Encyclicity," and another work, "De formibus Exotericher," which treats on the esoteric books of Aristotle. But his most valuable work in "De Origine Romanorum," devoted to the detection of the forgeries of Ausonius of Viterbo. He translated Athenaeus into Latin, and wrote notes upon Aristotle. Moreri.

FERRARI, Lewis, inventor of the first method of resolving biquadratic equations, was born at Bologna about the year 1520. He studied mathematics under the celebrated Cardan, who, having a problem given him for solution, gave it his pupil as an exercise of his ingenuity. This led to the discovery of a new method of analysis, which is precisely that of biquadratic equations. Cardan published this method, and assigned the invention to its real author, and, but for this liberal conduct of the master, the pupil, were not of publishing anything himself, would have been unknown to posterity. At the age of eighteen he was appointed a tutor in arithmetic, and was equal to the task of disputing with the most distinguished mathematicians of his own age. He was afterwards appointed professor of mathematics at Bologna, where he died in 1575. Ferrari was an excellent classical scholar, a good geographer, and well versed in the principles of architecture. He was, however, addicted to astrology. Hutton's Math. Dict. Moreri.

FERRARI, Francis Bernard, was born at Milan in 1577. He was educated in his native city, attracted the notice, and acquired the patronage of archbishop Borromeo, who, having projected a grand library at Milan, appointed Ferrari to travel through different parts of Europe to purchase the best books and MSS. that could be obtained. With this view he visited Spain and Italy, and procured a vast number of valuable works, which laid the foundation of the Ambrosian library. To this institution he was appointed the librarian, and created doctor. In 1638 he was nominated director of the college of Nobles, then recently erected at Padua, but the state of his health obliged him to resign that situation in less than two years. He returned to Milan, where he died in 1699, having attained to the ninety-second year of his age. He left behind him numerous works in ecclesiastical and profane antiquities in an unfinished state. His chief publications are, "De Antiquo Ecclesiasticorum Epistolae generis," lib. iii. Milan, 1613, 4to. "De Ritu Sacram. Eccl. Cathol. Conuenition." lib. iii. Milan, 1652, 4to. which was afterwards reprinted by Gravinus; and "De Ritu Veteranorum Acclamationibus et Plantis," lib. vii. this also is reprinted in the fifth volume of Gravins's Rom. Antq. Ferrari was author likewise of "A Treatise on the Furnace of Christians." Moreri.

FERRARI, Ottavio, was born at Milan in 1507, and to quickly did he establish his literary reputation, that at twenty years of age he was chosen professor of eloquence in the Ambrosian college. In 1684 he occupied the same post in the university of Padua, where he was also appointed professor.
professor of the Greek language, and by his means that fe-
mininity was restored to its ancient splendour. On account
of his extraordinary services he received a stipend of two
thousand florins; for a panegyric in praise of queen Chris-
tian he was rewarded with a golden collar, value one thou-
sand ducats, and another, published in honour of
Lewis XIV., obtained him a pension of 500 crowns for five
years. He was appointed historiographer to the city of
Milan, and compiled eight books of its history, but either
the want of necessary documents, or the fear of offending
the house of Austria, or his benefactor the king of France,
caufed him to leave his papers unfinished. He was well
known as an antiquary, and published several learned works
on that subject; there are "De re vellariis," to which he added
"Anatelas," and dissertations "De Lonicens Sepul-
chralibus veterum," "De Pantomimis et Mons," "De
Babrius et Gladiatore,". He died in 1634. Moreni.
FERRARI, JOHN BAPTIST, botanist of Sienna, deeply
learned in the Oriental languages, published, in 1622, a Syrac
dictionary, with a view of furnishing biblical scholars with
such Syriac words as occur in the scriptures. It is well and
highly spoken of by Simon and Labbe. He was author of
"Flora, feu de florum cultura;" alio of "Hesperides, fide
de Malorum Acerrorum cultura et us;"); He died in 1655.
Moreni. See FERRARIA.
FERRARI, PHILIP, was an Italian monk, who flourished
in the 17th century, and taught mathematics in the uni-
versity of Pavia. He recommended himself to the clemence
of several popes, as Clement VII., Paul V., and Urban VII.,
and was twice general, and twice vice-general of his order.
He was author of "Typographia in Martyrologium Ro-
nanorum," "Epitome Geograph. lib. iv.," but his principal
production was his "Lexicon Geographicum," which has been frequently reprinted. Moreni.
FERRARI, BENEDICTO, of Reggio in the Modenese
state, spent the chief part of his life at Venice, where,
though the inhabitants of that city cultivated, and encour-
gaged the drama with more diligence and zeal than any
other city in Europe, during the latter part of the 17th
century, and the beginning of the last, yet they were not
very early in its establishment; as the first regular opera or
drama fct to music which was performed at Venice after the
invention of recitative was "Andromeda," written by Ben-
detto Ferrari, and set to music by Francesco Minelli of Ti-
voli, in 1637. Ferrari was himself a celebrated performer on
the lute, an able poet, and a good musician; who, col-
lecting together a company of the best fingers in Italy,
brought this opera on the stage in the theatre of S. Caflano,
at his own expense, in a very sumptuous manner. An
e.xtraordinary influence of spirit and enterprise in a private in-
dividual of moderate fortune, to vie with princes in an ex-
bition of which they only could support the splendour.
(Le Glorie della Poet. et della Mus.) Ferrari was not only
qualified in an eminent degree for directing such enterprises,
but for supplying the principal materials; from his excellent
performance on the lute, he was very early styled by Ferrari
della Torba. He was a poet, a compiler, and a father in
his own drama. For five succeeding years, he annually pro-
duced an opera, which being collected into volumes in
1651, the printer informs the reader, that Benedetto had
still twelve more musical operas to give to the public. In
1638, "La Maga fulminata," by the same poet and musician,
was exhibited at the expense and risk of Ferrari and of five
or six of the performers, in a very sumptuous and mag-
ificent manner, though the expense did not amount to more
than 2000 crowns. A sum which, at present, (says the
author of "The Glory of Poetry and Music"
1730) is hardly
sufficient to satisfy the demands of an ordinary singer. But
at this time the performers either shared in the profits, or
were content with a moderate salary; public fingers being
then but seldom wanted, and that only in the capital cities
of Italy; whereas, at present, dramatic representations
abound in villages. Ferrari was author of both words and
music of two operas, "Armida," in 1639, and "Il Pastor
Reggio" in 1649; it was, however, much easier to set those
dramas than to write, as these operas preceded the invention
of airs, the dialogue being only carried on in recitative,
till about the year 1649, when, in the opera of "Giofone,"
written by Ciconi, and set by Cavalli, it is said that the
grace recitative began first to be interrupted by that ana-
crotic kind of liaue which has since been called aria.
Storia Crit. de' Teatri del Dottor Napoli Signorelli.
FERRARIA, in botany, so named by Burmann, in the
Epitome of the Imperial Academy of Natural Sciences
for 1761, in honour of John Baptist Ferrari, a Jesuit, who
published at Rome, in 1633, a quarto volume on the culture
of flowers, the pomposo plates of which are said to have been
drawn by Guido Reni and Pietro da Cortona. He pub-
lished also at Rome, in 1649, a full and splendid work, in
folio, on the culture of orange-trees. Linn. Gen. 165.
Gen. Ch. Col. Spatii of several inflated leaves.
Perianth none. Cor. of six petals, regular, cohering by their
claws, reflexed, pointed, crumpled, with involute points; the
three alternate ones rather the smallest. Stam. Filaments
three, united into a tube in their lower part, equal, spread-
ing above; anthers dilomatic, two-celled. Pet. German
inferior, obovate, obtuse, somewhat triangular; stipe thread-
shaped, the length of the flaments; rigmas three, dilated,
petal-like, cloven, deeply fringed, convexing. Peric. Cap-
ule oblong, triangular, of three cells and three valves;
partitions contrary to the valves. Seeds numerous, roundish,
in two rows.
Eff. Ch. Spatia inflated. Petals five, regular, crumpled
and fringed. Stigmas three, petal-like, fringed. Capsule
of three cells. Seeds roundish. This genus is very pro-
portioned by Mr. Gawler to the original species, and
another which he has described, excluding F. Pavia of
Limnaea, and isioria of Willdubon.
Jacq. Hort. Ind. t. 65; Curt. Mag. t. 144. (Fl. indicae)
ileiococcus fulvus, radice tuberose; Ferrar. de Pl. Cultura
168. t. 171.) "Border of the corolla three as long as
the claws. Lobes of the authors close." Native of the Cape
of Good Hope, cultivated by Miller at Chelfin in
1759. Art. Hort. Kew. v. 3. 305. It flowers with us early
in the spring, being kept in a greenhouse, like other Cape
bulbs. The laves are equitant, somewhat glaucous, inflat-
ed at the base, and the fmal leaves and spathe resemble them,
only being shorter. The flower is brachied above, bearing
numerous, very tenuous flowers, of a lingering and curved ap-
ppearance, variegated with purple and white, and bordered
with brown.
2. F. antherosa. Gaw. in Curt. Mag. t. 561. (F. vir-
dilora; Andr. Repop. t. 235. F. Ferrariola; Willd. Sp.
Pl. v. 3. 581. Mor. Ferrariola; Jacq. Coll. v. 4. 141.)
"Claws of the corolla equal to the border. Lobes of the
authors disarticulated." Native of the Cape of Good Hope,
introduced by Mr. G. Hibbert in 1820. It much resembles
the former, but differs essentially in the greater length of
the claws of the petals, the shape and greater size of the
antlers,
Ferrars, George, in Biography, was born at St. Albans about the year 1510. He studied at Oxford, and from thence he removed to Lincoln’s-inn, and became a distinguished pleader in Westminster-hall. He was patronized by lord Cromwell, and obtained the favour of Henry VIII. whom he attended in a military and civil capacity. In 1535 a considerable grant was made to him out of the royal demesnes in Hertfordshire, but, notwithstanding his ample income, want of economy brought his affairs into such a situation, that, in 1542, while reprentative for Plymouth, he was arrested for debt, and thrown into the compter. He was, however, set at liberty by virtue of privilege of parliament, and the officers concerned in his arrest were imprisoned for contempt of the powers and privileges of a representative of the people. In the reign of Edward he accompanied the protector, Somerset, to Scotland, as commissioneer of the army. He was afterwards master of the sports, at a festivity held at Greenwich for twelve days, in order to amuse the king. This appointment is supposed to have been occasioned by some mettalic flouris of his composition, intitled in the “Mirror of Magistrates,” the first edition of which appeared in 1559. Ferrars is laid to have been the author of “The History of the Reign of Queen Mary,” in the Chronicles published under the name of Richard Grafton. He published a translation of Magna Charta, from the French, into the Latin and English, and other laws enacted in the time of Henry III. and Edward I.

Ferrato Sasso, an historical painter known under that name, but whose real name was Giovanni Battista Salvi. He derived the former appellation from being born at an ancient castle so called, on the borders of the territory of Urbino, in 1504. He went to Rome to study the works of Raphael, then, as since, the admiration of the world. Francisco Penni assisted Salvi in his studies, who had obtained great skill in copying; but his original works do not exhibit much comprehension of mind. He died in 1590, at 86 years of age.

Ferrato, Cape, in Geography, a cape on the eait coast of Sardinia. N. lat. 39° 31’. E. long. 9° 34’.

Ferratt, Cape, or Cape Misjuff, a cape on the coast of Algiers. N. lat. 36° 9’.

Ferre, Cape, a cape on the S.E. coast of Martinico. N. lat. 14° 30’. W. long. 60° 30’.

Ferred-anah, a town of Africa, in the kingdom of Tunis, was formerly, according to Dr. Shaw, the largest city of Bizantium, though its ancient grandeur is exhibited only in a few granite and other pillars, which the Arabs have suffered to remain. It was well watered by a stream which ran under the walls, and by wells within the city, encompanied by a corridor, and vaulted over with cupolas. The circumjacent country, however, is dry, barren, and inhospitable, for want of water. Several circumstances lead us to conclude that it was the ancient Thala, mentioned by Tacitus, or Telepte; and that Thala and Telepte were the same; 15 miles S.W. of Tunis.

Ferrin on the Vocal Organs, in Music. See Voice.

Ferreira, in Geography, a town of Spain, in Granada: 18 miles S.E. of Granada.—Albo, a town of Portugal, in the province of Alentejo; 13 miles W. of Beja.

Ferreira des Aves, a town of Portugal, in the province of Beira; 15 miles N.E. of Viseu.

Ferreola, in Botany, from ferrum, iron, alluding to the hardness of the wood. Roxb. Corom. v. 1. 35.
Ferreti, Eximero, in Biography, born at Callèt-Franco, in Tuscany, in 1489, studied at Pisa and Sienna, and became secretary to cardinal Salviati at Rome. He was admitted an advocate at the age of nineteen; after which he was made professor of law, and secretary to Leo X. This office he filled with much reputation for several years, and then retired to his own country. On his return he accompanied Montferrat, the commander of the French army, to Rome and Naples. On his return he was taken prisoner by the Spaniards, and obliged to pay a high ransom for his liberty. He next went to France, and taught the law at Valence with great reputation. He was then employed in various diplomatic missions, and as councillor of the Parliament at Paris. At length, after various negotiations, he finally became protector of the law at Avignon, where his lapse was raised to a cardinal's crown. He died in 1552, and when his successor Crecenia began his lectures by fractures upon Ferreti, the scholars showed their attachment to their old master by hailing and driving him from the place. Ferreti was a man of general learning, and well acquainted with classical literature. He gave an edition of the principal orations of Cicero. Boyle. Moretii.

Ferreti, an historian and poet of Vicenza, was born about 1266, and took a considerable part in the restoration of polite literature in Italy. He wrote, in Latin, a history of Italian affairs, from 1250 to the year 1288. This is one of the best compositions of the age, and was first printed in Muratori's Collection of Italian writers. Moretii.

Ferretti, in Geography, a town of France, in the department of the Upper Rhine, and chief place of a canton in the district of Altkirch. The place contains 6,517 inhabitants, on a territory of 226,314 square miles, in 31 communes.

Ferretto, in the Glass Trade, a substance which serves to colour glass. This is made by a simple calcination of copper, but it serves for several colours. There are two ways of making this: the first is as follows: take this plates of copper and lay them on a layer of powdered brimstone, in the bottom of a crucible; over these lay more brimstone, and over that another layer of the plates, and so on alternately till the pot is full. Cover the pot, put it in a wind-furnace, and make a strong fire about it for two hours. When it is taken out and cooled, the copper will be found to calcined that it may be crumbled to pieces between the fingers like a friable earth; it will be of a reddish, and in some parts a blackish colour. This must be powdered and sifted fine for use. Neri's Art of Glass, p. 30.

The other way is less easy, but it makes a more valuable ferretto. It is this: make a number of stratifications of plates of copper and powdered vitriol alternately in a crucible, which place on the floor of the glass-furnace near the eye, and let it stand there three days; then take it out, and make a new stratification with more fresh vitriol, and calcine it again as before; repeat this operation six times, and a most valuable ferretto is produced.

Ferri, Paolo, in Biography, who flourished in the 17th century, was born at Metz in the year 1591. He pursued his theological studies with so much zeal that he was introduced to the ministerial office when he was but 19 years old, and even then he had appeared as an author by a volume of poems written in the moments of relaxation. He possessed very extraordinary pulpit talents, and was the most popular preacher among the reformed in his province. He died of the stone in 1669, in his 79th year. The works published during his life were chiefly theological, but he left behind him collections for a history of Metz, in three or four volumes folio, which are referred to by Calmet as abounding in curious researches. In the height of his popularity he was charged with having received an annual pension of five hundred crowns from cardinal Richelieu, as a bribe for his services in attempting to promote an union between the Catholic and Protestant religions. This charge has been fully investigated, and proved to be without the smallest foundation. Bayle. Moretii.

Ferri, il Cavalier Baltazar, of Perugia, in the 17th century, is inflamed by Roufseau, in his "Muf. Dict." as the most extraordinary vocal performer that ever existed. "This singular and prodigious finger," says he, "who had such talents as all the sovereigns in Europe courted and feized by turns, was loaded with gifts and honors during his whole life, and his powers and glory all the more extended with his life, and which lasted after his death. Every panegyric that was written upon this musician, breathes rapture and enthusiasm; and his contemporaries all unite in affirming, that a talent so perfect and so rare, was above all competition, and had even silenced Envy herself. It is impossible, say they, to express the brilliancy of his voice, or the graces of his style. He had all the characteristics of different styles in the highest perfection; he was lively, dignified, grave, and tender, at his pleasure, and all hearts were melted by his pathos. Among the infinite passages of the extremest difficulty which he performed with his voice I shall only repeat one. He ascended and descended in one breath two full octaves in a running stroke, in chromatic degrees of half notes with such accuracy, though without accompaniment, that, if suddenly the bafe was struck to any one of these intervals, whether flat or sharp, the exact intonation was instantly felt in an astonishing degree by the audience." Bontempi Iloria Muf.

We used to wonder whence Roufseau took this splendid account, as we found nothing so marvellous elsewhere; in Quadri's ample list of opera fingers, from the year 1734 to 1744, amounting to 273, no such name as that of Ferri occurs. We find him not in Padre Martin, Algarotti, Planelli, Napoleon Sgionelli, Artega, or Eximier, and it seems as if Bontempi, in imitation of Apelles the painter, who composed the face of his Venus of the best features of all the beauties of Greece, had rather told us what was to be wished in a perfect finger than what really ever did exist in any one mortal; and we cannot help thinking that Bontempi has coloured his piece the higher from Ferri having been his countryman. One great finger may have possessed two or three of his excellencies at milt. But exaggeration is the constant companion of panegyric and fatire. If a finger of the name of Baltazar Ferri ever saw the light, and had transcendent powers, they are certainly magnified à la Herfcheil: but his name not occurring in any other musical work, or dramatic perfonce of the innumerable operas that we have collated and examined, obliges us to doubt the authenticity of the account given us from Bontempi by the ingenious and enthusiastic citizen of Geneva.

Monf. Laborde has abridged the tale from Roufseau, and placed the name of Ferri in Quadrio's list, between Cavalli and
and Picta, among fitters who flourished between 1690, and 1700; but non efi inventus either there or elsewhere.

FERRI, Ciro, an historical painter, born at Rome in 1634. He was a favourite disciple of Pietro da Cortona, whom he assisted in finishing several of his works at Florence, and at Rome; and whose style he so nearly adopted that their pictures racy sometimes be mistaken for each other. Generally, Ferri has left grace of design, left care in his actions and draperies, and his comports of mind; but he has more fulness and carefulness of finish than his master. His St. Ambrose in the church of that saint at Rome offers the fairest comparison between them and Romanelli, a fellow scholar with Ciro Ferri. His principal works in fresco are in the Palace Pitti, at Florence, and at St. Maria Maggiore of Bergamo.

FERRIER, Jeremias, a Protestant minister, and professor of divinity at Niames in Languedoc, in the beginning of the 17th century, maintained in public debate that pope Clement VIII. was properly and truly Antichrist. For this liberty of speech he was arrested and thrown into prison at Toulouse; from the effects of which he escaped, in consequence of an arrest from Henry IV. forbidding persons to molest him on account of that business. Notwithstanding Ferrier's zeal in the issue referred to, he was one of the first who, in the political assemblies of the proprietors, opposed their proceedings in support of their civil and religious privileges and immunities. He began soon to be infested of having been induced by a bribe to desert his cause, and was forbidden to appear in their assemblies again. His conduct in other respects was equally reprehensible; and he was prohibited from exercising his ministry within the province of Languedoc. He now turned his attention to the law, but the populace, who are ever indignant at the treachery of public characters, attacked him publicly in the streets, with roses, and other missile weapons, so that his life was in imminent danger. Not contented with the injury inflicted on his person, they proceeded to ransack his house, burning and destroying his goods and books, and treating with much brutality his wife and children, whom the prudence of the magistrates preferred from greater mischief. Hence he became an avowed convert to the Catholic faith, settled at Paris, and took some pains to advance his fortune. His zeal was now equally great in defence of his new opinions, at least of what were considered his new opinions, and he published a treatise, entitled "De l'Antichrist et de les Marques contre le sainct et l'autre Catholique." He was likewise supposed to be the author of "Catholique écart, ou discours des Alliances du bon et tres Christien contre les colonnies des enemis de son etat." M. Ferrier was employed by the king in many affairs of great national importance, and was, in 1626, appointed privy counsellor. He stood also high in estimation with cardinal Richelieu. He died in 1626, and on his deathbed dictated an epitaph, in which he declared his hearty attachment to the Catholic faith; he went much farther, and even extorted from his children a promise that they would live and die in the communion of Rome. Bayle. Morel.

FERRIERES, in Geography, a town of France, in the department of the Ouan, and chief place of a canton, in the district of Juey; the place contains 689 and the canton 4,981 inhabitants, on a territory of 145 kilometres, in 16 communes. — Also, a town of France, in the department of Loiret, and chief place of a canton, in the district of Montereau; the place contains 1,610, and the canton 9,625 inhabitants, on a territory of 275 kilometres, in 7 communes. Vol. XIV.

FERRILITE, in Mineralogy, a name given by Mr. Kirwan to rocks found at, and in the neighbourhood of Rowley Regis, Staffordshire, and known by the term Rowley flag. It has been considered by many as habit, by others as Floetz greenstone, and by some called win, an indefinite term used in the north of England, and applied to various hard stones.

Its colour is greyish-black, inclining to greenish-black, and, when exposed to the weather, brownish. It occurs massive in great beds, or strata, in the vicinity of Rowley, Didley, Walfall, and the south-west part of Staffordshire; and in some instance in uncommon distinct concretions, particularly at Pockhill, near Walfall, where it is quarried for mending the roads.

Internally it is glistening, from minute crystals of hornblende and felspar, particularly the fractured surface of the latter, which is foliated.

The fracture is generally fine-grained, uneven, but often flat, conchoideal, and fine splintery. The fragments rather sharp edged.

When disintegration has taken place to a considerable extent, it occurs in large globular concretions, which appear to be composed of concentric laminations.

It is generally opaque, but sometimes faintly translucent at the edges, gives a whitish grey streak, hardish, feretates glists, brittle, and difficultly fusible, but less so than basalt of Werner; specific gravity 2.7 to 2.9.

It melts easily, without addition, before the blow-pipe, into a black glass.

It consists of felspar and hornblende in a confusedly crystallized state; it has been analysed by Dr. Withering, with the following result:

<table>
<thead>
<tr>
<th>Component</th>
<th>Percentage</th>
</tr>
</thead>
<tbody>
<tr>
<td>Silica</td>
<td>47.5</td>
</tr>
<tr>
<td>Alumina</td>
<td>31.5</td>
</tr>
<tr>
<td>Oxid of Iron</td>
<td>21.0</td>
</tr>
</tbody>
</table>

It is probable, as so great a portion of it consists of felspar, that it contains potash, but which, at the same time when this analysis was made, was not suspected to occur in the mineral kingdom.

It is also probable that the iron it contains is in a low degree of oxidation, as it exerts so much influence on the magnetic needle. This effect has been long known, as Dr. Patt, in his "History of Staffordshire," mentions, that he drew the compass needle 6" out of its proper direction.

The lower stratums of the Derbyshire coal-flags, which very accurately resembles ferrilite, in its external character, is also very magnetic.

Mr. Kueir has, in Shaw's "History of Staffordshire," given an interesting account of this ferrilite, and lately Mr. G. Watt (in Philos. Trans. 1804), has given a still more interesting detail of experiments made on this SUBSTANCE, by melting, and cooling it with different degrees of rapidity.

When cooled suddenly from the fluid state, it assumed the appearance of an opake black glass, but when the heat was so slowly withdrawn that it was several days in cooling, its appearance was as fomy, and texture as crystalline, as the original rock.

For observations on the phenomena, and conclusions illustrative of the igneous formation of basalt, and other rocks, see Philos. Trans. 1814.

FERRITER'S ISLAND, in Geography. See Blaes.
FERRO, or Hiero, the most westerly of the Canary islands, about 15 miles in breadth, and 45 in circumference. The ascent from the sea is difficult, as it is on all sides high and craggy; but on the summit it is tolerably level and fruitful; abounding with many kinds of trees and shrubs. It produces better grapes, herbs and flowers than any of the other islands; so that bees thrive and multiply here exceedingly, and yield excellent honey. The greater part of the wine of Ferro, which is bad, is distilled into brandy; and there are only three fountains of water on the island. On account of the scarcity of water, sheep, goats, and swine do not drink in summer; but they are accustomed to dig up the roots of fern, and chew them in order to quench their thirst. The larger cattle are watered at those fountains, and at a place where water drifts from the leaves of a tree. The English and French geographers formerly reckoned their longitude from Ferro; but Englishmen now count their longitude from Greenwich, and the Frenchmen reckon theirs from Paris. N. lat. 27° 45'. W. long. 17° 46'.

Ferdogan or Feradon, a mountain of Scotland, in Perthsire; 18 miles S. of Blair Athol. Its height is estimated at 2548 feet above the level of the sea.

Ferro, a handlime; ferry-port of Spain, and harbour for the royal navy, in the province of Galicia, the entrance of which is formed by Cape Prior. It is situated N.N.E. of Corunna, and ten Spanish leagues from Cabo Ortegal, and has been, since the middle of the eighteenth century, one of the most famous maritime places in Europe, and one of the best in Spain. Before the year 1752, Ferro was merely a kind of hamlet, inhabited by the sailors of coaling vessels, and fishermen; but a town has since been raised with an increasing population. The harbour is very safe, being on every side protected from the winds; it is surrounded by redoubts, mounting five cannon on each front, and four on each side; the whole is connected by an intrenchment and a parapet, which mask the interior works. It has one parth, containing about 5600 entitled inhabitants, and occasionally many more, who are attached to the navy and the harbour; and it has two hospitals, one for the inhabitants, and the other for soldiers and sailors. It has also a school for midshipmen, magnificently built; the handloom arbal in the kingdom; a machine for hammering copper to the height vessels; and an extensive rope-walk. The naval barracks are large and commodious, and capable of containing 5600 men. Here is also a good dock-yard. This place is at present the first arsenal of the royal navy of Spain: it was erected by order of Ferdinand VI., the father of Charles III. Art and nature have combined to render the position of the harbour impregnable. The basin for the fleet is immense; each ship having a separate warehouse, where the tackle, rigging, and spare stores are marked, and placed in the greatest order. The "prefidario" is composed of 600 galley slaves, who are employed in the most laborious works of the harbour. Two caisles, that of St. Philip, and that of the Palms, defend the approach of the coast from Corunna and Ferro, and the roads between them. Ferro being more a military than a civil place, has only an alcalde mayor, and some alcaldes of districts, to attend to the police of the town; but it has a military commandant, a governor, an attendant, a complete and numerous staff, who serve for the fortifications, the harbour, and the garrison, which is always very strong. As Ferro is altogether intended for the royal navy, general commerce and all foreign merchant-ships are excluded, except such coaling vessels, &c. as supply articles of necessaries. The environs of the town have many fountains of excellent water, and the town has abundance of river and sea fish. It has only one manufactury, which furnishes sail-cloth. N. lat. 43° 21'. W. long. 8° 11'.

Ferro, a small island in the Pacific ocean, near the coast of Peru. S. lat. 9° 15'.

Ferruginous, denotes a thing to vartake of the nature of iron, or to contain particles of that metal. It is particularly applied to certain mineral springs, whose water, in their passage along the strata of the earth, meets with the ore of this metal, or with pyrites containing it, part of which they waft off, and carry with them, and thus become impregnated with the principles thereof. Such are what we call chalybeate waters.

The waters of Tumbridge, those of Forges, and of the iron spring at Bourges, and many others, are ferruginous.

Ferrugo, the rust of iron, or a kind of calx found on the surface thereof. The rust of iron is a refringent; applied by way of paper, it represses the flour ulcers; and drink, prevents conception; it cures the erysipelas, and exanthematous eruptions. It is of good use in a paronychia, roughness of the eyelids, and a coulodyma. It also strengthens the gums, relieves under the gout, being rubbed on the part affected, and makes the hair grow after an abscission. Wise on water, in which red hot iron has been quenched, being drank, is good for the colicin passions, dysesthesia, disorders of the spleen, cholera morbus, and relaxations of the bowels. See Iron.

Ferrule, in a Sb, a small iron hoop, fixed on the extremities of the yards, booms, &c.

Ferrum. See Iron.

Ferrum Equisinum, in Botany, Horse-shoe Vetch. See Hippocris.

Ferry, a liberty by prescription, or the king's grant to have a boat for passage upon a river, for the carriage of horses and men for a reasonable toll: it is usually to cross a large river. Termes de Ley.

A ferry is no more than a common highway; and no action will lie for one's being disturbed in his passage, unless he allege some particular damage, &c. (3 Mod. Rep. 294.) The not keeping up of a ferry has been held to be inoffensible. If a ferry be granted at this day, he that accepts such grant is bound to keep a boat for the public good. Holt, Ch. J. Shaw. 257.

Ferryland Harbour, in Geography, a bay on the east coast of Newfoundland. N. lat. 47° 5'. W. long. 52° 51'.

Fersin, a town of Perie, in the province of Irak; 22 miles S. of Sava.

Fersina, a river of Tyrol, which rises in a lake near St. Boldo, and runs into the Adige. 2 miles N. of Trent.

Ferte-Allais, La, a town of France, in the department of the Seine and Oise, and chief place of a canton in the district of Etampes. The place contains 786, and the canton 8,583 inhabitants, on a territory of 1673 kilometres, in 18 communes.

Ferte-Bernard, La, a town of France, in the department of the Sarthe, and chief place of a canton in the district of Mimers, surrounded with walls, and containing three fairsbours, 21 miles N.E. of Le Mans. N. lat. 48° 11'. E. long. 0° 44'. The place contains 2314, and the canton 11,720 inhabitants, on a territory of 1814 kilometres, in 14 communes. This is the birth-place of Robert Garnier, a poet.

Ferte-Chaandons, Le, a town of France, in the department of the Nièvre; 12 miles N.W. of Moulins.

Ferte-Fresnay, Le, a town of France, in the department
FERTILE, fruitfulness, that quality which denomina-
tes a thing fertile or prolific.
FEKULA, a little wooden pallet or slice, reputed the
schoolmaster's sceptre wherewith he chastises the boys by
linking them on the palm of the hand.

The word is Latin, and has also been used to denote
the prelate's crozier and staff. It is supposed to be formed of
the Latin, feris, to strike; or, perhaps, ferula in this sense
may be derived from the name of a plant, called, in Latin,
ferula; in English, fennel-staff; the item wherein was an-
ciently used to correct children with.

Under the eastern empire the ferula was the emperor's
crozier, as seen on divers medals; it consisted of a long flem
or shank, and a flat square head. The use of the ferula
is very ancient among the Greeks, who used to call their
princes ἀναγόμαι, q. d. ferula-drawers.

In the ancient eastern church, ferula or nardus signified a
place separated from the church; wherein the penitents or
the catechumens of the second order, called αὐγολογοι,
μερισματος, were kept, as not being allowed to enter
the church; whence the name of the place, the penions therein
being under penance or discipline: sub ferula erant eccles.

FERULA, in Botany, a name in Pliny, derived by some
from feriо, to carry, because its light hollow stalks were carried
in the hand, as walking-sticks; by others from ferio, to strike,
because they were used to chastise school-boys. Fennel-giant.

Gen. Ch. General umbel of numerous rays, globoso;
partial similar to it. General involucrum deciduous; partial
of numerous, small, linear leaves. Perianth scarcely discern-
cible. Cor. Universal uniform; flowers all fertile; partial
of five oblong, straightish, nearly equal petals. Stam.
filaments five, the length of the corolla; anthers simple.
Pist. Genuin inferior, tuberine; stigmas two, reflexed;
stigmas obtuse. Peric. Fruit oval, somewhat compressed,
marked with three elevated lines on each side, separable
into two parts. Seeds two, very large, elliptical, flat on
each side, marked with three distinct ribs.

Eff. Ch. Fruit oval, compressed, with three ribs on
each side. Calyx obdose. General involucrum deciduous.
Flowers uniform, all fertile.

Olf. The stalk of the principal umbel sometimes
throws out lateral opposite flower-stalks.

The inflorescence of umbelliferous plants, whose stems, though
annual, and consequently properly herbaceous, have, when
dry, a woody hardnesh; hence a quilling ancient is report-
ed to have called Ferula wood and no wood. The specious
in Wildenow are 12, but the synonyms are not free from
confusion. The leaves of all are extremely compound,
with narrow, nearly linear, leaflets or segments, often
fining. The flowers are generally copious, yellow, dis-
pelled in a corymbose manner on a round, upright, tall,
hollow stem. The plants when wounded exude an acrid or
fertid resin.—They generally grow in the south and east of
Europe.—The chief species are,

Na. Sc. of Dioecordes. "Luciffs linear, very long and
simple." This was formerly supposed to yield the gum
called Sagoferia, but modern naturalists have thought
otherwise. It is fearfully cultivated but in curious botanic
gardens.
FER

gardens, on account of its cumbersome size and weed-like aspect. It is common in fields about Rome, flowering about Midsummer.

F. Asf-furtida. Linn. Mat. Med. 40. (Asf. furtida; Kempt. Am. Exot. 555. t. 556. "Leafless alternately flatted, acuti. Native of Furtida, the flowering of which is brought to us. (See Furtida.) We know nothing of this plant but from Kempter's account and figure, from whence the above character is taken.

F. perfeta. Wildl. 1415. (Asf. furtida; Hope Tr. of R. Soc. for 1785, 36. t. 3, 4. "Leaflets many-crested, acute, decurrent. Primary unfollic.'—The seeds of this plant were sent from the mountains of Ghilan in Persia to the Peterborough Society, and two roots were committed to Dr. Hope at Edinburgh; whence Chelsea and other gardens have obtained living specimens. The leaves do not accord with Kempter's figure above quoted, and, therefore this is supposed a distinct species from the last, yielding, nevertheless, genuine Asf-furtida, with the flavour of which every part is strongly impregnated, and which exudes in the form of a milky fluid wherever the herb is wounded. The flowers are rather glaucous. Flowers deep yellow. It is perennial and hardy with us.

The fritillaries in the Levant make use of the seeds to transport fire from one island to another. This custom is of the earliest antiquity, and goes far to explain the warlike in Furtida (Op. et Die. t. 5. v. 5.) who, speaking of the fire stolen from heaven by Prometheus, says, that he carried it in a furtula, & corona regina, since the foundation of this fable is undoubtedly owing to what Diodorus Siculus (1. 3.) tells us of Prometheus, that he was the inventor of the seal, or tauros, with which fire is thrown from the flint. It is probable that prince made use of the pitch of the furtula instead of tinder, and taught men to preserve fire in the flake of that plant. Its flake is strong enough to serve for a support, but is too light to wound those who are beat with them. Hence we are told by Diodorus Siculus (abi supra) that Bacchus, one of the greatest legislators of antiquity, enjoined primitive mortals, when they drank wine, to use these furtula cases, because they frequently broke one another's heads with those they used to wear of another kind.

Ferula, in Gardening, comprises plants of the herbaceous, perennial, flowery kind. The species chiefly cultivated being the common fennel giant (F. communis); the glucorum fennel giant (F. glauca); the Tangier fennel giant (F. Tuquetiana); and the broad-leaved fennel giant (F. ferulago). They are all plants which rife to a great height in fudy soils as fuit them.

Method of Culture.—All these plants are capable of being readily propagated by fowing the seeds either in the autumnal or spring fenon, in drills on beds of light earth, at one foot apart, and three inches distant. As the plants advance in growth they must be kept properly clean from weeds, and be well thinned out in order to afford full room for their spreading out.

They should continue in these beds for about two years, when they may be carefully taken up in the beginning of

the autumn, and be planted out where they are to remain. They mostly succeed in the bell manner in the rather moist mellow loamy soils.

They are rather hardy, and well suited for being planted for ornament, in the more extensive borders and clumps of pleasure grounds, where they often continue for several years without requiring any other attention than that of being kept clean from weeds.

Ferula, in the Materia Medica. See Asa-furtida. Ferula, a word used by the ancients to express the horns growing on the deer or stag at the age of two years.

Ferula, among Sages, called also splinters, are little chards of different matter; as of wood, bark, leather, paper, &c. applied to bones that have been disjoined when they are set again.

The bark of the herb fennel-giant, called by some, in Latin, ferula, was anciently much used on this occasion; whence the name ferula became common to all.

FERUS, John, in Biography, who flourished in the 16th century, was a native of Metz, where he took the habit of the Franciscans, and became warden of the order. He preached many years with great reputation, and died in the year 1554. His great work as an author was entitled "Commentaries" on almost all the books of the Old and New Testament. These are characterized by Dupin as large and eloquent discourses, in which the holy scriptures are faithfully explained. He was a candid as well as learned expositor, so that his writings have been in high estimation with Protestants, as well as by the liberal of his own denomination. The author had nearly suffered for his boldness in defence of a friend, and the works of Ferus were infected in the "Index Expurgatoriis." Like many good and excellent men of all persuasions he denied the lawfulness of war, holding it to be repugnant to the distinguishing principle of Christianity, which is universal benevolence. Moreci.

FERZA, in Natural History, a name given by the Persians to that gem which we call the turquoise or Turquoise-flone, a blue, opaque, and fault gem. See Turcois.

FESCAMP, in Geography. See Fescamp.

FESCANNINE, in Antiquity. Fescanneine veres were a kind of satirical verses, full of wanton and obscene expressions, sung or recited by the company, with many indecent gestures and dances, at the solemnization of a marriage among the Romans, and also at the festival of "Harwell-home." Hor, ep. 1. lth. v. 147.

The word is borrowed, according to Macrobius, from fascinum, a charm; the people taking such fongs to be proper to drive away witches, or prevent their effect; but its more probable origin is from Fescanninum, a city of Campania, where such verses were first used.

FESIN, in Geography, a town of Egypt; 18 miles N. of Abu-Girégé.

FESOLI, or Fiesoli, Congregation of. See Jeronymites.

Fesse, in Heraldry, one of the nine honourable ordinaries of the escutcheon, which it divides horizontally in the middle, and separates the chief from the point. It is supposed to represent a broad girdle or belt of honour, such as those with which knights at arms were anciently girded. It polishes the centre of the escutcheon, and contains in breadth
breadth one third part thereof. Thus, he beareth azure, a felle, or, by the name of Elliot.

When the felle takes up less than its proper breadth, it is called a bar.

**Fesse-point** is the exact centre of the ecuelleton.

It is thus called, as being the point through which the felle line is drawn from the two fides; and accordingly it divides the ecuelleton into two equal parts when the ecuelleton is parted per felle.

**Fesse-ways, or in Fesse,** denotes things borne after the manner of a felle; i.e. in a line or range, across the middle of the shield, which the French call en fesse.

**Fesse, party per,** implies parted across the middle of the shield, from side to side, through the fesse point.

This the French express by one word, couped.

**Fesseldorf,** in Geography, a town of Germany, in the bishopric of Bamberg; four miles S. W. of Weißenfayn.

**Fessier,** in Anatomy, the name given by the French to the glutae muscles, which are distinguished as the grand, moyen, and petit. It is derived from fesse, the buttock.

**Festal, Constantius,** in Biography. Besides the works of such musicians as may be classed under the several schools of Italy, there are extant many admirable productions of a much higher period than Palestrina, preferred in the collections of the curious, by Italian composers, the particular place of whose birth or residence has not been recorded. Among these, there is one who for his genius and abilities well deserves a niche in every history of music. This is Constantius Fellsa, of whose compositions there are several in the British museum. There is likewise a motet of this ancient master in the same collection, printed in the fourth book of the "Motetti della Corona," which was printed so early as 1519, ten years before Palestrina was born.

In the third book of Arcadelt's madrigals, printed at Venice, 1541, there are also seven compositions by Collanza Fella, in which more rhythm, grace, and facility appear, than in any production of his contemporaries, that we have seen. Indeed, he seems to have been the most able contrapuntist of Italy during this early period; and if Palestrina and Constantius Porta be excepted, of any period, anterior to that of Carissimi. His motets, for three voices, printed in 1543, are in the church style of the times, a model of elegance, simplicity, and pure harmony; the subjects of imitation are as modern, and the parts sing as well, as if it was a production of the present century. We could not resist the pleasure of scorning his whole first book of three-part madrigals, from the second edition printed at Venice, 1550; for we were astonished as well as delighted to find compositions to much more clear, regular, phrased, and unembarrassed than we expected.

**Festa in Capitis,** in Middle Age Writers, grand holidays, in which the whole choir of the cathedrals were cape.

**Festenberg,** in Geography, a town of Silefia, in the province of Ols.; 10 miles N. of Oels. N. lat. 51° 21'. E. long. 17° 30'.

**Festi Dies,** among the ancients, were feast-days or holidays. Numa distinguished the days of the year into felli, profelli, and intercali. The first were those dedicated to the gods; the second were those allowed to men for the management of their own affairs; the third were shared between the gods and men.

The felli days, again, were divided, according to Macrobius, Saturn, cap. 10. into sacrificia; epules, or banquets; ludii, or games; and seria; and the profelli into sacra, consilia, comprehending flatus, praebites.

**Festing,** Michael Christian, in Biography, an eminent musician, whose instrument was the violin, and who, during many years, was the leader and principal conductor of almost every musical establishment in London.

This performer, with a noble head, little genius for composition, and not a deep contrapuntist, by good feme, probrity, prudent conduct, and a gentleman-like behaviour, acquired a weight and influence in his profession, at which hardly any musician of his class ever arrived. He led during many years at the opera, at Ranelagh, at the concert at Hickford's room, at the Swan and Castle concerts in the city, and often at Handel's oratories. Nor was there a benefit concert for any English professor at that time without a solo on the violin by Mr. M. C. Feiting; and yet there is not a ripieno player on the violin at the opera now, whose hand and abilities are not superior to those of Feiting upon that instrument. Learn hence, ye young professors, that something else is necessary, besides musical talents, to carry you reputedly and comfortably through the world.

**Festing-Men.** See FESTIVALS.

**Festing-Penny,** in Rural Economy, a term provincially applied to the earned given to servants when hired at fairs, or other places.

**Festino,** in Logic, one of the moods of the second figure of syllogisms.

In a syllogism in syllogino, the first proposition is an universal negative; the second, a particular affirmative; and the third a particular negative.

**Festival.** See FESTIVAL and FESTUN.

**Festonersgroat,** in Geography, a town of Germany, in the bishopric of Bamberg; 16 miles S. W. of Bamberg.

**Festoam,** in a General State. See GARLAND.

**Festoon,** in Architecture and Sculpture, is a decoration in form of a garland or cluster of flowers.

The word is French, fêson, which signifies a garland, formed of the Latin, festum, feast.

It consists of a drap or collar of flowers, fruits, and leaves, tied together, somewhat bigger in the middle, and fuppedead by the two extremes; from which, beside the main part which falls down in an arch, two lesser parts hang perpendicularly.

This ornament is made in imitation of the festoons or long chissers of flowers, hung by the ancients on the doors of their temples, &c. on festival occasions.

Festoons are now chiefly used in friezes, tablets, and other vacant places, required to be filled up and adorned, They are sometimes used over or under a niche.

Gen. Ch. Cal. Glume of two valves, ereti, containing many florets, in a flender, roundish, two-ranked spikelet; its valves awl-shaped, pointed, the lower one divided in to two valves; the lower one large, of the form of the calyx but larger, somewhat cylindrical, pointed, awned. "Neclary other of two ovato-lanceolate, acute leaves, gibbous at their base; or of one rather concave, horizontal, notched leaf." Schreb. Stam. Filaments three, capillary, the tee...
shorter than the corolla; anthers oblong. P. f. Germain turbinata; styles two, short, reflexed; stigma downy, Pariet. none, except the corolla closely enclosing, and united to, the feed, not burling. See one, oblong, flender, very sharp at each end, marked with a longitudinal furrow.

Eff. Ch. Calyx of two valves, Spiklet oblong, some-what cylindrical, two-ranked, with sharp-pointed glumes.

A rather large genus, of flender, narrow-leaved, rigid grasse, of a glaucous or greyish-green hue, whose species are often very difficult to define. Some diversity of opinion has existeiled among botanists respecting the generic distillation between Actinida and Browni. (See Browni.) The terminal awn of the former is generally conflant, to which Dr. Smith has added the smoothness, or at least only fine pubescence, of the edge of the inner valve of the corolla; considering the moiit important mark of Browni to confit in the strong bristle fringe of the fame part. With this last character will always be found the proper habit, colour and proportion of the latter genus, whether the aewn be accurately described.

Willdenow has 26 species of Actinida, but many more are now known. Of these 26, 15 have the panicle pointing to one side; the reft have an equally spreading panicle.

The Flora Britannica describes 12 species, to which two have since been added in Engl. Bot. v. E. escul., t. 1917, a glaucous kind found on barren open heaths in Surer and Suffolk; and F. triflora, t. 1918, found by Mr. Crowe at Saham, Norfolk, and since by the Rev. Mr. Holme, F. L. S. at Hinton, Cambridgeshire, and by Mr. G. Don in Scotland. This is Browni triflora of Linnaeus, very near F. gigantea, t. 1820, and like that, approaching too much to the habit of a Browni, but both of them have the two midst effential characters of Actinida.

F. escula. Engl. Bot. t. 585, common in dry open ground, has been much celebrated by Stillingskeet as good for feep, but some late observations have dired the opinion, it being doubtful whether those animals eat it, though it grows where they feed. From this F. escula, t. 1555, was first separated, as a species, in Fl. Brit. having been brought a variety, caufed by its mode of place of growth. But its glumes are very differently shaped from thoife of F. escula. There is more doubt whether anemophilina be really diffini from escula, and also whether rubra, t. 2056, and all its acknowledged varieties, be specifically different from durifcula, t. 470, and dumortier of Linnaeus and Willdenow. On all these subjects expertiments and repeated obervations are wanting. Soil and situation cause great differences in the extent of the creeping roots, and the downiness, as well as size, of various parts. Some of our British species are trierly worth the annuals, as brennise, Engl. Bot. t. 1411, myuros, t. 1412, and uniglumis, t. 1437, the latter remarkable for having more or one valve to the calyx, the other being, as it were, abortive. Others are valuable perennial meadow grasses, as pratensis, t. 1592, and elato, t. 1593.

Of the foreign species, F. pomila of Villars and Willdenow, much better named varius by Jacquin, has an elegantly party-coloured panicle, and is frequent in Switzerland, and other alpine countries in the southern parts of Europe. F. spica is famous in botanic glory as being the long-dubious Anthocyanum paniculatum of Linnaeus, or Nardus spica nardinae of Baunin, and the Poa Gerardii of Allioni. See Trans. of Linn. Soc. v. 1. 111, t. 19, and v. 2. 101. This is a tall handsome perennial grass, with a dense bronze-coloured panicle, and purple anthers. F. fusca, a native of the Levant, has long creeping roots, with very

woolly fibres, formed, like rubra, to bind loose sandy soils. Its brownish panicle approaches in beauty to Poa fragilis. F. indica, copied by Willdenow from Retzii, is the very same plant as fusca.

F. spin fa, Linn. Suppl. 111, a native of the Cape of Good Hope and the Canaries, is a wonderfully rigid, spinous, widely-creeping species, so doubt formed to grow in the moist and sand. This is referred by Willdenow to Poa, see his No. 41, perhaps not amis, but then F. fusca will go near to be a Poa allo, notwithstanding its awns.

F. flavens of Linnaeus and Willdenow is removed by Scopoli and others to Poa. F. decumens is also made a Poa in Fl. Brit., but it is more naturally perhaps, as Haller thought it, a Melica. Thus even the above hit in Willdenow, imperfect as it is, becomes full shorter.

We know of no genus of grasses, that requires to be more studied, either in a botanical or economical point of view, than F. escula.

FESTUM, in a General Essay. See Feat.

FESTUM, in our Laced Books, is frequently used for a general court or assembly, because such were anciently always kept on the great festivals of the year.

Thus, in our chronicles, we read, that in such a year the king kept his festum at Winchester, &c. that is, he kept a court there at that time: " Rex apud Wiston. maximum festum & convivium celebravit, tempore Natalis Domini, convocatis ibidem principibus & baronibus totius regni."

TESTUS, Pompeius, in Biographie, a well-known grammarian, but of what particular age has never been ascertained. He wrote an abridgment of Vernis Phaccus "De Verborum Significatione." Scaliger pronounced this as one of the most useful works connected with the Latin language. It has passed through many editions; the one by Dacier in ulum Delphini, 1681, is reckoned the best. Moreri.

To FETCH Way, in Sea Language, is to be shaken or agitated from one side to another. The term is usually applied to a mast, bowprit, &c. when it is not sufficiently wedged, being loose in the partners; or to any body which is thrown out above by striking with the break or handle.

FETE, Fr. a feall, an entertainment of singing and dancing, introduced in an act of an opera, which always interrupts or fulfills the action. (See Ballet.) These obtrusive entertainments, says Rouleau, are only amusing in proportion as the opera itself is tiresome. In an interesting drama, well conducted, it would be impossible to hear them. We have sometimes thought the fame of the masque in Shakespeare's Tempest, though not in the feat of Romeo and Juliet, which is analogous and connected with the plot.

FETHARD, or FEATHARD, in Geography, a market and town of the county of Tipperary, Ireland, which before the union was represented in parliament. It is at present rather in a state of decay. Fethard is 76 miles from Dublin, and nearly seven north from Clonmel.

FETI, or Fetti DOMINICO, in Biographie, an historical painter, born at Rome in 1559. He was a disciple of Lodovico Cigoli. From Rome he went to Mantua, with the cardinal Gonzaga, on whose accession to the dukedom of
of Mantua he was declared painter to that court. In the works of this painter, who hardly merited to high an exaltation, there is a peculiarity of feeling and expression, but marked with colouring of a brown or blackened hue. He appears to have made his studies among the Lazaroni, as his characters are in general of a low cast, and even his best have their draperies thrown in a common and vulgar manner. Notwithstanding this, his small pictures, being executed with great freedom and firmness of touch, are much admired, which is not a little affihled by their general harmony in the tone of colouring. His works are scarce, as he died when only thirty-five years old at Venice.

FETICHE, in Modern History, a name given in Guinea to their divinities; one of whom is supposed to preside over every separate canton or district, one over every family, and one over each individual, which he worships on that day of the week when he happened to be born. On this day they are drest in white, and, as an emblem of their purity, beinrear their bodies and cloths with a kind of white loam or clay. Those of the better fashion, and especially the chiefs of the people, have, besides this birthday, another weekly festival dedicated to their fetiches, on which they kill a cock or a sheep; which sacrifice is confirmed by the prayers. The word fetiche, in a strict sense, signifies whatever represents their divinities; this may be a mountain, a tree, a large rock, a peculiar fowl or fish, with the head of an ape, or any such thing, as their fancy suggests. They not only believe these material substan-ces, or fetiches, endowed with intelligence, and the power of doing them good or evil, but also that the prieft or fetichere, being of their council, is privy to all that those divinities know, and thence acquainted with the most secret thoughts and actions of men. The household, or family fetiche, narrowly inspects the conduct of every individual in the house, and rewards or punishes according to the respective merits of each. Their rewards consist in the multiplication of their wives and slaves, and their punishments in the want of all these; but the most terrible of all punishments is death. At Cape Coast there is a public guardian fetiche, the highest in power and dignity. This exalted fetiche is a rock, that projects into the sea from the bottom of the cliff on which the castle is built. To this rock's year the black are offered by the priefts with ridiculous gestures and strange invocations, affuring the spectators that he receives verbal anwers from Taha, what times and seasons will be propitious; and for this intelligence every fisherman presents him with an acknowledgment suited to his ability.

Fetiches also denote among the negroes pieces of sophisticated gold, in which is a mixture of one-half or one-third part of silver and copper. These fetiches are cut by them into small bits, to the value of three farthings each, which serve for the current coin of the country. The fetiches of artificial and base gold are strangely shaped in mounds of a black ponderous earth. The negroes have also fetiches of unalloyed mountain gold, which they keep for ornaments, and sell them into trade.

FETIE, in Geography, a town of the Arabian Iraq, on the Embrates; 50 miles N.W. of Baffora.

FETISLAW, or KLADOWO, a town of Servia, on the Danube; eight miles E. of Orfova.

FETLAR, FILLAS, or Theodore's fles, one of the Shetland islands, lying two miles E. of Yell, and nine miles in circuit, consists for the most part of a rich black loam and fonce fand, which yields barley, oats, and palfure. It is separated from Yell by Colgrave sound, and has several creeks, but no secure harbour. Fetlar and North Yell contain 227 houses, and 1389 inhabitants. N. lat. 62° 58'. W. long. 1° 6'.

FETLOCK, in the MONEY, a tuft of hair growing behind the pattern-joit of horses.

Hence, the joint where it grows is called the fetlock-join1.

FETTOVA, in Geography, a town of European Turkey, in Bulgaria; 25 miles S. of Rufzak.

FETSA, in Modern History, is a name which the Turks give to the written judgments or decisions of the muft. The word in the Turkish language signifies sentence, and in Arabic, reply, or judgments of a wife man.

FETTEE, in Geography, one of the branches of the Indus.

FETTERCAIRN, a town of Scotland, in the county of Kincardine; near it is an ancient ruin called Penellas castle, in which Kenneth III. was murdered; 11 miles N.W. of Montrose.

FETU, FETUS, or AFFUS, a kingdom of Africa, bounded on the west by the river Benji, and kingdom of Commendo; on the north by the country of Atti; on the east by Sahi; and by the ocean on the south.

The crown is elective; and the capital, called also Fesus, stands in the inland country. Bussinou assigns to this kingdom 160 miles in length, and nearly as much in breadth; he describes it as commencing at mount St. Jago, or the river Seel, and terminating at mount Monton, or Montfort. It was formerly very powerful; but has been much reduced by civil divisions, so that it is now subject to the absolute control of the king of Commendo. Before these conquests it was filled with populous villages, and exhibited signs of wealth and plenty. Its principal riches consisted of grain, cattle, oil, and palm wine; and it was rendered beautiful and pleasant by the groves that shaded all the roads, and sheltered passengers from the rain and sun. It is extremely well situated for European settlements, on account of the neighbouring trading kingdoms and the cheapness of living. The Dutch had a fort at Elmina, which fee.

FETUS. See FORTUS.

FETWAS, in Geography, a town of Hindoostan, in Bahar; 20 miles S.W. of Patna.

FEU, CAPE, a cape on the E. coast of Majorca. N. lat. 39° 4'. E. long. 2° 28'.

FEU DE JOIE, in the Military Art, meeting a salute occasioned by some joyful occurrence, is generally confined to three distinct volleys fired by troops drawn up at open order, in which the soldiers elevate the muzzles of their firelocks to an angle of about thirty degrees, or more, thereby to prevent the discharge from doing injury to these in their front.

But in large armies this ceremony is conducted on a greater scale: the park of artillery firing round volleys between the several volleys, for which, in lieu of a word of command, signals are given by beat of drum, or eventually by the discharges of three cannon; the first indicating that the whole should "make ready," the second that they should "present," and the third that they should "fire." The re-loading is performed by attending to the full-man of each corps respectively.

In some instances the feu de joie is performed by discharging a "running fire" from one to the other flank, in lieu of firing by volley. This makes the ceremony last much longer, and proves more striking; especially when the feu-d'epis attached to the several battalions exchange as it comes to their turn. When the force is very considerable, each of the three rounds of "running fire" may occupy from a quarter of an hour up to a full hour. The music generally performs some loyal strain during the intervals of such protracted fires, and the ceremony is always concluded by
F E U

Feuds were called by various names, according to their respective natures: as feudum antiquum, which descended to a feu, &c. from his ancestors; opertum, refuting back again to the lord of the feu, where the blood of the last peron left feid in feu-simple is utterly extinct and gone; bavangium and individum, a title of nobility, not of a divisible nature, and defendable to the eldest fon in exclusion of all the reft; impriumeum, an improper or derivative feu; maturarium, defending to the fei from the mother; novum, one newly acquired by the feu, to which, in ancient times, only the defendants from his body could succeed, by the known maxim of the early feudal confitions; novum held ut antiquum, defendable in the fame manner as a feudum novum; patrunum, defendable from father to feu; and praetum, a proper feu, diftinguished from one improper, which are the two grand and general divisions. Blackti. Com. vol. ii.

FEUD is alfo used in our ancient confuits for a capital quarrel or enmity, not to be satisfied but with the death of the enemy; and thence usually called deadly feu. Feud, called also feida, and faida, in the original German signifies guerra; i.e. bellum, war. Lambert writes it fizc, and faith it signifies capitales inimicitias, or implacable hatred.

In Scotland and the north of England, feud is particularly used for a combination of kindred to revenge the death or any of their blood, against the killer and all his race, or any other great enemy.

FEUDAL, or FEUDAL, of or belonging to a feu or feu. We say a feudal matter, feudal jurisprudence, feudal seizure, feudal fytem, &c. A feudal lord, in default of fealty and homage from his vassals, may feize the fruits of the feu. A Neapolitan lawyer, called Curavita, has a Latin treatise of the feudal law, intituled "Practices Feudales." About the year 1790, a compilation of the feudal laws, as practised in Lombardy, was published at Milan, in two books, by two senators and counsels of that city, Gerardus Niger, and Obertus de Odo. In imitation of the "Pandects," they contain the opinions of lawyers, on questions concerning the feudal customs, with some imperial confitions, relating to feuds. They were long afterwards divided into five books by Cujacius, their bell commentator, before whose time they had obtained so great an authority in many countries of Europe, that they were received in courts of justice as parts of the civil law. The learned Craig ascribes this authority to imperial confitions contained in them, or by which they were confirmed; but Du Monlins, Giannone, and others say, that, like the books of Julianian, they acquired by degrees the force of laws, from usage, from the approbation of the people, and from the tacit consent of princes, who permitted them to be publicly taught in universities, enriched with commentaries, and cited in tribunals for the decision of causes. It does not appear that any such regard was paid to them in England; though in many points our laws were similar, as being derived from the same principles, and directed to the same ends. Yet it is not improbable that even in the latter times of king Henry II., and, still more in the next century, some parts of the English laws, concerning feudal eftates, may have been regulated according to their decision, by the statutes that were made, and, in the determination of doubtful cases, by the opinions of the judges.

When once the use of feis was thoroughly established in France, they would needs extend it much farther, and almost all the great officers of the crown thus became feudal; even the courts of justice were drawn in; in order...
The design of these infercations was to render the offices hereditary, after the manner of fees, which were now become so; and thus the offices of the grand chamberlain, grand butler, &c. came to be held by hereditary right.

As the northern nations brought in the use of coats of arms, by preferring down in their families the armorial bearings of their ancestors, shields, &c. as hereditary marks of honour, so they also, according to some, brought in the feudal law, by means of which, arms grew up to further perfection, as is evident by many armorial figures of ancient families, representing the acknowledgments and services they were obliged to perform to their own lords and superiors.

Thus, roses, cinquefoils, spurs, rowels, bow and arrows, hunting-horns, ships, and the like figures, were expressive of the services they were bound to do their lords; and hence these figures have become common in arms through all Europe. For instance, the old barons of Arran and Lorn were obliged to furnish their lord with a ship in time of war; and thence it is that their arms carry ships or llynx-plods to this time.

**Feudal System.** See Fee.

**FEUDATORY,** or **FEDATORY,** a vassal or person who holds of a superior in fees; i.e. on condition of yielding him fealty and homage, or other service. See FEALTY, Fee, Homage, and VASSAL.

The electors, princes, and free cities, of Germany, were all feudatories of the emperor.

**FEUDIOTE,** a recompense for engaging in a feud or action, and for the damages consequent thereon; it having been the custom of ancient times for all the kindred to engage in their kindred’s quarrels; according to that of Tacitus De Morib. Germanor. “Sicopere tam mimeticas fuerat patris, feu prophini, quam mimeticas, necesse ed.”

**FEUDIST,** a lawyer, or doctor, learned or much conversant in fees or fees. Du Molin is reckoned a great feudist.

**FEUDO,** in Geography. See St. Gotthard.

**FEVE.** See Acrelia.

**FEVENIST,** in Geography, a river of Carinthia, which runs into the Dravo 6 miles N.W. of Villach.

**FEVER,** in Medicine, a term employed to designate various conditions of the body, in which more especially the heat is augmented, the pulse increased in velocity, and the other functions more or less deranged.

The word, fever, has always been used with great latitude, as well by medical writers, as by mankind in general; and scarcely two physicians have agreed in the definition of it which they have given. The increase of the animal heat, however, which is commonly both visible to the touch of others, and disagreeing to the sick, has been the object of minute observation; whence the denomination of the disease, in almost all languages, bears a reference to this symptom. By the Greeks the word pyretos, pyretic, from πυρήτως, fire, was the appellation applied to fever; and the name used by the Romans, febris, was deduced from febre, or febræ, (signifying to be hot,) by a tranposition of letters common in most languages. From the latter our word is derived, probably through the medium of the French. That the idea of heat is predominant in the use of the term fever is obvious from the popular expressions which represent a person much heated, in any way, as “in a fever,” "Vol. XIV.

and which designate the cold and hot flages, or the rigorous and delirious heats of intermissions, by the words "ague" and "catarrh." Physicians, however, include, in the term fever, the whole of the phenomena which belong to the disease, the cold as well as the hot and sweating flages; that is, the beginning as well as the middle and end of the disease.

Fever, in the most extensive signification of the term, is the most general of all the morbid states to which the human constitution is liable; for, it is common to both sexes, to every period of life, and to all climates and countries. Sydenham affirms, that the various forms of fever constitute two-thirds of the diseases of mankind; and he has calculated, that as large a proportion as eight of nine of all who die are cut off by febrile diseases; a proportion which is probably not overestimated, if we include in the calculation not only all the forms of intermittent, remittent, and continued fevers, and the fevers accompanied by eruptions on the skin, such as small-pox, measles, scarlet fever, &c., but also the various local diseases and affections of the body, which are accompanied by fever, such as inflammation of the organs, whether induced by internal causes or external violence.

In reviewing the numerous forms of fever, however, it is evident that, for the practical purposes of the physician, this general application of the term is too vague and indefinite; since the circumstances under which fever occurs are materially different in various respects. The most obvious distinction, which has induced an universal division of fevers into two great classes, consists in a difference of origin; some arising from general causes operating on the body at large; while others depend on inflammation, or other local affection of a particular organ. The former have been designated primary, or idiopathic fevers; the latter secondary, or symptomatic fevers. In the more accurate medical vocabulary of the present day the term fever is applied only to the idiopathic fevers: in the other class of febrile diseases the state of fever is but a symptom, a secondary consequence of inflammation, or some other morbid change of a particular part of the body, which constitutes the primary disease; which this is removed, the fever ceases; but in proper fever, the symptoms are probably independent of any pre-existing organic disorder, and are not regulated in their course or termination by the progress or removal of any other disease. Idiopathic fever alone is, therefore, the subject of our attention at present; the various species of symptomatic fever will be found under their respective terms of application, according to the organ which is the seat of the primary disease. Thus, for the purulent and perinephritic fevers, depending on inflammation of the lungs, see Pleurisy and Perirephritis; for those arising from inflammation of the bowels, see Enteritis; and so forth.

Under the head of idiopathic fevers, those febrile diseases, which originate from a specific contagion, such as small-pox, measles, scarlet fever, &c., might with propriety be comprehended; inasmuch as the eruption on the skin, which characterizes them, is not the cause of the fever, but appears subsequent to the occurrence of the fever itself. Nevertheless, as these eruptive fevers differ most materially in their cause, their phenomena, and their termination, and originate from a distinct species of contagion, it is useful to separate them from the simple idiopathic fevers.

This plan has been adopted universally by the zoölogists. Dr. Cullen has constituted three orders of his first class of diseases, entitled pyretic, or febrile diseases, from the division which we have just described; the first order, comprehending the simple idiopathic fevers, is entitled "febræ," or fevers; the second, including the symptomatic fevers, is entitled...
entitled the order of "phlegmatic," or inflammations; and the third, comprising the eruptive fevers, is denominated the order of "exanthemata," or efflorescences. It may be added, that this scientific physician has likewise constituted two other orders of febrile diaphases; the fourth consisting of "hemorrhagies," from the lungs, uteri, &c.; and the fifth, entitled "profuse," or fluxes, containing two diaphases, catarrhal and dysenteric, which depend on a peculiar inflammation of the mucous membranes of the tracheal tubes, and of the alimentary canal. See Cullen. Nefol. Method.

Fever, properly so called, or idiopathic fever, is the subject of the present article. It occurs under the form of ephemeral, intermittent fevers, or agues; remittent, and continued fevers; the last of which appear under a variety of types, in the infallibility of the plague, gaol-fever, or typhus, low, nervous fever, &c. See the conclusion of this article.

Notwithstanding the great prevalence of fever in all ages and climates, and the universal attention which it has excited among medical observers, from the time of Hippocrates downwards, the diaphase still remains the subject of much discussion; and its essential nature, or the proximate cause of its symptoms, is still a problem in medical science. This obscurity will appear the less surprising, however, when we consider the almost endless varieties under which fever occurs: for not only are its modifications so various, that of those fevers, which are nominally the same, scarcely any two influences accurately resemble each other; but, of all the symptoms which constitute these varieties, not one can be found which is invariably present in every case,—not one, therefore, which can be considered as characteristic of the disease. In the technical phræologick, we are not acquainted with any pathognomonic symptom of fever. Hence, although the concourse of symptoms, which mark the presence of fever, is well known, and easily recognized by a moderate degree of observation and experience, and consequently capable of being accurately described, yet it is not easy to frame a definition of fever, which should comprehend every variety that may occur.

Boerhaave, the able and learned professor of physick at Leyden, at an early period of the eighteenth century, investigated the subject of fever more rationally than his predecessors: he found that these symptoms were generally observable in all fevers; and therefore he deemed the characteristic symptoms of fever, in which he has been followed by the notologists who have succeeded him. "In every fever, arising from internal causes," he says, (Aphorism 563.) "there is always a feverishness, a quick pulse, and heat, varying in degree at different times of the fever." But of these three symptoms, he considers the second, or quick pulse, as the essential or pathognomonic symptom, and not the heat, as was the opinion of the ancients. He observes again, in the 57th aphorism, "These symptoms, indeed, are present in every fever, but the quick pulse alone is present throughout its whole course, from the beginning to the end, and by that only the physicians judge of the existence of fever." It cannot be questioned, that these three symptoms are found in the great majority of instances of fever, and that the quickened pulse is the most universally observed, and continues during the longest period of the diaphase. But, on the one hand, these symptoms are common to the symptomatic fevers, as well as to the idiopathic; and, on the other, they have each been observed to be absent in different influences, even the quickness of pulse. By these three symptoms Dr. Cullen has characterized the whole class of febrile diaphases, the idiopathic, the eruptive, and the symptomatic fevers; in addition to which he has introduced the leison of some of the functions, especially of the muscular strength, which generally accompanies them. His definition of the class Pyrexia is as follows. "Foil horrorem, pulsus frequent, calor major, plures functiones laxe, viribus praefedit autem imminuit." These symptoms, occurring generally in the order here mentioned, are deduced from a correct generalization of the common occurrences in febrile diaphases; but if it can be shown that each of them has been occasionally absent, it will be a sufficient proof that none of them can be deemed essential to the existence of fever. On the contrary, it will be equally easy to prove that all these symptoms have been occasionally present, without the occurrence of fever.

The chilliness, shivering, horror, rigor, or horripilatio, which is commonly one of the first symptoms of idiopathic fever and often of symptomatic fevers, as has been observed by the best writers on the subject, is occasionally absent; the fever begins at once in the hot flage, or with some other symptom, as nausæa, or head-ache, to which the hot stage succeeds; and no cold stage, whether marked by the feelings of the patient, or of a by-faller, or by the application of a thermometer, occurs. For this fact we have the authority of Celsus; and among modern physicians Gorter, Burtheus, Fordyce, and others, have distinctly attested its truth. On the other hand, cold, eliminated by the means just mentioned, often takes place, wherein no fever can be admitted to be present, as in hysterical complaints. See Celsus, De Medecina, lib. iii. cap. 5, where he says, "saepe praebet a calore inimico," or Celsus. Corn. Med. Pract. 52. Burtheus, Inflit. Med. Pract. vol. i. p. 83. Fordyce, Differt. on Simple Fever, p. 11.

With respect to the quick pulse, which is deemed by Boerhaave, and his commentator, Van Swieten, as the effence of fever, and the only criterion by which the physician judges of its existence, the evidence of its absence, which the records of medicine afford, is very abundant. It might seem extraordinary indeed if quickness of pulse were the essential symptom of fever, that the ancient fathers of physick should have become so well acquainted with the diaphase, without paying much attention to the state of the pulse. Yet it is certain that Hippocrates has seldom mentioned the pulse, and lays little stress upon it; and we are informed by Galen, that he (Hippocrates) was the first writer who mentioned the pulse. The pulse, however, was noticed afterwards by Herophilus and Erasistratus, and particularly mentioned by Aretaeus. In the time of Celsus it was an object of considerable attention with physicians; but he expressly remarks, that in trusting to the pulse, as a test of fever, we depend on a most fallacious criterion (fallacilimina res); for not only external heat, the bath and exercice, but also fear, anger, and the other passions and emotions of the mind, even the anxiety of the patient on the approach of the physician will excite and depress, and otherwise modify the pulsations. "Quas venas autem," he concludes, "confectus medici movet, quam facile milie res turbant." De Med. lib. iii. cap. 6.

But not only is the pulse quickened by heat, exercice, and mental emotions, as stated by Celsus, and by other causes, when no fever can be said to exist; but farther, continued fever has been observed to go on even to a fatal termination, without any increased frequency of the pulse. The frequency of the pulsations in health varies according to the age, sex, climate, season, and to the particular constitution of individuals. It is only about a century since the pulsations were counted, and within that period authors have not agreed as to the number which constitutes a febrile pulse. It is admitted that in the adult age of men, the number of pulsations of the heart and arteries is commonly about 73 in a minute. (See Pulse.) But in particular constitutions
the pulse of health is found regularly at a much higher or lower rate: sometimes beating 80 times or upwards, sometimes 70, 67, or less in a minute. Dr. Fordyce counted the pulse of an old man in the Charter house, whose natural number did not exceed 25 contractions in a minute. It is obvious then that the disputes about the number of pulsations which constitute the febrile flat are frivolous: for the man whose natural pulse was 40 would be in a high fever in other respects when his pulse reached 60; while the person, whose pulse in health was at 85, might labour under slight febrile indisposition when his pulse beat nearly 120 times in a minute. But let us advert to other facts. Syl- denham long ago stated, that in the first days of a fever which he calls febris biamalis, the pulse continued like that of a person in health, "sanum pulsim non admodum absumus." (Tractat. De Hyrope, pollicerpto.) Werlhoff has noticed the same fact in small-pox, and Greding in a contagious epidemic fever. (Ludwig, Advers. Med. vol. i. p. 1. cap. 1. p. 22.) The pulse has been observed to be slower than natural, in several instances of malignant fever, by many clinical observers, both ancient and modern. Several of these are particularly referred to by Burletius (Loc. citat. p. 84. et seq.) It may be sufficient to mention Russil (Nat. Hist. of Aleppo, p. 232.), Sauvages (Nolod. Method. tom. ii. p. 327.), and De Haen (Nat. Medendi. p. 1. cap. 2. p. 53 et 117.) Nay, it sometimes happens, as in a case recorded by the last mentioned writer, that the pulse, which was slow during the continuance of the fever, becomes more frequent during the state of convalescence and health. The pulse, indeed, has been often observed to undergo considerable changes in the course of fever, when the reft of the symptoms continued unaltered. Dr. Fordyce remarks, that he "has seen, in many instances, a fever take place, and go on as a continued fever, so that in the middle of the second week the pulse has been frequent, from 100 to 110, or even more; the tongue covered with a brown fur, and dry; the skin dry; there has been great depilation of strength, colliquatives, violent pain of the forehead, delirium, strong evening exacerbations with rapidity of the eyes; in such cases the author has known the pulsations become as few as 60, 50, or even 45 in a minute, all the other appearances of the disease remaining the same, or the fever even increasing in all respects. This small number of pulsations, after continuing for two or three days, has given place to a number of pulsations as great as before, so that if a man had attended to the other circumstances of the disease, and not felt the pulse, he would have had no reason to suspect that the pulse had been fewer during that time. This the author has frequently seen in the patients attending St. Thomas's hospital, as it was shewn to him by Dr. Cullen, Sir John Strirling, Sec. &c." (Loc. citat. page 15.) It may be added, that Dr. Home remarks that patients have died of typhus under his observation in whom the pulse was not quickened. (See his Clinical Experiments.) On the whole, then, it cannot be doubted, that Bouchave maintained an erroneous doctrine, in flating the quick pulse to be pathognomonic of fever. See also the works of Pringle and Lind.

The increased heat is still less entitled to be deemed an essential symptom of fever, notwithstanding the labours of the Galenists to prove it the proximate of the whole disease. It is curious to observe the sophisms by which they attempted to reconcile the doctrine of their master, with stubborn facts, that are incompatible with it. Thus Senners affirms, that "it is not the heat generated in the heart, and thence communicated to the rest of the body." (which is Galen's hypothesis) that produces or constitutes fever, but the morbid dispersion which the heat occasioned, and which is inconsistent with the proper performance of the functions. Hence the heat occasioned by passion, violent exercise, or the bath, is not to be deemed fever, unless it reaches that degree of inflammation which disturbs the functions." (De Febribus, lib. i. cap. 1.) But the excitement of heat, by the same canes which raises the pulse, according to the observation of Celsus, its occurrence in hysterical and other diseases, not febrile, and its frequent absence during the whole course of fever, for which we may flate the authority of Fordyce, and other observers, prove that heat is not the essential symptom of fever. "Its heat, is, of Alcmares, cui credimus, color, aque fallax." (Celsus, loc. citat.)

The other symptoms, alluded to by Dr. Cullen, in his definition of febrile diseases, namely, "the disturbance of several of the functions, especially the depression of the muscular strength," although they commonly occur both in idiotopathic and symptomatic fevers, are common to a great variety of diseased, and were not flated as pathognomonic symptoms.

As there is no symptom, then, which, being invariably present, characterizes the disease, called fever, we can only obtain a knowledge of the existence and nature of the disease, from an attention to the concomitance and succession of the symptoms. This attention is extremely important in a practical view, not only from the great variety of fevers which require an appropriate variety of treatment, but also from the necessity of modifying the treatment in different stages of the same case of fever. We shall, therefore, detail the symptoms of fever in the order in which they usually occur, including the whole of those which have been seen in various cases, and leaving the modifications of the disease to be more particularly noticed under their respective appellations. The paroxysm of an intermitten fever is generally pointed out as the most perfect example of the febrile flat, both in respect to the distinctness and the regularity of the symptoms, which characterize it. This has already been described under the article Ague. When the paroxysm is lefs severe, and does not recur, it is denominated an Ephemeris, (which see.) There is perhaps more of fancy, however, than of sound observation, in the affinity which has been described between the intermitten and continued fevers; and especially in the assumption of the intermitten paroxysm, as the prototype of all febrile diseases; and in considering continued fevers, as consisting but of a series of these paroxysms, the succeeding one commencing before the termination of its predecessor, so that no period of intermission intervenes. Such, however, has been the practice of our best authors; Dr. Cullen, the tymeniac, has been followed by Dr. Fordyce, the practical physician, in this account of the disease.

Symptoms of Fever.—The commencement of fever is generally marked by some degree of languor, listlessness, and general uneasiness; the patient feels himself ill, without being able to refer his uneasy feelings to any particular part of the body. There is also a little fevers, or a desire frequently to change the posture, but at the same time the sense of weariness disposes the patient to rest, this inclination the motions when made are sluggish, and frequent yawning and stretching accompany the attempt. The mind is affected in a similar way; it cannot rest upon any object; the attention is not under the command of the will, but wanders from one subject to another; and the ability of exerting the muscular powers, or of performing any of the body becomes actually diminished; there is likewise an actual inability of exercising the faculties of the mind; the patient cannot think or reason, even upon his ordinary affairs, with
his usual state. Along with these symptoms, but more frequently after them, he feels a sensation of cold, commonly first in his back, but afterwards over the whole body; the same kind of sensation that he feels when surrounded by a colder medium than he is accustomed to: he wishes, therefore, to go near a fire, or into the rays of the sun, or to put on warmer clothing. At the same time the face and extremities are observed to be pale, the features shrivelled; the bulk of every external part is diminished, and the whole body covered with hairs, as if cold had been applied to it. This sensation of cold varies much more in different instances of incipient fever, than the languor and latitude before-mentioned: in some cases it is very slight, in others not at all felt or noticed; whilst in many instances, particularly in the intermittent fevers, it becomes so great as to produce a tremor or quaking in all the limbs, with a chattering of the teeth, and frequent rigors of the trunk of the body. In this state, the actual heat of the surface, whether measured by the sensations of a by-flanker, or a thermometer, is considerably diminished; in the extremities in particular it is many degrees below the standard of health. (See Burletus, loc. cit.—Currie, Medical Reports on the effects of Water, cold and warm, in Fevers, &c. p. 168, 2d edit.) Not only on the surface, as is generally imagined, but even over the whole system, the heat is probably diminished; the air expired from the lungs, feels cool to the back of the hand, held near the mouth. Dr. Currie states, that he has found the heat under the tongue, and at the axils, as low as 94, 93, and 92 degrees of Fahrenheit’s thermometer. (The healthy temperature of the human body, it may be observed, is about 98° of the same thermometer.) Dr. Fordyce affirms, that 93° was the lowest degree of heat that he had witnessed under the same circumstances. (First Dissertation on Fever, page 40.) The sensations of the patient, however, do not always correspond with the actual degree of cold, as measured by the thermometer, or by the sensations of others; for it has been remarked, especially towards the termination of the cold stage of the fever, that the patient feels himself cold, even on those parts of the body which are burned, by the application of a thermometer, to be of the natural heat, or even hotter than they usually are in health. With this state of coldness, the sensibility of the body is considerably diminished; all the sensations, but especially those of touch and taste, are less accurate and distinct than in the healthy state. Dr. Fordyce remarks, that, "in the attack of fever, such a degree of insensibility, with a feel of coldness, has in many cases taken place, that even hot habiliments have been applied in such manner as to coagulate, may, perform the chemical analysis of the part, without any sensation of heat having arisen in the mind of the patient." (Loc. cit. p. 49.) The diminution of the faculty of sensation is very various in different instances of the attack of fever.

Upon the first approach of febrile languor the pulse is not always altered in respect to frequency, but it always becomes weaker than before; sometimes it is also slower than in health for a short time. But as the sense of cold increases, it becomes smaller, and gradually more and more frequent, and often irregular. While the contractions of the heart and arteries are thus feeble, all the secretions of the system are likewise diminished. The tongue and mouth become dry and clammy, in consequence of the diminished supply of saliva and of the mucus of those parts; the skin also becomes dry, as well as pale and cold, there being little or no matter of perspiration poured out. The changes in the urine are still more remarkable; the impaired action of the secretory vessels of the kidneys is evinced by the diminished quantity of the urine, at this period of fever, as well as by the paleness of its colour, in consequence of its holding less of the mucilaginous and fatty parts in solution than in health, and by the absence of any cloudiness or deposition when it cools. There is generally also a smaller quantity of secreted matter evacuated from the intestines at the commencement of fever, or in other words a degree of constipation, which implies a deficiency of the fluids secreted from the inner surface of the alimentary canal, as well as of the bile and pancreatic liquor, by which the faces are rendered more liquid and moveable, and the bowels are stimulated to action. Analogous to these changes in the state of the secretions are the sudden and considerable detumescence of swellings, which may happen to subside on the surface of the body, and the drying up, or effusion of the discharges from ulcers and wounds, during the cold stage of fever.

The respiration also suffers some change in the attack of fever, being often short and frequent, and sometimes attended with a cough, more particularly in intermittent fevers. There is at the same time a great anxiety, or a sense of weight, fullness, and great uneasiness in the breast. This diffusing feeling, which has been thought by some physicians a pathognomonic symptom of fever, and hence denominated febrile anxiety, is totally different from, and independent of, the general uneasiness all over the body, which was before mentioned, and often occurs in a very in proper degree. It resembles that anxiety which takes place from grief, fear, and other depressing passions of the mind, and which is also accompanied by paleness, and diminution of size of the veins, which are seen on the surface. The patient likewise feels irregularly, as one under the influence of the passions just noticed, and frequently sighs deeply, as if to free himself from the load that oppresses the region of the heart.

At the beginning of the attack of fever, sometimes as the very first symptom, but often later, a dull pain is felt in the small of the back, which seems to occupy the lumbar vertebrae, but is not accurately referred to any particular point. It is very similar to the pain which arises from weakness or fatigue; but, unlike that, according to Dr. Fordyce, it is equally felt in the horizontal, as in the erect posture of the body. The head at the same time is affected with pain, which is commonly felt in the forehead over the eyes, and feels to the patient as external; sometimes it likewise occupies the back part of the head, and occasionally it is felt all round the head. In severe cases it becomes more severe, but commonly increases as the attack proceeds; it is usually attended with a sense of weight, and is often augmented by light falling upon the eyes. A similar pain generally arises all over the body, which the patient often describes as felt in all his bones, without being able to particularize in what part of the body it is felt. Sometimes it is more particularly confined to the larger joints; and it is occasionally attended with great foreheads, as from over-fatigue. Such foreheads, however, is more commonly confined to the subsequent periods of the disease.

From the commencement of the attack of fever the natural functions are always deranged. The changes in the appearance of the tongue are among the first indications of this derangement. At first the tongue appears to be thinly covered on its upper surface with an extremely viscid fluid, especially in the middle and towards the root, the edges and point being nearly free from it. The under surface of the tongue, below the point, is fearfully covered with this matter. Sometimes, at the very beginning of the disorder, the covering of the tongue is a solid crust of a whitish
FEVER.

colour, adhering so firmly as to be incapable of being scraped off; sometimes it verges towards a brown colour.

At the approach of the cold stage of fever the axillary is commonly affected; the appetite for food ceases, and aversion even to the light or smell of food often takes place. Dr. Fordyce remarks, that he "has known several individuals where persons fitting down to the table with a ravenous appetite, an attack of fever having suddenly taken place, in less than two minutes they have been unable to eat any thing, and have been seized with perfect aversion even to the smell of food." (Loc. cit. p. 93.) Sicknees at the axilla often comes on at the first attack, and this is increased occasionally to such a degree as to produce vomiting. More commonly, however, this does not take place at the very commencement; but the disorientation of food increases gradually to nausea, then to vomiting, which in some cases is very severe, not only the contents of the stomach being evacuated, but likewise the bile of the duodenum, and of the glands, the secretory duets of which open into it. Bile, therefore, and the pancreatic juice, are thrown up, together with the contents of the stomach, and the other fluids secreted into the stomach and duodenum. Of these fluids, however, the bile is the most conspicuous from its colour, taste, and smell, and it has, therefore, often been observed by practitioners, while the gastric and pancreatic, and other juices secreted into the duodenum, as they are not very conspicuous from their sensible qualities, have not been taken into the account. Combined with the aversion to food, and sicknees, there is generally a considerable degree of thirst.

Few other symptoms, which are observable at the commencement of fever, remain to be mentioned. The rate of the countenance is very peculiar and characteristic, from the moment of the attack. It not only becomes pallid, or of a dirty hue, in common with the rest of the surface of the body, but it assumes an expression of dullness or heaviness, partly in consequence of the languid action or relaxed condition of the muscles of the face, and partly from the same condition of the muscles of the eye-ball, by which its form and motion are altered, and its usual brightness and quickness are impaired. The disposition to sleep is diminished or lost; or, if it occurs, the repose is short and interrupted, and very imperfect, so that there is much dreaming, during which the ideas that present themselves are mostly of an unpleasing kind.

When the sensibility of cold, and the attendant symptoms have continued for some time, (the period being very various in the different kinds of fever,) the cold becomes less violent, and is alternated with flushes of heat. In the more severe continued fevers, it frequently happens that the cold is not permanent for any length of time, but that this alternation of chills and heat takes place from the beginning. By degrees the cold goes off entirely, and a heat greater than natural is extended, at first equally in different parts, but at length generally over the whole body; but even when it is so far advanced, that the heat, measured at the axilla or under the tongue, is greater than the standard of health, a slight access of external cold will produce a general chilliness. There is no regularity in the restoration of the heat to the surface; in some parts the heat is above what is natural, while in others it remains below this standard; and hence arises that mixed sensation of cold and heat, which every one acquainted with fever has experienced, in the transition from the cold to the hot stage of the paroxysm. This inequality of the distribution of the heat is less in the simpler forms of fever, and greater in those which are more complicated and irregular. In general the sense of cold predominates, even after a morbid heat has taken place at the axilla, under the tongue, and in different parts of the thorax and abdomen. At length, however, the heat of the surface becomes general and uniform, rising to 102°, 103°, and sometimes 104°, of Fahrenheit's thermometer. Different authors indeed speak of febrile heat four or even five degrees higher than this; but such heat has never occurred under the observation of Dr. Fordyce or Dr. Currie, the best authority on this subject: the writer of this article has frequently employed the thermometer, in cases of continued fever, and never observed a higher temperature of the body than 104°, in intermittent or continued fever, the patients being in cool apartments, with very light bed coverings. The sensation of heat becomes at length strong and steady, and the action of external air does not produce a return of chilliness as before; this sensation is most powerful in the extremities, particularly on the palms of the hands and soles of the feet.

The incrcase of the circulation takes place at the same time as the returning heat, and often in the same unequal manner, being evidently greater in some particular parts, than in others. It is very frequent, that one part shall become red and engorged, while the other is pale and contracted; the veins of the one being full, and the blood flowing in them more rapidly, while those in the other remain contracted. This shall continue for some time, when the parts become affected in the opposite way; the arm which was florid and dilated, becoming pale and contracted, and vice versa. This shifting, however, remains but a short time in simple fever, perhaps not above half an hour; in the paroxysms of intermittent it continues longer, and still longer in the first attack of continued fever. Universal redness at length takes place; the features of the face and other parts of the body recover the usual fize, and become even more turgid; and the superficial veins evince the greater circulation now going on through them by their fullness and increased fize. The skin is relaxed and smooth, no longer exhibiting the goose- skin appearance, by its contraction round the little glands and roots of the hair, but it continues for some time dry. The pulse now becomes fuller and stronger, and its frequency continues or is still farther increased; in simple fevers, it beats occasionally at the rate of 140 or 150 strokes in a minute, with a considerable degree of fullness and hardness (Fordyce); but in the hot stage of intermittent, and in the heat of continued fevers it is most commonly from 9 to 110, at this early period of the disease; subject, however, to great variation according to the constitution of the patient, and the type of the fever. The respiration, though more free than during the chilliness, continues full, frequent, and accompanied by a sense of load and anxiety, which the patient endeavours to remove by occasional labours efforts, and deep sighing. The respiration shall remain diminished: the skin is parched, no perspiration breaks forth; the tongue and mouth are dry and parched, and the fur on the former becomes thicker, the urine, though it becomes lighter coloured than in the cold stage, remains transparent, and deposits no sediment; and the bowels are colicky. The thirst is considerably increased as the heat advances, the nausea and vomiting gradually diminish, but the aversion to food is augmented.

The corporeal strength and the mental powers become more oppriessed; the sensibility, however, is restored in general with the returning circulation and warmth of the surface; sometimes it becomes even more acute than in the healthy state, so that the skin is more easily irritated, the eyes are occasioned with the light, and the heat noise is heard with
FEVER.

with pain, and greatly disturbs the feelings of the patient. The attention becomes left under the control of the will, and the faculty of recollection and the reasoning power are exerted with difficulty, and imperfectly, so that some confusion of thought takes place, which often arises to delirium, when the hot stage is completely formed: occasionally, indeed, a degree of delirium occurs in the beginning of the cold stage, but more frequently in the subsequent periods of the fever. The delirium consists in various and disordered dreams, which conflict or occur in the disordered and irrational fancies, which take place in the first stages of fever, may be considered as the flightest degree of delirium. (See the articles Delirium, and Dreams, in Pathology.) In the next degree the patient, when he awakes, is some time before he can attend to the impressions made on the organs of sense: he does not know his bed, his bed-chamber, or his attendants for a few minutes, but seems to awake as if it were a second time, and becomes perfectly feasible. If the delirium is in a little greater degree, the ordinary impressions of external objects produce no effect; the ideas, which float in the mind rapidly, seem to be excited without train or connection; the association being carried on by the internal impressions alone. If the attention of the patient, however, be strongly excited by external impression, he is capable of distinguishing the surrounding objects, and of returning correct answers to questions put to him; but that strong impression being withdrawn, he relapses into his delirous dream. As the delirium increases, with the advance of the fever, the faculty of distinguishing the objects that surround him gradually diminishes; he begins to overlook his ideas in words, i.e., to talk incoherently; the ideas which present themselves rapidly, and without apparent connection, are generally disagreeable and distressing. He is sometimes in a church-yard among tombs, sometimes falling from a precipice, sometimes pursued by wild beasts, in the midst of conflagrations, &c. The delirium increasing, he becomes completely insensible to external objects. This is a common progress of the alienation of mind in fever, beginning on the second or third day, or later, and increasing to the fourteenth or fifteenth, if the patient survive so long; at first being only obvious in the night, or during the imperfect slumber, or in the waking moments, when external impressions are fewer, or almost entirely excluded; but afterwards continuing night and day without intermission.

With the beginning of the hot stage, the head-ache is commonly increased, and appears to be diffusible from that which took place in the cold stage. The latter pain, Dr. For-}

dyce remarks, always feels to the patient as external; it is clearly a pain affecting the integuments of the head, perhaps the skin alone, atvoid the pericranium; but the pain which arises in the second stage is felt by the patient internally, and gives him the idea that there is something distending the head or the brain, so as to attempt to burst the cranium. (See First Diff. on Fever, pp. 83 and 228.) In the mean time the carotid and temporal arteries heat full and flush, the eyes are rather red, and the face is flushed. Connected with these symptoms, which obviously imply an increased quantity and impetus of the blood carried to the brain, the organs of sensation, while fully capable of conveying impressions to the mind, nevertheless produce sometimes erroneous impressions. Thus the patient can see, but he mistakes objects; he fancies one individual is another, or that a man is a pail: and his organs of hearing, which are also more easily affected, do not convey the same perceptions, which the same organs would excite in health. The same thing happens with regard to his other senses.

All the symptoms above enumerated increase from the second day of fever. The tongue grows more foul, and the crust which forms upon it thicker, until the middle of the second week. Towards the end of the second week this crust often disappears more or less, and the surface of the tongue looks raw when moist, and when dry has a polished glaze, especially about the middle, some of the crust remaining upon the fides towards the edges (Fordyce.) Before these symptoms, however, have advanced to the degree just described, the general heat has continued for an indefinite time, (in the ephemeral and intermittent fevers a few hours, in continued fevers several days,) it often happens, that a partial moisture begins to appear upon the skin, generally on the forehead, which extends gradually downwards to the neck and breast, and at length a free sweat takes place from the whole surface of the body. At the same time the symptoms of the first stage of the fever begin to abate, sometimes one giving way first, and sometimes another, so that it cannot be said which has the priority; sometimes the weight and anxiety about the precordia are first observed to diminish, sometimes the change of the pulse from hardnefs to softness is the first obvious amendment, and sometimes the relaxation of one or other set of secretory vessels, &c. Such a change of the symptoms, terminating speedily in a restoration of the health, has been called, by a term borrowed from the Greek, a Grfe, (which fever,) and the excrated fluids, which are poured forth at the time of this change, have hence been denounced critical discharges. The most striking appearance; both to the patient and by-hand, and the precipitation, which is freely carried to the extent of profuse sweating, in intermittent, and the simpler forms of fever, but sometimes amounts only to gentle moisture. While the sweating continues, all the symptoms of the previous stages abate; the preternatural heat is gradually diminished; the pulse becomes softer and less frequent; the breathing is likewise frequent, and more free, and is unaccompanied by sighing, and the anxiety and heaviness in the chest are greatly alleviated; the head-ache gradually goes off, and the pains of the limbs and extremities cease; the numbness and vomiting no longer distress the patient, who now acquires a relish for light nourishment; the thirst is removed; the mouth and tongue become moist, as the salivary and mucous glands pour out their fluids, and the tongue becomes gradually clean, first upon the edges, afterwards in the middle and near the root, the crust, which had formed upon it, coming off in small flakes, until the whole surface is in its ordinary state. The secretions of the liver, pancreas, and intestinal glands being restored, the bowels begin to act, and the evacuation from them comes to its ordinary quantity. A loose fluid is commonly passed, at the end of a paroxysm of intermittent fever; and sometimes a diarrhoea comes on in continued fever, and being the most obvious, is then considered as the critical discharge. The urine generally undergoes some peculiar changes in the crisis of fever; it is not only secreted in larger quantity, but, although bright and transparent when discharged, if allowed to remain for some time, it is observed to grow turbid, as if containing a quantity of a yellowish-red powder, and at length to deposit flaky crystals of a dirty red colour, commonly termed a leucorrhoea sediment. Tumours, which were diminished during the cold, and more painful in the hot stage, return to their usual size during the sweat, and ulcers again begin to discharge matter. The intellectual functions are also restored during the crisis; the attention of the patient is no longer absorbed by his uneasy feelings, the confusion of his head is relieved, and he is not harassed by the perpetual recurrence of disordered images to the mind, especially in his flumbers; a disposition to calm sleep
Fever.

It was remarked by Hippocrates, and the majority of the ancient physicians, that these crises occurred more frequently on particular days of the fever, which they, therefore, observed with great care, as affording both particular indications in practice, and the means of prognosticating the phenomena of the subfrequent periods of the disease. Hence they called these days Critical days, (which we have already described under that head). These periodic changes, happening on particular days, are, however, seldom distinctly noticed in this country; they seem to occur more decidedly in warm climates, where all fevers have a greater tendency to assume the remittent form. Dr. Cullen, who believed that even in this country these critical days were observable, though less distinctly than in hot climates, explained their occurrence upon the principle, that continued fevers were in some degree disposed to take on the types of intermitents; and in this principle he has been followed by Dr. Fordyce. (See Cullen, First Lines, § 642, and Fordyce, Third Discur. on Fever, part i. p. 126.) But it must be remarked, that the doctrine of critical days, as taught by Hippocrates, was ridiculed by Aclepiades and Celsius, who practis in the same climate with Hippocrates; and in the same climate with Galen: (See Celsius, loc. cit. lib. iii. cap. 4.) and Herophilus altogether denied its truth. See Critical Days.

In this country, and in cold climates in general, continued fevers are seldom terminated by crises. Some practitioners have maintained, that a crisis never takes place, whilst others have insisted that crises happen in all continued fevers. Dr. Fordyce judiciously remarks, that these extremes of opinion are both inconsistent with correct observation. It is admitted, however, that crises occur much less frequently in this climate than in hotter countries; and we think that the physician just mentioned considerably over-rated the proportion, when he says, that "not above one-third of the fevers which happen in London are terminated by a crisis." (Loc. cit. p. 126.) We believe the proportion to be very far below this statement. In the great number of instances of fever, no crises takes place, but the disease terminates in a more slow recovery, or in death.

The symptoms, before enumerated, increase gradually to the end of the first, or middle of the second week; sometimes by the seventh day the symptoms have attained their greatest severity; sometimes, too, the second week is gone through without very severe symptoms, and in other cases symptoms of the greatest difficulty and danger then occur, and there are all gradations between these extremes.

The appearances in the second week, when the fever is not extremely severe, are often as follows. The pulse is frequent, beating from 100 to 110, in the evening, and in the morning somewhat less; the skin continues dry and hot, in various degrees; the tongue is covered with a brownish fur; the appetite is often totally lost; thirst continues, but is often complained of less during the second than during the first week; and the depredation of strength is considerable. The sleep is disturbed and short, and the delirium is manifested in the intervals by the incoherence of the observations of the patient, until he is completely roused by some strong impression on the senses. In the morning the delirium is less than in the early part of the night, and the sleep sometimes tolerably quiet; even during the day there is considerable confusion, and occasionally much fitfulness of intellect. Hence perhaps the thirst, as well as the headache, and pains of the back and limbs, is less complained of, rather than from actual relief or diminution of these symptoms. The eyes have a dull and confused appearance, and commonly some degree of redness, from a number of small vessels dilated with blood. Sometimes a degree of fluxor comes on in the morning, and continues till the more active delirium of the night. If this state should remain, Dr. Fordyce observes, till about the fourteenth day, the evening attacks become by degrees less, but the fluxor continues, with delusions, and inattention to external objects, and these appearances remain the very last symptoms of the disease.

Very frequently about the end of the second week, and often sooner, the symptoms begin gradually to diminish in severity. The first appearance of this abatement is not uncommonly a cleanliness and healthy look about the edges of the tongue; sometimes, although not very generally, a sweating takes place all over the body, and the skin afterwards continues moist; more commonly the moisture and softness of the skin appear in a less marked manner. The delirium abates altogether in the day, and returns less severely at night; or if the patient be dealt with some fluxor, these symptoms are little changed in the twenty-four hours; but remains until the whole of the disease has disappeared. The depredation of strength goes off, but leaves real weakness behind. The urine deposits sometimes a copious lateritious sediment for a day or two, and afterwards returns to its natural appearance. Sometimes there is a copious lateritious sediment in the urine made in the night, and a mucus one in that made in the day time. The colic stools go off; and the faces return to their ordinary appearance; and all the secretions become gradually incrusted, not equally, but sometimes one more speedily, sometimes another. The eyes, unless when the delirium has ended in fluxor, begin to have a more healthy appearance, are more composed and clearer, and express a greater attention to the objects around them. The sleep returns, but not equally; the patient sometimes sleeping a quiet, at other times a restless night. The appetite returns, although seldom regularly; sometimes it is voracious, but the patient is withstanding satisfaction with a very small quantity of food; in the other cases it returns very slowly. Although the depredation of strength sometimes goes off almost at once, yet it leaves the patient often with a greater feeling of weakness. Thus, however, the whole disease disappears, and the patient recovers his strength very quickly.

But although this favourable termination of fever occurs in a large majority of instances in this country, it is nevertheless a diffical frequently fatal, and, under particular circumstances, the cause of great mortality.

When fever terminates fatally, the symptoms present themselves chiefly under two different aspects, but variously modified, approaching to each other, or even partially combined. The individual varieties are impossible to describe; a knowledge of them can only be attained by personal observation of numerous cases at the bed-side of the sick. One of the forms, just alluded to, consists principally of a great aggravation of the symptoms of the hot phase. The heat of the skin continues great and pungent, and its surface dry and parched; the countenance is flushed, and the eye suffused with redness, and intolerant of light; the headache is severe, little or no sleep is obtained, the delirium is augmented, and is accompanied with extreme restlessness, often with vociferation, and even great muscular strength, so that the patient is with difficulty confined in bed; and the pulse is frequent, with considerable hardness. About the end of the second week these symptoms suddenly change; the delirium ends in an indistinctness or confusion approaching to fluxor, the articulation becomes indistinct, the
the breathing laborious, the strength fails rapidly, cold sweats, and convulsive motions ensue, and the patient is cut off in a few hours. Sometimes symptoms of inflammation of the lungs supervene, and continuing together with the delirium, hot skin, frequent pulse, and brown tongue, the patient dies with symptoms of suffocation; and sometimes inflammation of the integuments, or other important organs, being superadded to the original fever, accelerates and modifies the fatal termination. This has been called inflammatory fever. The other form of the disease, above-mentioned, is extended more commonly to the third week, sometimes later, and the progress of the symptoms is more gradual. The depression of the muscular powers continues to increase with the disease; the eyes become dull, dull, and listless; the countenance dejected, and of a dusky hue; the delirium is attended with a low muttering, and the patient lies without the disposition or the power of making any exertion, or he picks the bed-clothes; the tongue becomes eroded with a dark brown or black matter, a similar fords collects upon his teeth and lips; the pulse is frequent, beating from 120 to 150 times in a minute, and is at first thin, small, and feeble; the respiration is also weak, generally frequent, and interrupted by sighing or a dry cough; the voice becomes indistinct or inarticulate; and there are light convulsive twitches, or subfusus tendinum. At length the prolifation of strength becomes extreme; the patient lies on his back, being unable to support himself in any other position, and even slides down towards the bottom of the bed; he is altogether insensible to external impressions; the phinlachts, as well as the muscles of voluntary motion are relaxed, and he paffes his hands and wrists involuntarily in bed; the pulse becomes very feeble, tremulous, and feecernly to be felt at the wrist; partial, clammy sweats break out; the eyes appear glazed and fixed, and the other features shrink; the patient is unable to swallow; his breathing becomes irregular and laboured, attended with some noife in the throat, as the fatal event approaches; the extremities grow cold; and, often after several days, with a dark hue, the patient falls insensible, or life finally ceases. When fever assumes this form it terminates febrile, or the nervous, malignant, &c. fevers of authors.

There are some other appearances, which, though not the ordinary attendants on fever, occasionally occur, especially when the disease is of a severe kind, and which have been considered as evidence of malignancy, or of putrefcence. Generally in the second week of the disease, but sometimes as early as the fourth or fifth day, (see for John Pringle's Observations on Diseases of the Army, part iii. chap. 7, and Huxham on Fevers, chap. vii. p. 97.) an eruption of spots, not elevating the cuticle, of a red colour, sometimes pale, often darker, or even of a livid or purple hue, appears on the skin; these spots, or petebites, are thickl upon the brow and back, left numerous on the legs and arms, and are feblom, if ever, seen on the face. They were first described, among the moderates, by Ingraffia of Naples, afterwards more particularly by Franclarius, under the names of livide, pustule, or petebite; whence also the false apppellations were given to the fevers themselves. (See Franclarius de Morbo Contagioso, lib. iii. cap. 4.) At first they appear in fever, most frequently in cloae and crowded situations; formerly they were very frequent attentants on the fevers which occurred in the persons under confinement in close cells, or crowded apartments in our prisons. Dr. Willan has stated, however, upon the authority of the present surgeon of Newgate, that since a general attention to ventilation and cleanliness has been adopted, petechiae do not now appear more than one cafe of fever in thirty in that prison. He has also added, from the observation of the physician of the Fever Institution, in London, (the writer of this article,) that the proportion of cases, in which petechiae occur in that institution, is about one in forty-two. (See Willan on Cutaneous Diseases, order iii. gen. Purpura, p. 468.) Sometimes the purple spots are of a large size; in which case there are often also livid blisters, or stripes like the strops of a whip, rubicuse, and hemorrhages break forth from the internal parts, as the bowels, lungs, stomach, and wherever the surface is covered with a very thin cuticle, as from the nostrils, the gums and mouth, &c.

A rash of a different species, which Dr. Willan has termed rogalus, "a rose-coloured effuence, variously figured, without wheals or papule, and not contagious," (Loc. cit. ord. iii. gen. Purpura) sometimes makes its appearance in fever, of the typhous type; sometimes it precedes the formation of purple spots and blisters, and in other cases it is seen early in the fever, but remains only for a short time without any material consequences. Some other cutaneous appearances occasionally occur, as mentioned by Huxham, (Loc. cit. gen. Purpura,) such as milary fulides, a feebly effuence about the lips and nose, and aphthae.

After-Care on Diffusion.—An examination of the bodies of those who have died of fever, though it has often thrown light upon particular symptoms, especially on those which have occurred late in the disease, has nevertheless failed to elucidate the subject of fever in general. The appearances which have been presented to the view of the dissector have been so various, the organs affected so different in different instances, even when each difference could not have been anticipated from a knowledge of the symptoms, that the principal general inference which can be deduced from the observations of the anatomists may be expressed in the words of Ricients, (Seclis Praxis Medica, lib. xxvii. cap. 2. Appendix,) "that acute and dangerous fevers... carollum fieri fumme intercet peculiare virescere capillus affectionem, et ploe- rumque inflammatione; quare iniquum omitter eura hypochondriacum, capitis, thoracis, uteri, renum, et vesicae ut in manu non observatum, non longum parent inquietissimum intercum, ut ci. quod fieri patet, lublimatur." Some one or other of the viresce are most commonly disturbed, especially by inflammation, in the course of those fevers, each of which demands our attention respectively, in conducting the cure, according to the severity with which it suffers. Dr. Donald Monro has remarked, that, in fatal fevers, "the feble matter is apt to fall on particular parts, and there to create absceffes; particularly in the brain, the lungs, and the glandular organs." (Treatise on Military Hospitals, vol. i. p. 257.) On the whole, it would appear, that the brain is the organ which has been found to have suffere moft by the attack of acute idiopathic fever. But we have to ob- serve, with regret, that diffcctions of bodies, cut off by fever, have been often too incompletely examined, to enable us to draw any satisfactory comparative conclusions from them. Thus even for John Pringle acknowledges that of the few diffcctions made under his inspection, none were directed to the brain or to the bowels only, all the cavities being examined but by a small number of cases. In those instances of fever, in which the functions of the brain were much disordered, that organ has exhibited several morbid appearances; the most frequent of these are a congestion of blood; the vesicles of the pia mater, or the veil and membrane, being all diffcnded, as if injected; the brain itself, when divided, presenting a number of red points, which pour out blood; the arachnoideal coat is not frequently at the same time separated from the pia mater by the interposition of a gelatinous or serous fluid; the
these membranes are both occasionally thickened, their transparency being partially lost, and they sometimes adhere closely together in particular parts, as well as to the dura mater. Occasionally an effusion of serum is found in the ventricles of the brain. Sometimes, though comparatively in rare instances, the inflammation of the brain has been so decided, as to have terminated in suppuration, or abscesses of the substance. These have been chiefly observed in the lobes of the cerebrum, the cerebellum in general being less liable to disease: but two instances of purulent matter being formed in the cerebellum are noticed by Sir John Pringle. (Loc. cit. part iii. cap. 7.) Even suppuration of the cerebrum is not a common result of fever in this country. Dr. Fordyce says, that he has cau.sed the heads of many patients, who have died with very great delirium in fever, to be opened, and never found any marks of suppuration. Most commonly the brain appeared exactly as it is commonly found. Sometimes the blood-veils were dilated with blood, but never was any suppuration found; generally no uncommon appearance at all." (Third Diflert. on Fever, part i. p. 68.) In the yellow fever, Dr. Jackson states, that "the brain upon dissection appears to be more or less affected in the majority of subjects who die in the acute stage of the disease; the membranes are then inflamed, or the blood-veils turgid to an extraordinary degree, give an appearance of commencing gangrene rather than of inflammation, properly so called; water is sometimes found in the ventricles, with evident effusion in the interstices; but this is an effect not general, not even frequent." In the accounts of an epidemic fever, which occurred at Geneva, in the year 1803, published by two physicians, it is stated by both that congestion of blood was often found in the brain, but in other cases the brain was in its natural state. And a Dr. Esfield, who published an account of an acute typhus, as it prevailed at Leghorn, in 1799, observes, "in very many careful dissections of the brain (though I only once detected an abscess, and this was in the right hemisphere, about half an inch in diameter) the vessels, particularly those in the vascular membranes, almost always appeared turgid with blood. The four ventricles abounded with water, and sometimes a good deal of extravasated blood was present. The cortical substance was inflamed, soft, and fucid," (See Beddoes 1803.) The following circumstances does not necessarily imply inflammation. It was observed by Chamcon (Obf. Clin. Pract. Obf. 25.) that the substance of the brain in every part is often found harder than natural after malignant fevers. This, Dr. Clutterbuck remarks, we know to be a common effect of inflammation in other parts. (Inquiry into the Heat and Nature of Fever, part i. p. 173.) The writer of this article lately witnessed an unusual firmness of the brain of a patient, dead of putrid fever, but the brain of the abdominal vifera had already become very putrid. The congestion in the brain was very considerable. Not only, however, are these congestions and inflammatory phenomena of the brain frequently absent, but sometimes together with them, and not seldom in their absence, similar appearances are observed in other vifera, more especially in those of the abdomen. Dr. D. Munro included other organs with the brain in his mention of the morbid changes produced by fever: and Sir John Pringle remarks, that when contagious fever proves fatal, it generally terminates either in the actual mortification of some part, or in an abscess of the brain: and he adds, that "the intestines more particularly are disposed to mortify." He likewise quotes the Trait de la Pelle, to prove that some of the vifera were always mortifid and inflamed, the brain and lungs most frequently, in those who died of the plague at Marcellia. Dr. Etiolfe, continuing his description of the appearances discovered by the dissection of those who died of the Lepide fever, says, "the lungs were often found deliroied, inflamed, ulcerated, gangrenous, covered with much exuded lymph. The liver inflamed (especially the concave surface) tender, fucid, full of blood, or pale and bloodless. I did meet with inflammation and gangrene of the uterus, the urinary bladder, the prostate and other glands (particularly the mениsicus) of the colon and rectum." "The pains in the head were sometimes so violent, and the delirium so furious, as to indicate inflammation of the encephalon, which however was discovered in the abdomen." In three dissections of persons cut off by an epidemic fever in Normandy, Dr. Monnet found the vifera of the brain and its membranes gorged with dark blood; the lungs were also diseased; all the ramifications of the mениsicus arteries full of black congealed blood; the intestines in part inflamed, in part putrid and gangrenous, in two of the cases a prodigious congestion in the small curvature of the fomach and in all the intestines, especially the small. Of the fever which raged at Leghorn, in the summer of 1804, Thiebault reports, "that there were few of the vifera which it did not leave sometimes found, sometimes gangrenous, or at least with black spots on the surface. This alteration was especially seen on the concave part of the liver, the inner surface of the fomach and intestines, often in the right side of the lungs and diaphragm; the abdominal vifera, and still more the abdominal muscles, were excessively flabby and tender. The cavities of the thorax and abdomen, the pericardium and the ventricles of the brain, contained a yellow liquid, often fucid, and of a dark bloody tinge. The superficial vifera of the vifera, especially those of the brain and intestines, appeared dilated, and their extremities filled with a black matter. Nothing was found constant but the gangrenous nature of the alterations, and their being more concentrated on the fomach and intestines than in the other vifera." (Recueil, period xxxiii. 12-13.) Palloni (Offervaz. Med. Livorno, 1804.) gives a very similar account. In his dissections, the force of dissection still more plainly appears to have been exerted upon the abdominal and contiguous vifera. During the similar epidemic of 1802, in Spain, professors Sabater and Ramos found in the abdominal vifera fanious and purulent effusion with gangrene. It is expressly said that, in the two other great cavities, the head and the thorax, essential changes were seldom found. In some subjects, however, black gangrenous points appeared upon the lungs, and in others upon the brain. "The alterations in the abdominal vifera were the only ones that can be considered as the direct and immediate product of the disease." (Berthe, Precis de la Maladie d'Andaloufe, 1822, p. 182, & 6.) Dr. St. Bury's, both fesuation to the Philadelphian diphtery, informs us, in his dissection on malignant fever, (1834.) that the brain was generally found in a dilated state, the membranes being considerably inflamed, the dura mater being sometimes aggutuated to the pia mater, the blood-veils turgid with blood as if injected, the brain firmer than usual, wateer frequently in the ventricles, and sometimes blood effused between the membranes. The fomach was always diseased; great inflammation observable throughout: erosions of the villous coat frequent; inflammation extending to the intestines; bladder diseased; liver, fleshy, putrid, kidneys generally found; lungs puffed, inflamed, and heart inflamed." We quote these observations from Dr. Beddoes's researches, not having the original works. We add, that in two cases which we lately investigated by dissections,
dissection, the villous coat of the small intestines was ulcerated in parts, and altogether destroyed in others; the brain at the same time bore marks of great congestion in the one case, and its ventricles were much distended with serum in the other.

We have dilated upon the subject of the morbid structure occasioned by fever, (which must ever be deemed highly important,) because it is too much neglected, partly from a mistaken fear of contagion from the dead body, which deterred even Morgagni from such investigation; and partly from preconceived hypothesis, which has led to the examination of only one cavity of the body, when diffuse might be discovered in all.

Ratio symptomatum, or explanation of the Symptoms.—

The first symptoms of every fever obviously indicate a diminution of the nervous power. Of the nature of this power we only know that it originates in the brain, and is communicated to every part of the animal frame by the medium of the nerves; and that the action of those parts, their motion and sensibility, depend upon this communication. The first symptoms of fever, then, indicate that loss of this nervous power is produced and imparted to the organs of the system; or, to use a common expression on this occasion, that there is a torpor or atomic condition of the brain and nerves. This is shewn by the languor and latitude, connected with the relaxation of the muscles. A similar condition is produced by the depressive passions, acting through the medium of the mind on the nervous power; whence the whole body becomes relaxed, as is shewn by the lengthened muscles of the face, the loss of strength, &c., and if the muscles of the heart are also relaxed, fainting is produced. The depression of strength depends upon the same cause; the muscles being unable to move the body with the usual force, and the powers of the mind being impaired. The muscular energy and powers of the mind are much connected in the animal economy; so that if the body have been fatigued, they will not exert its powers of attention, memory, and judgment with alacrity, or even with much force. A fact in mathematics would be unable to trace the steps of an intricate problem, after having contended in an athletic game; or, on the other hand, after having fatigued the mind by going through a new and laborious demonstration, he would be unable to exert the powers of his body in a fox chase. We cannot think much, and use strong exercise at the same moment. Both these powers, therefore, seem to depend alike on the nervous energy, and the simultaneous diminution of both implies the diminished state of that energy. Yet this is different from ordinary debility, and has therefore been distinguished by the term depression of strength; the powers of the body not being lost, but only prevented from acting by the disease; for if the disease ceases in eight or ten hours, (as in the paroxysm of an intermittent,) the depression of strength ceases likewise, and both the body and mind can exert themselves with a vigour nearly equal to that which they possessed before the disease began, or in perfect health. The nervous power is diminished, 'like the action of a spring, which is overcome by the temporary pressure of a weight, that does not destroy its elasticity.' Another result of the muscular relaxation is the feeble action of the heart, on which many of the symptoms depend. This is evinced by the feeble, small pulse, by its occasional irregularity, and even flowlessness, at the onset of the fever. This languor of the circulation, especially in the extreme vessels, is the cause of the palefia of the skin, and the shrinking and diminution of size in the features, and every other external part, as well as of moth'd swellings. The condition of the surface is the same, to all appearance, as is produced by the application of external cold, which constricts, or rather diminishes the action of, the small superficial vessels; whence the cutis aspera, or goose-skin contraction and roughness of the surface takes place. Whence also the skin is dry, at the same time, as perspiration cannot be produced from vessels in which the circulation is nearly suspended. It must be observed, however, that the action of the capillary vessels of the skin is not entirely regulated by the action of the heart and great arteries; for the former are sometimes dilated quickly, as in the blush of flame, or collapsed, as from external chill, when the pulse remains unchanged. From the same cause, (the languor of the circulation, and the contracted condition of the extremities of the arteries,) the other secrétions are diminished. The mouth and tongue become dry from the scanty supply of saliva; the pancreatic juice, the bile, the mucous and serous excretions in the alimentary canal being diminished, as well as the muscular actions of the bowels coiled, the faces are not puffed forward, and capillare andas place; the urine is not only small in quantity, but of pale colour, from the diminution of the saline and mucilaginous animal matter, which are secreted by the kidneys in health, and give it its peculiar colour. From the same imperfect circulation the discharges from the skin and ulcers cease in the attack of fever.

Until we obtain a more accurate knowledge of the origin and nature of animal heat, and of the means by which it is maintained at the regular temperature of $97\frac{1}{2}$ or 98°, notwithstanding the varieties of the atmospheric temperature in which we live, we shall not be able to explain satisfactorily the changes which the heat of the body undergoes during the different stages of fever. We know, however, that the variations of the heat are much connected with the functions of respiration and circulation. In what are called cold-blooded animals, the function of breathing is performed at long intervals, and is capable of great suspension without injury to life; and general coldness better than heat is the physiologic action of the blood is diverted from the lungs, as when the facial organization of the heart remains in after life. With the circulation the connection of animal heat is so well known, that, in popular language, redness, or a florid colour of the skin, (which arises from its vessels being dilated with blood,) is almost synonymous with heat. In all influences of acute inflammation the sense of heat is in a great measure proportionate to the vascularity and redness of the part affected. At the onset of fever, then, both the actual cold and sense of cold are doublets of the effect of diminished circulation on the surface, which is somewhat augmented, perhaps, by the imperfect respiration which is then carried on. It is not so easy to explain satisfactorily the sensibility of cold existing, when to the feel of another person the heat is natural. This may be attributed partly, perhaps, to the state of torpor in the brain, partly to the disordered condition of the sensitive extremities of the nerves, and partly to the actual chill, which remains in particular parts, while others have become warm. The sensibility of the organs in general, we have said, is impaired, and the sensations are occasionally not only diminished, but deprived. This also arises principally from the deficient circulation in the extremities of the arterial system. Sensibility is greatly dependent upon a sufficient circulation of arterial blood to the extremities of the nerves, as well as to the brain. Those parts of the body through which red blood does not flow are pœnified of little or no feeling; such are the cuticle, the nails, hair, tendons, &c. While, on the contrary, parts that are extremely vascular, as the true skin, are endowed with acute sensibility.

Again,
FEVER.

Again, the increased flow of blood to any part is generally attended with increase of the sensibility of the part; whence the augmented sensibility, the foreheads and tendernefs of parts that are inflamed. Hence, then, we may explain the diminished and depraved sensibility of the skin, and organs of fente, in the cold flague of fever. Even the turpor of the brain itself is increafed, and therefore partly to be accounted for by the weakened circulation in it, at that period of fever, and is probably, in many cases, a secondary effect.

To the enfeebled circulation also, much of the anxiety, and fente of load about the region of the heart, the fighing, yawning, and stretching of the limbs, is to be attributed, as well as the short and disturbed respiration. The force of the heart being unable to propel the blood to the extremities of the arteries on the surface, a greater quantity must be accumulated in the great veifs about the heart and in the lungs; whence the load and oppreffion, the labour and irregularity of respiration; whence also the fighing and yawning, which are a fort of inftinctive action, by which we dilate the lungs, give a fierer paffage to the blood, and therefore relieve, for a time, the uneasy fentiment. According to Dr. Fordyce, indeed, this fentiment has been proved by difection. "In thofe difeafes," he fays, "which have been made of patients, who have died in the attack of simple fever, the large veins going to the heart, that is, the vena cava, both fuperior and inferior, the right auricle of the heart, and the pulmonary arteries, have been found difted with blood, to a much greater degree than they are commonly, when death takes place from other caufes." (Firft Differt. p. 92.) Sometimes a cough attends the cold flague of fever, arising from the irritafion of this accumulated blood in the thorax.

The hifligfnefs and general uneafinefs which are at the fame time present, are almost the necefsary confequence of thofe morbid conditions of the fenfium, of the circulation, of the breathing, and of the muscles of all parts. Uneafy feelings lead us inftinctively to fearch in frequent changes of poffure. Besides thofe uneafy feelings, however, there are head-aches, and pains in the back and the limbs, which have been differently explained by different physicians. Some have ascribed the head-ache to the flate of the brain in the cold flague of fever, but erroneously, in the opinion of Dr. Fordyce, fince, whether it occupy the forehead over the eyes, or the back part of the head, it is equally external to the fenfations of the patient. In like manner, the fpinal marrow, as it is improperly called, being a continuation of the fubftance of the brain through the tube of the fpine, has been confidered as the seat of the pain of the small of the back which commonly occurs. (See Clutterbuck on Fever.) But why it should occur only in that part of the back, and not along the whole fpine, it might be difficult to explain: while, on the other hand, if it were an affection of the great muscles of the limbs, and it very much resembfes the pain of weaknefs and fatigue,) it fhould, like this pain, be greatly benefited by the horizontal poffure; which, indeed, we believe to be the fact, notwithstanding the affection of Dr. Fordyce. And the occurrence of fimilar dull pains in all the limbs renders it probable that it is chiefly muscular, and connected with a deficiency of nervous energy, as in muscles which have been exhaufled by fatigue.

The affection of the fluxom, indicated by the fift of appetic, feekefs, thirst, and food terrene, home or all of which are among the symptoms of the febrile attack, may not be fo capable of a fatisfactory explanation. It might be obferved, however, that there are at leaft three fources of arrange-ment to this organ in the cold flague of fever; namely, the state of the muscular fibres of the fluxom and of its fecretions, which suffer in common with the other muscles and fecretions of the body; the great fympathy which exists between the fluxom and the brain; and, above all, perhaps, the intimate fympathy of the fluxom and the skin. It femei demoniftd, from the effects of flimulant and tonic fubfiances in augmenting the appetite for food, and the power of digestion, that a certain vigour of the muscular part of the fluxom is neceffary to, and co-exifls with, the proper exerfice of thefe functions; and, therefore, that a re- laxation and defility of the fame part must be the caufe of a diminution of them. Observation also has taught us, that when the muscles are exhaufled by exercise, the fluxom partakes of the fatigue, and the appetite and digefive power are greatly impaired or loft. The influence of a morbid condition of the brain on the fluxom, by fympathy, is well known to be great, infomuch that some writers have confidered this influence as amply fufficient to account for the diforder of the fluxom in fever. Both in inflamation of the brain, and in the cafe of external injuries of the head, ficknefs and vomiting are among the moft invariable symptoms. Dr. Clutterbuck remarks, that the fluxom not only receives nerves from the great intereoral nerve, but a|lo communicates directly with the brain, by means of the eighth pair of nerves, or por vagum. Hence he adds, "it is little to be wondered at, that the functions of the fluxom in fever, and the fummonus of the other organs of the body, should fuffer a deviation from the natural flate. In this way the uneasy fenfation often felt at the pit of the fluxom in fever, the total want of appetite, the loathing and difgust commonly experienced even at the fight of food, are naturally and easily accounted for." (Loc. cit. p. 74.)

Dr. Cullen, on the other hand, is difposed to confider the flate of the skin as the principal occafion of the affection of the fluxom, in confequence of the fympathy between the two organs. The fym pathetic influence of the flate of the skin in inducing diforder of the fluxom is fupported by a curious fact obferved by Sydenham in the plague. In the attack of that difeafe, he remarked, that vomiting occurred, which prevented both food and medicine from remaining on the fluxom; and that the means by which he was enabled to alay this fymptom, was inducing perfpiration by the aid of external covering; as foon as the skin became moift, the ficknefs diminished, and the loathing and miseries were then retained. (Sydenham, Op. fecl. ii. cap. 1.) We fhall hereafter remark the occurrence of the hot flage generally removes the vomiting, that of the sweating flage always.

This doctrine is ftilI further supported by a confideration of the origin and removal of the triflis, which occurs at the onfet of fever. The fentation of triflis doubtleslly arifes from different caufes, and under different circumftances, the mere drynefs of the mouth and fenes, from evaporation of the moisture, in confequence of the heated breath, or from deficient fecretion, may be attended with that fenfation; uncommonly it feme to be excited by a peculiar occafion of the fluxom, while the mouth and fenes remain moift, as appears from the third which arise from falted food in the fluxom, or food of difficult digefion, or too great in quantity; or, as Dr. Fordyce fashion, it feme to be fometimes occafioned by a diminished proportion of water in the blood-cells; as, in the cafe of diabetes, when the kidney is made up to a fuperior activity or excretion, and a great defcance of fluids by perfpiration. The author, however, confiders the matter as not capable of being determined, (see his Firft Differt. p. 223.) although he is difposed to refer it to a particular affection of the fluxom. (Ibid. p. 80.) This opinion, we think, is scarcely to be questioned for a
moment; since thirst often occurs in fever, when the tongue and fauces are moist, and generally before any diminution of the watery part of the blood has taken place. But several circumstances condense to prove an intimate connection between this affection of the stomach, which occasions the fastation of thirst, and the state of the skin. It has been found by seamen, when accidentally deprived of drink, (as by lieutenant Bligh, and his men, in their miserable voyage in the South sea,) that by immersing the body in water, or applying wet clothes to the skin, the thirst has been relieved. Dr. Currie relates the case of a gentleman, who was prevented from taking any substance, solid or fluid, into the stomach, in consequence of an obstruction in the esophagus. In the first days of his abdomen the fastation of thirst was very troublesome; but it abated, and, as he declared, was always removed by immersion in the tepid bath. (Med. Reports on Water, etc. p. 275.)

The same author has stated from numerous experiments, that the thirst, which continues in the hot stage of fever, is almost instantaneously removed by the application of cold water on the skin, which at the same time induces perspiration, and relieves the febrile paroxysm. (See Cott.) On the contrary, the swallowing of cold drink, in the hot stage of fever, which relieves the thirst, is often followed by a relaxation of the perforatory vessels of the skin; and, when cold, drink does not produce a sensible increase of circulation in the skin, the influence which it affords to the thirst is momentary only; which evidently proves the reciprocal sympathy of the organs. (Currie, loc. cit. 178.) And this is farther proved, as we have already stated, by the cessation of thirst when the sweating stage of fever is established.

All the symptoms, then, of the onset of fever, constituting the phenomena of the cold stage, are explicable, directly or indirectly, on the supposition of a depression or diminution of the nervous energy, however induced. In like manner, the symptoms of the hot stage and the subfequent phenomena, in continued fevers, are referable to an imperfect recovery, as it were, of the nervous power, and more immediately to the increased action of the heart and arteries, and of the capillary vessels.

The heat, the redness of skin, and flushed countenance, the returning size of the external parts, the restoration or even increase of the sensibility of the organs, are all the result of the diuresis of the extreme vessels by the hot blood, as the opposite symptoms of the cold stage were the consequence of an opposite condition of the circulation. Hence the frequent fevers of the body, which cannot bear its own pressure without pain; hence intolerance of light in the eye, and the quick sensibility to noise in the ear, both of which increase the head-ache, which is now more acute, and deep-seated: hence also defeased parts become more painful. The quick, and strong pulse, implies the greater force of the heart, and of the arterial action; nevertheless the dryness of the skin, and the continued suppression of the rest of the secretions, evince the continuance of a morbid condition (a constitution or poison, it has been called) of the extremities of the exhalent and secretory arteries, by which their functions are impeded. This condition bears a considerable analogy to the state of inflammation, (see Inflammation,) and when this stage of fever, and these particular symptoms are very fevers, the fever has been called inflammatory fever.

Connected with, and in a great measure the result of this morbid condition of the circulation in the brain, is the delirium, which, though it occasionally occurs in the cold stage, is usually absent until the hot stage has been formed. It is often accompanied by a throbbing or strong beating of the carotid and temporal arteries, redness of the eyes, and flushed countenance, which give us reason to believe that it arises from over-excitement of the brain, by the quantity of blood thrown up into it by the increased action of the heart. In this state the ideas crowd themselves, as it were, upon the attention of the patient, and change rapidly from subject to subject; he is unable to court the records of sleep, in consequence of the torrent of images which are presented to the mind. The condition of the brain appears to be similar to that of the whole of the sentient parts: as the eye is more acutely sensible to the impression of light, and the skin to that of touch; so the brain or the sensorium is more easily excited to thought, by the impressions of internal irritation, which are exceedingly multiplied in this state of fever. Hence the incessant dreaming which distresses the patient, if he falls into an imperfect sleep; and as the internal feelings are all of a painful nature, whether we consider the anxiety, the head-ache, the pain of the back and limbs, or general uneasiness, &c. the dreaming ideas, which are associated with these feelings, are also a painful and disturbing nature. (See Dream, in Pathology.) If this increased action of the vessels of the brain continues, a degree of prefire is apparently produced by a more permanent diffusion of them, and a fever and deadness come on. If the patient die in this state, a general congestion of the vessels of the brain is found upon dissection; but the mere active delirium, unattended by fever and deadness, may even prove fatal, yet no traces of the morbid condition of the vessels of the brain shall be discoverable after death. (Forbyee, Third Diff. 1. p. 99. 109.) In these cases, it sometimes happens that the delirium ceases some hours previous to death, although the other symptoms of fever continue. This obviously arises from the linking powers of the circulation; whence the action of the arteries of the head is reduced to something approaching to the natural state, before it ceases altogether with death. Delirium is occasionally connected, it is supposed, with an enfeebled action of the vessels of the brain; in which case it affinmes another form, is not accompanied with any violence, but with great feebleness, and a low muttering rather than a hoarse noise. It is the delirium mone of authors. (See Delirium.) We believe, however, that even this low delirium is commonly the result of some degree of congestion of the vessels of the brain, arising from local inequality of the arterial action, although that action may not be violent. The sweating, like the dry heat of the second stage, is produced in a manner not very well understood. It was supposed by the older physiologists, as by Albanius, Haller, &c. that the sweat, as well as the insensible perspiration, is a mere exudation of the watery part of the blood through the cuticle: hence it was said to arise, in fever, from a mechanical relaxation of the extreme arteries, which were supposed to be spasmodically contracted during the hot stage. But it has been observed, by later physiologists, that this opinion respecting the nature of the perspiration is contrary to all analogy, and founded only upon experiments made on the dead body. The opinion of Dr. Forbyee and Mr. Cruickshanks appears to be the true one: namely, that the matter of perspiration is secreted from the blood by the capillary arteries, and thrown out on the surface by organic pores in the cuticle, (however difficult to be discovered,) connected with the extremities of these arteries; and that in this process there is not a separation merely, but a new combination, as in similar influences of secretion. (See Dr. Currie, loc. cit. p. 200.) Although, therefore, the occurrence of perspiration has been considered as the cause of the cessation or diminution of the symptoms of fever, (and certainly
certainly no such change takes place without some appearance of moisture on the skin, yet it is probably only one of the signs or effects of that affection, in common with the reiteration of the other secretions, which are also diminished or suspended in the attack of fever. This point, however, seems to be ascertained, that the process of perspirations is a cooling process, and the principal means by which the overheating of the body is prevented or removed. The heat of fever declines gradually, as the perspiration goes on; but the rapidity with which it declines is varied by the quantity of bed-clothes, and the degrees with which the body is enveloped. While perspiration goes on, it is difficult to raise the temperature of the body above the natural standard, and under such circumstances it is capable of bearing very extraordinary degrees of heat, as was proved by the experiments of Sir Charles Blagden, Dr. Forsythe, and others. Whether the refrigerating effect of sweating depends solely on the evaporation, or whether an absorption of heat takes place in the process of the secretion of perspirable matter, is not certain.

The turbid urine, throwing down a sediment of a lateritious or brick-dust appearance, arises from the reiteration of the secretion of the kidneys, which now separate the lithic acid, as well as the animal extractive matter, in greater quantities than in health; but the urine contains, at these times, only a super-abundance of those substances which it contains in a state of health, there being no new or morbid matter produced in it. This change in the urine has been likewise explained upon the supposition of a spasm in the secreting arteries in the kidneys, which suffered only the thinner parts to pass, or pale urine, in the first stages of fever; but being relaxed in the sweating stages, the thicker parts were allowed to pass, and thus occasioned the sediment. But the kidneys, like the other secreting organs, are not mere vesicles, nor are those thicker parts existing in the blood, previous to the commencement of the sweating stage; they are then produced by the action of the kidneys. There is, however, an intimate connection of sympathy between the action of the perspiratory vessels of the skin, and the secretion of this over-proportion of lithic acid, and animal mucilage by the kidneys: for it is generally producible at pleasure by a dose of Dover's powder, or other sudorific medicine.

The symptoms, which occur in the later periods of fever, when it goes on to a fever or fatal degree, are explicable as the effects of an extreme prostration of strength. Hence the tremors, and slight convulsive motions, or furtulent, of the tendons and muscles; hence also the irregular vision, with the appearances of little bodies flying before the eyes, (microscopically on the retina, or nervous membrane of the eye; hence the general indigestibility, the difficulty and labour of respiration, the involuntary discharge of stools and urine, the difficulty of swallowing, &c;)

The regular periods at which the paroxysms of intermitting fevers, and the exacerbations of remitting, and even of continued fevers, return, require some notice, although a satisfactory explanation may not be attainable. The fact has been generally referred to the influence of habit, which is productive of many phenomena in the animal economy. (See Habit.) It is observable, that all men, even in a state of good health, have a sort of febrile condition introduced in the evening, which goes off in the morning: there is some depression of strength or dizziness both of body and mind, and the pulse is quicker than in the morning. In proportion as the health is more delicate, this state is more evident. It is probable that this diurnal paroxysm is to be attributed to the effect of the irritations of the day, which are suspended during the night; and this diurnal habit might be sufficient to account for the usual evening exacerbation of continued fever. A similar diurnal habit is likewise observable in many of our actions and functions; as in the returns of sleep and waking, and of our appetites and excursions, which, if prevented from taking place, or being gratified at the accustomed period, are apt to cease or become less urgent. This is often remarked with respect to the desire of sleep, to hunger, and to evacuation of the bowels. These facts might afford an analogous explanation of the periodical returns of intermittent fevers, if they were all supposititious; but they afford us little assistance in accounting for the return of the paroxysm of those fevers at the end of forty-eight hours, in the case of tertian, or of fifty-two, in the case of quartan fevers. But it is remarked by Dr. Cullen, that even those dilatant paroxysms are in some degree connected with the diurnal revolution, as the times of their accession are generally fixed to one time of the day; so that quotidian come on in the morning, tertian at noon, and quartans in the afternoon. (First Lines, § lvi.) Some writers have attributed all these periods to the habit, but as the second and third paroxysms of a tertian occur as regularly, often more so, at the end of forty-eight hours, than the seventh and eighth, habit could not be the cause of the return in the former inexpressions, whatever might be supposed with respect to the latter. On the whole, we can only conclude that a disposition to these periodical changes is a general fact in the animal economy. See Periods of Disease; also Catenation.

General Prognostics in Fevers.—In continued fevers the event cannot be prognosticated with any approach to certainty. The dilatation is in its nature of a dangerous tendency; and although there shall be no unfavourable symptom for the first seven or eight days, yet the fever may afterwards assume a dangerous character, and terminate fatally: while, on the other hand, recoveries occasionally take place, when the severity of the symptoms seemed to preclude all hope. A large proportion of the cases of fever, however, if properly treated, terminate favourably. Under the various forms which fever purports on, we can arrive at a correct notion of the probable termination of each particular instance, by taking a comprehensive view of the living machine; by estimating the relative importance of the several organs and their functions, in the maintenance of life; and, therefore, by observing accurately the number of these, which are affected by the disease, and the degree in which they are deranged; and we must further take into the consideration the species or type of the fever, its general tendency, as well as the particular tendency of the prevailing epidemic; and likewise the peculiar circumstances of the patient, in respect to age, constitution, previous habit of body, mode of life, &c.

The prognostics of a favourable termination is deduced principally from the lesser degree of violence in the symptoms in general, or the smaller number of those which are fever; and likewise from several changes in the course of the disease, which experience has ascertained to be salutary.

Favourable Symptoms.—If the foetidus continues unaffected until the middle of the second week, and a delirium moderate in degree should then come on, it is not unfavourable; it implies a moderate affection of the brain. Deafness is most commonly a favourable symptom in this country; it implies, indeed, a morbid condition of the brain, but one which experience has proved to be free from the danger which attends the opposite condition.
FEVER.

The symptoms of a failure of the vital powers, however, which are more common in the fevers of this country, are less under the control of medicines, and therefore more dangerous; and moreover especially when conjoined with a congestion, or low degree of inflammation, in any of the important fevers. We shall note these symptoms of failure of the *sir upa* vis, as they are connected with, and exhibited by, the disordered state of the functions of the leading organs. It has been stated, under a former article, that death is always occasioned by an interruption of the functions of the brain, of the heart, of the lungs (see Death); and accordingly the symptoms which occur in the functions of the meninges, and in the circulation, and respiration, in fevers, are those which mark the greatest degree of danger.

The defect of energy in the senorial functions is indicated by the extreme muscular debility; or prostration of strength, in the latter periods of continued fevers. Thus, if the patient is unable to support himself on either side in bed, but falls back into the same position by the influence of gravity; or the bed, a dangerous debility is indicated. Tremors of the hands, (as well as of the tongue, when protruded,) and of other parts, which with a slight increase pass to subfutus or flattening of the tendons, and these again into convulsions, are bad symptoms, as they imply an imperfect and irregular distribution of the nervous influence from the brain. After the tremors and subfutus tendinum patients frequently recover; but rarely, if ever, when convulsions supervene. Sir John Pringle remarked, that a tremor of the hands in the beginning of fever was one of the most constant signs of that fever being of a typhous nature. (Loc. cit. part iii. chap. 7. § 2.) When the diaphragm is affected (palmodically), giving rise to hiccup, it is a fatal symptom; as it is likewise the relaxation of the sphincter muscles of the bladder and the straight gut, (rectum,) which allows the urine and the feces to pass involuntarily, and which marks an extreme degree of debility. And when the muscles of the gullet, and those of respiration, become so far enfeebled, that the act of deglutition becomes difficult or impracticable, and the act of breathing is short and very labored; that is, generally, to be considered as near at hand. The foaming at the mouth, and the rattling noise in the throat, which is called by nurses the dead-crotches, are the first more immediate precursors of death; and are occasioned by air of respiration passing through the mucous and saliva, collected in the mouth and throat from total inability of swallowing it. Other unfavourable symptoms, indicating the deficiency of the nervous power, are found in the different degrees of slumber and delirium, which are more indicative of danger, in proportion as they appear earlier in the disease; but which often occur, nevertheless, to a very confiderable extent, in cases which terminate well: so that we must take the other symptoms into consideration before we decide upon the danger of these. Dr. Fordyce has stated, that "although the patient should be insensible to all external objects, though he should sleep very little, or scarcely at all; yet, if the deglutition and respiration should remain unimpeded, the patient is not to be despairs of; it happens most commonly that he recovers. But if he respirs with great difficulty or hardly at all, or if the deglutition be almost totally prevented, or if attempting it throws the patient into convulsive
convulsive contractions, he rarely recovers." (Third Differt on Fever, part i. p. 111.) Nevertheless, he judiciously estimated the unusual continuance or increase of delirium as a dangerous symptom; for, "on the other hand," he adds, "if the other febrile appearances do not keep pace with the delirium; though the pulse should become more quick and less obstructed; though the tongue should become cleaner and softer; though the colour of the skin should become more natural, the secretory veins more relaxed; if, however, the delirium should still continue, without fever or pulse-feeling, and the other marks which have been pointed out as accompanying fulness of the vessels of the brain; in such case, notwithstanding the practitioner and bystanders are flattered, the patient is frequently cut off." (Ibid.) The more active delirium is often accompanied with an inflammatory condition of the brain, even in fevers arising from contagion, in which the other organs evince a defect of power, and the rest of the symptoms are also indicative of great debility: this combination of a local inflammatory action with general defect of power, whether it be considered as implying an inequality of the distribution of nervous influence, or be explained by any other hypothesis, is invariably dangerous, in whatever organ the inflammatory action takes place, but particularly when it is in the brain. It is necissarily embarrassing to the physician, and difficult to treat successfully, from the opposite nature of the remedies required for the suppression of the local inflammation, and of the general prostration of strength; the nature of the one affections absolutely contra-indicating the treatment, which the nature of the other as decidedly requires. Connected with the defect of senofinal power, the absence of thirst, while the tongue and mouth continue exceedingly dry and parched, is deemed an unfavourable symptom; and a delirious patient fancying himself well, is equally unfavourable, as implying a great obtuseness of the sensibilities.

In respect to the circulation, all unusual perturbation in the action of the heart and arteries is in some degree unfavourable; but especially extreme frequency and freckles of the pulse, and irregularity. When the pulse beats above 120 times in a minute, or more, in fever, it must be considered as an unfavourable symptom; when it reaches 150, or upwards, the prognosis is extremely unfavourable. Although in some fevers, as in hydrocelephus, the pulse has been counted at upwards of 200 beats in a minute; yet, in fever, before it comes to 150, it is generally too incul and feebie to be counted at the wrist, and the pulse is then to be considered as adequate; the pulse, indeed, has sometimes been so obtuse as not to be felt at the wrist, for a day or two before death, when it might be felt at the temples, or in the axilla. In this state, the extremities are generally cold, which is another fatal symptom, when combined with those before-mentioned. Sometimes, from an irregularity in the action of the heart, the pulse intermits. An intermitting pulse, according to Dr. Forید's opinion, "is always a very dangerous symptom, excepting where it also took place when the patient was in health, and before the disease arose; but in the attack it is particularly hazardous." (First Differt. p. 85.) It is certain, however, that an intermitting pulse occurs in some cases along with favourable symptoms; we have seen it in a few cases, and only under such circumstances, in all of which recovery took place. It is remarked by Dr. Gregory, the present professor of physic at Edinburgh, that when the intermission is connected with an obscenity or indignation of the pulse, and the other parts of the face, are also among the unfavourable symptoms, as implying great irregularity of the circulation.

Great derangements of the respiration, whether such as denote a degree of inflammation in the lungs, (constituting the pneumonia typhodes of authors) which, from the contra-indications already mentioned, is extremely difficult and embarrassing to the practitioner, or such as denote the failure of the muscular powers, before alluded to, are always extremely unfavourable symptoms.

Deficiency of the nervous or vital power is farther indicated by the effusions of blood which take place from the extremities of the arteries under the skin, forming the petechiae, ecchymoses, and blotchtes, before described. These are always symptoms of a fever diseased, but far from being mortal. The larger they are, and the nearer they approach to purple in their colour, the more they are to be dreaded. (Pringle, loc. cit.) Dr. Huxham observes, that "when black, livid, dun, or greenish spots appear, no one doubts the malignity; the more florid, however, the spots are, the less is to be feared; it is a good sign when the black or violet petechiae become of a brighter colour. The large black or livid spots are almost always attended with profuse hemorrhages. The small dusky brown spots, like freckles, are not much less dangerous, than the livid and black; though fluxes of blood do but seldom accompany them. The violets, or large livid or dark greenish marks, seldom appear till very near the fatal period." (Loc. cit. chap. viii.) The petechial hemorrhages mark a greater degree of the same condition of the fluids and fluids. Black and very fetid fluids are bad, as indicating a strong putrefactive tendency of the bile and forbes in the bowels, and as arising from blood effused into the canal. The urine sometimes deposits a black and fetid sediment, which conffits of effused blood, and is equally unfavourable. Thee, together with the black fur which collects about the teeth and mouth, the fetid breath, the disposition to gangrene in parts inflamed by blisters, or by the preasure of the body in bed, the loose texture, and black colour of the blood, &c., are the symptoms, which have been considered as denoting a patrid condition of the fluids in these forms of fever. It cannot be questioned, that there is often a putrescent tendency in the circulating fluids and in the fluids, so that they readily undergo the process of putrefaction, when discharged or after death; but it is well ascertained, and has been confirmed by direct experiments, that an actually putrid state of the finalized portion of the circulating fluids is incompatible with life. It is sufficient, however, to know that these symptoms denote great danger, or a great tendency to death, and to have learnt from experience, the remedies which contribute to remove the symptoms, and to counteract that tendency.

The changes which take place in the urine were formerly much attended to, and although not so much is to be learnt from its appearances, respecting the nature and progress of the fever, as was once supposed, nevertheless this excitation ought not to be neglected by the practitioner. It is an unfavourable symptom when the urine, after having been turbid, becomes again pale and limpid; as it implies a return of the torpor or contraction of the extreme vessels, i.e. a renewal of the febrile attack, and is therefore commonly followed by other bad symptoms, as by delirium, congestions in different organs, &c. Incontinence of urine, whether dependent on a laxity or paralytic state of the sphincter muscle of the bladder, or whether the urine is expelled involuntarily from a tumor or indulgence of the patient, is always unfavourable; if this is overlooked, excretions are apt to take place from the patient lying wet, whence inflammation.
inflammation and sometimes gangrene arise. A difficulty in distilling the urine, or palping it frequently in small quantities, indicate considerable irritation and congestion of the bladder, and are therefore bad symptoms: a suppression of urine may be considered as one of the worst symptoms of fever. When the urine exudes an offensive odour, or is black in its colour, especially when containing the black or bloody sediment before mentioned, it indicates a state of the body which is dangerous. Even the ordinary healthy appearance of the urine, combined with symptoms of severe fever, is considered as indicating an unfavourable state. (See Lommius, Medicinal Observ. lib. 1. p. 5.)

Vomiting, especially of blood, or of matters of bad colour and smell, is a symptom of extreme danger. Obstructive colliensives in the latter stage of fever, which is generally accompanied with feverish headache, is very unfavourable. It seems to imply great torpor in the bowels, in consequence of the affection of the nervous system. Diarrhœa, in the late periods of fever, is generally unfavourable, especially when the feces are liquid, and at the same time very pale, or black, and fetid: the pale colour implying the absence of the bile and proper fluids of the intestines; the black and fetid condition indicating a corrupted state of the bile and other secretions, or a mixture of blood, and a putrefactive tendency of the whole contents of the bowels. A more copious discharge of unmixed blood from the intestines is a dangerous symptom; if hiccup or convulsions follow it, death generally soon ensues. This condition of the bowels seems to arise in many cases from a neglect of opening them, or removing the fords in the beginning. A great dilution of the abdomen, or of the epigastric region, arising from flatus, which the stomach and intestines have not sufficient power to expel, is often among the late and fatal symptoms of fever.

The changes of the countenance afford very important indications in respect to the severity and probable event of the disease. With a small share of experience, indeed, any person will recognize fever, from inspection of the countenance alone: and the disease never advances to a dangerous state without being accompanied by proportionate alterations in the features. In extreme debility, the eyes are often sunk or collapsed; sometimes they remain fixed and unmoved, which state is connected with the coma and stupor; and occasionally arises from a spasm of the muscles of the eye-ball, in which case they are also sometimes prominent; at other times there is a constant rolling of the eyes, which is often connected with delirium; or there is a distortion, or fquint, which commonly implies some pressure or other affection of the optic nerves. All these are of course unfavourable symptoms; as is also that curious defect of vision, from impaired sensibility of the retina, which gives rise to the appearance of mufaee volatantes. When the white part of the eye is principally seen, the pupil being turned upwards, and the upper eye-lid a little let down, it is unfavourable, as implying a spasmodic contraction of the muscles of the eye-ball, and great relaxation in those of the eye-lid. The prognosis is also bad, when a fog of film is formed over the eye, or mucus collects within the eye-lids, on their edges, or at the angles of the eye, or when the cornea is red; or when one eye seems larger than the other, implying irregular motion of the muscles. Any distortion of the features is a bad symptom, for the same reason, indicating the great affection of the functions of the senilium.

Great redness, a constant motion of the arms, uncovering the balsam, or the arms and legs, which nevertheless are not hot, picking at the bed-clothes, as if to catch flies or insects, grinding the teeth, (which is a spasmodic affection of the muscles of the lower jaw,) are all symptoms of considerable danger, as indicating great derangement of the nervous system. The changes of the voice, as connected with debility of the muscles of respiration, as well as of the lesser muscles of the larynx, are also unfavourable signs. The tone and articulation are thus variously altered, and the thick black crust and fur which collect on the tongue and lips, and in the fauces, farther contribute to impair the speech, by preventing the free motions of those parts. A cold sweat, cold extremities, and great collapse of the countenance, together with laborious respiration, and rattling in the throat, are signs of impending dissolution.

The cause of Fever.—At present we shall confine our attention to the remote causes of fever; the proximate cause will be the object of discussion in the sequel. (See CAUSE, in Medicine.) It is not always easy to distinguish between the predisposing and the exciting causes of fever; and circumstances which have been ranked among the latter by some physicians have been considered by others as operating only in the former way; and it would seem that in certain cases, where the predisposing causes are applied suddenly or to a great extent, they actually become exciting causes of the disease. The middle periods of life appear to be more liable to fever, than either of the extremes of old age or infancy. Inflammatory fevers in particular are more readily produced in the vigour of the constitution, or in youth, from the period of puberty to the age of 35 or 40. Whatever produces either of the opposite states of plethorism and asthenia, or ination and debility, predisposes the habit to fever, and favours the operation of the exciting causes; plethorism giving a predisposition to fevers of the inflammatory kind, while ination predisposes to intermit-tents, remittents, and to the nervous or typhous fever from contagion. Hence, with respect to the last mentioned circumstance, the connection between had durt, or fear of food, and fever, has been observed from the earliest periods of history, and pellagia and famine have been commonly mentioned in connection with the occurrence of contagious fever in London, during the winters of 1799 and 1800, was occasioned by the predisposition to be affected by contagion, which the fear of provisions in those years produced; and that the almost total disappearance of such fever, since that period, must be ascribed to the absence of such predisposition; since the exciting or occasional causes continue to exist as before. Galen justly remarks, "Opotet enim hoc in toto servor na membra repugere, quod nulla caufarum fines patientis aptitudo agere potest." (De Difer. Febr. Trans. of Leonicenus, lib. 1. 1809.) It is not improbable, however, that the depraved aliment, which is used in times of scarcity, may of itself actually produce fever. The weakness produced either in the nervous system, by depriving the patient, such as fear and grief, or in the fanguineous system, by great evacuations, appears to constitute a great predisposition to be affected by fever. With respect to the depressing passions, there cannot be a doubt of the influence which they exert in predisposing the body to suffer from the exciting causes of fever. The observation that the pain occasioned by the prevalence of a contagious epidemic disease, tends to favour its progress, is as old as Thucydides; who has mentioned, that those who were low in spirits, and felt much fear and anxiety during the dreadful pestilence which he has described, were cut off most speedily. Diemerbroeck quotes an observation of Pigneur, who compares the effect of imperfect aliment on the body with that of the depriving passions on the mind,
in facilitating the access of the plague. "Sicut mala
vitæs ratio preparat humores, sic animi paﬃones preparat
spiritus ad recipiendam pellem; et tristitia, terror, ira, ac
metus, sunt pabulum ac nutrimentum pestis." And
Bauderonus obseruer, "Conﬁdentem ut plurimum fervatur;
contra metu(end) facile corririuant." (See Dierembroeck,
de Pefel, lib. i. cap. 8. § 9. and again, lib. ii. cap. 7. Annot.
where much evidence on this point is collected.) The
debility occasioned by fatiue, from violent or long con-
tinned exerciion, is another cause which predisposes the
body to be affected by the exciting cau ses of fever. This
is, without doubt, one of the reasons why soldiers, har-
rqrafed by fatiues of a campaign, so readily fall into fever
when conﬁned in hospitals and barracks. The fact was so
generally observed, at the time of the epidemic fever which
Dierembroeck has described, that many among the lowest
people abstained from hard labour; even the peasants during
the hay-harvest were unwilling to work and collect the hay,
being taught, by many lamentable examples, that those who
undertook any severe work were immediately afterwards
feized with the plague. (Loc. cit.) It is probable, in-
deed, that very violent exerciﬁes, as well as violent and
indulgent ﬁtts of pafﬁon, may at once throw the fyllem into a
febrile state; we are certain that an epidemic, beginning
with ﬁvering, which is succeeded by heat, and, lately, by
sweating, is not an uncommon refeult of a fever’s day’s jour-
ney, nay, in those who are unaccustomed to such exer-
ciion. Exeexs in the gratiﬁcation of the venereal appetite,
as contributing to debilitate greatly, especially the nervous
fyllem, is jujly ranked among the predisposing cau ses of
fever. Evidence of the pernicious inﬂuence of this exeexs
was abundantly manifested during the last plague at Marccilles,
in which the recently married people suffered greatly. In-
omoderate study or other application of the mind, which not
only implies a fedentary life, but particularly an encroach-
ment on the hours of sleep, which greatly debilitate and
exhaust the nervous fyllem, also favours the action of the
exciting cau ses of fever, if it does not actually in some cases
bring it on.

Yet notwithstanding the unquestionable inﬂuence of a
debilitated state of the constitution, in general, in giving a
predisposition to fever, it has been observed, that persons
labouring under particular diseases, which are connected
with much debility, are not liable to be affected by the
exciting causes of fever. Dr. Gregory remarks, in his
letters, that he has known persons much debilitated by
dropy, and pulmonary consumption, who have been greatly
exposed to the operation of contagion, without being at-
tacked by fever; and Dr. Lind observes, that those who
labour under feaver are less liable to be attacked with fever
from contagion, than those in health. (Treatise on
Scurvy.)

There is a particular predisposition attached to certain
constitutions, (which are not to be distinguished by any
external character,) to be affected by the exciting cau ses of
feaver, upon every ﬂight exposure to them. This is daily
exempliﬁed in respect to contagion, and is often observed
with respect to the eﬄuvia of maladies. The predisposition
to be affected by both these causes, but more especially by
the latter, is diminished by the habit of exposure; so that
new-comers are more certainly feized with intermittent and
remitting fevers, for inﬂuence in the countries where they
prevail, than the inhabitants: and the attendants on patients
labouring under continued fever are perhaps less liable to be
infected than visitors. The greatest predisposition to inter-
 mittents appears to be occasioned by a previous attack of
the disease, inasmuch that a relapse is often produced, at
some distance of time by very light cau ses, and even, it
would appear, without exposure to the original exciting
cau se.

Particular seasons, especially those in which great heat
prevails, or, in low countries, those which are very wet,
seem to give rise to a great predisposition to fevers; the hot
seasons producing a tendency to bilious and inﬂammatory
fevers, the wet to intermittent and remittent, and the
combination or alternation of the two is particularly per-
nicious. The history of medicine shews us, that it is in
such fevers that contagious and pestilential fevers have
most generally prevailed. (See Epidemic.) Great heat,
indeed, appears to be frequently an exciting cause of fever,
especially in warm climates. (See Insolation.) An
exposure to cold and moisture appears also to favour the op-
eration of the exciting causes of fever, especially of the mias-
ma of marshes in the production of intermittent and re-
mittent fevers. It is hence, probably, that the night-air
appears to be so fatal near the coasts in tropical climates, as
related by Dr. Lind, Dr. Badenoch, (Med. Ofﬁ. and
Inquir. vol. iv. p. 156.) Bontius, Ronpe, and others. Dr.
Lind has stated, that, "during the ﬁckly season, a boat,
belonging to the Medway man of war, which attended on
more every night to bring fresh provivals, was three times
successively manured, not one of her crew having survived
that service."

We must here notice a circumstance respecting the pre-
disposition to fevers, in warm climates, which was ﬁrst
noticed by Dr. Lind, of Windsor, in his inaugural essay,
published at Edinburgh in 1768, and afterwards more par-
ticularly examined by Dr. Jackson and Dr. Balfour; namely,
the inﬂuence of the moon, or of the sun and moon con-
JOINTLY, in giving a predisposition to fevers to the human
body. Dr. Mead, indeed, had collected some evidence of
the inﬂuence of these luminaries in this climate, (see his
treatise De Imperio Solis et Lunae,) but that inﬂuence has
been said to be much more obvious in tropical countries,
in producing relapses or ﬁrst seizures of fever. Dr. Lind
observed eight feamen attacked by a relapse at the same
time, during the occurrence of a lunar eclipse, which of course
implied a full moon. Dr. Jackman made some observations
on the subject in 1776, in the West Indies, and found that
of 30 cases of remitting fever, 28 had happened on one or
other of the seven days preceding a new or full moon; in
the following years his observations were continued, and
seemed to conﬁrm this result. (See London Med. Journal,
vol. viii. p. 25.) In 1785, Dr. Balfour published "A tre-
atise on the Inﬂuence of the Moon in Fevers," in which he
states that the attack of the bilious remittent fever of Bengal
almost invariably commenced on one of the three days which
immediately preceded and followed the change of the moon;
and that the changes of this planet are no less remarkable
for occasions relapses. "For my own part," he says, "I
have observed this tendency to relapse at the full and
change invariably for these fourteen years; and in particular
cases can prognosticate the return of the fever at these
periods, with almost as much conﬁdence, as I can foretell
the revolution itself." Dr. Lind, however, fifteen years
after the publication of his thesis, seems to have changed
his opinion, and was disposed to attribute the frequent at-
tacks and relapses of these fevers "to the noxious vapours
arising from the swamps, produced by the high tides, which
happen at the time of the full and change of the moon, and
overwhelming a great part of the country, leave it in a mirrhy
state at low water. This I am induced to believe to be the
sole cause," he adds, "that because this lunar inﬂuence
certainly ceases, when the patient is removed but a few miles
from
Fever.

from the swamps that are left uncovered by the tide at low water; secondly, because intermittent fevers are not observed to follow lunar periods at many places within the tropics, even at Canton, where there is a large river and great tides, by reason of the indolent Chinese keeping the river within its bounds." (Lond. Med. Journal, vol. viii. p. 146.) But Dr. Jackson contends, that at Savannah la Mar, in Jamaica, the connection of the moon with fevers is more remarkable than in any other part of the world, in which he has been; although the tide scarcely ever rises eighteen inches, and the bank is sandy. (Ibid. p. 302.) Dr. Balfour has supported his original doctrine in subsequent publications "on lollunar influence" to which we refer the reader for farther evidence. See also Dr. Jackson's Treatise on the Fevers of Jamaica.

Exciting causes of Fever.—Dr. Cullen was of opinion that idiopathic fevers were induced by the operation of two exciting causes only; namely, contagion, or human effluvia, and the misfnata of marshy or swampy ground; the former giving rise to continued, and the latter to intermittent and remitting fevers. (See Effluvia, in Medicin.)

It seems probable, however, that this opinion was adopted rather in conformity with his hypothesis respecting the nature of fever, than from a comprehensive observation of facts; and his reasoning in support of it is liable to much objection, if not to an easy refutation. "As fevers are so generally epidemic," he says, "it is probable, that some matters floating in the atmosphere, and applied to the bodies of men, ought to be considered as the remote cause of fevers; and these matters present in the atmosphere, and thus acting upon men, may be considered either as contagious, that is, effluvia, arising directly or originally from the body of a man under a particular disease, and exciting the same kind of disease in the body of the person to whom they are applied; or misfnata, that is, effluvia, arising from other sublances than the bodies of men, producing a disease in the person to whom they are applied." (First Lines, § lxviii.) Now, it has been demonstrated by modern experiments, that contagious effluvia are not capable of floating in the atmosphere, to the distance of even of a few yards, without losing their infectious quality, and that the noxious powers of misfnata are similarly, though not equally, limited. (See Contagion.) And, although fevers are often epidemic, yet they are seen daily sporadic, i.e. limited to individuals, who breathe the same air with thousands who escape; and we have endeavoured to show, that the flippage of the existence of those causes of epidemics floating in the atmosphere, is not only gratuitous, but absolutely in opposition to a number of facts. (See Epidemic.) Besides, even vulgar observation has left no room for doubt, that many of the circumstances, which induce a predisposition to fever, or favour the operation of contagion, misfnata, and other exciting causes, of such kind, exist themselves the exciting causes of the simpler forms of fever, whether denominated chymereps, simple fever, fycnochus, or by some other term. That such fevers are frequently occasioned by exposure to great heat, and to cold and moisture, by fatigue, anxiety and grief, without the least intemperance, that is admitted by physicians in general; (see Fordyce Fleet Diff. on Fever, p. 136 to 179.) Husham on Fevers, p. 2. &c.) and when it is considered how frequently we see individuals affected with fever and even fatal fevers, when no source of contagion was known, when no epidemic was prevalent, and when the rest of the family, whose mode and circumstances of life were in all points the same, were not affected by any diæse, we can scarcely hesitate in affixing the origin of the fever to some one of the causes just enumerated. The statements of the ancient physicians accord accurately with those of the moderns, just quoted, on this subject. "Quod igitur ex laboribus," says Galen, "ira, tristitia, et lobis ardoribus, atque frigibus, vigillis, et eruditibus, erictibus, et crapulis. quidam fabicitarie confpiciuntur, nemo eft qui, ipso doctus experientia, non arguo." (De Different. Febr. li. i)

Contagion is, however, the exciting cause of the most dangerous and fatal forms of continued fever, whether occurring in gaols, hospitals, ships, camps, or among the dwellings of the lower classes of the people, and thence denominated gaol-fever, hospital-fever, &c. or malignant, putrid, contagious fever, typhus, &c. Of the nature, origin, and mode of communication of contagion, as well as of the means of preventing its operation, avoiding its influence, and destroying its powers, we have already treated at length in a preceding article, to which we refer the reader. See Contagion.

Many physicians of the last century were of opinion that intermittent fevers were produced by contagion; among these were Boerhaave, Van Swieten, Baglivi, Cleghorn, and Fordyce. It is probable that these fevers may have sometimes spread in hospitals, like erysipelas, puerperal fever, and other disorders, not in themselves contagious, before the present system of ventilation and cleanliness was fully adopted; but, we believe, that few physicians at present support that opinion. Lancisi was the first who pointed out the connection of intermittent fevers with the effluvia of marshy ground; his observations, however, were long overlooked by medical men. But, in our own country, we have now ample evidence of this connection; it is chiefly in the low and flemmy counties, as in Lincolnshire, Cambridgeshire, the hundreds of Essex, &c. that agues originate; and those which are seen in London, and other parts remote from the fens, can generally be traced to those counties. In the neighbourhood of the Pontine marshes, near Rome, the fact is so universally known, that the villages are all perched upon the hills; and there are fearely people sufficient in the levels to expedite travellers from the poll-houses. The army physicians have also obtained much decisive evidence relative to this fact. The nature of the exhalations of marshes, which give rise to intermittent and remitting fevers, is not however ascertained; it is obvious that it is not moisture alone, evaporating from the surface of the marshes; it appears to be rather the result of the decomposition of animal and vegetable matter in water. (See Miasmata.) Sir John Pringle remarks, "that neither canals, nor even large inundations, where the water is deep, are nearly to dangerous, or exhal: to much nauseous vapours, as marshy grounds, or meadows that have been once flooded and lately drained; and that fields, though dry in appearance, may yet be most by the transpiration of the subterraneous water." (On Diseases of the Army, part ii, chap. 2.) "It has been generally remarked," Dr. Rolli observes, "that the effluvia of marshes are most active, when the water is boiled off, and the earth appears, which was certainly the case in St. Lucia; the greater part of the regular intermittents, that is, of the milder fevers we had, happened when the rains were most frequent, and before the stagnating pools discovered their bottoms; but the most dangerous remittants appeared when the marshes had no water, but a slaty matter on their surface. Cairo is healthy while the Nile inundates the neighbouring lands; but when the mud is exposed, on the retreating of the river within its banks, the fevers begin to rage as the miasmata rise. These effluvia, like thefe of contagion, as we have already stated, are limited in their operation, we mean in the distance
Fever.

Fever: to which they are capable of being communicated through the air, in an active state. Dr. Lind observes that, in ships lying at some distance from a swampy shore, the men escape intermittent fevers, though infected in fogs; but when they approach near shore, or communicate with the land, they become affected. Those who were sent on shore for provisions, especially in the night, as mentioned by Dr. Badenoch, speedily perished in consequence of the fever thus induced: partly, perhaps, in consequence of a pre-disposition to be readily affected by the miasma occasioned by the cold of night, and partly from the condensation and more active state of the miasma arising from the same cause. These effluvia rise to so small a height, that folders lying in the first floors of barracks in Jamaica were little affected than those in the ground floor, as stated by Dr. Hunter: who has also affirmed, that a few hundred yards often include the limits between healthy and unhealthy ground in camps. (Observ. on the Diffuses of the Army in Jamaica.) See Epidemic, under the second head; where other facts are enumerated, and some observations added respecting the disappearance of intermittent and remittent fevers in London, and other large cities, in consequence of the removal of the sources of miasma, by improvements in the structure, and cleanliness of the streets, &c. Under all these circumstances, intermittent and remittent fevers are most prevalent in autumn, in which season, especially when wet, they are the fatal endemics in low and damp countries. Of this we have a recent example in the mortality occasioned by the late unfortunate expedition to the island of Walcheren; which, indeed, might have been anticipated; (Oct. 1809,) for Sir John Pringle long ago observed, when speaking of the United Provinces, "But the air is warld in Zealand, as that province is not only low and watery, but surrounded with the cozy beaches of the eastern and western Schelcht, and the most marshy parts of the country; so that almost every wind, except from the sea, adds to its native moil and unhospitable air." (Loc. cit. part i. chap. 1.) In the autumn of very wet years, intermittents have been observed to occur even in high, and at other times dry situations; thus they were produced in certain high parts of Northamptonshire, where they were not known to have existed either before or since, in the year 1782, which was remarkable for the wetness of the summer. (See the Syllabus of Lectures given at Guy's Hospital, p. 15.) The operation of heat, in augmenting the deleterious effects of these miasmatas, is evident, as well from the general occurrence of intermitting and remitting fevers in the autumnal season, as from the more frequent and formidable fevers of this sort, which are generated in warm climates; witness the periodical fevers of Cairo on the burning of the Nile, and those which occur near the other great African rivers; as on the coast of Guinea, where the country is often half depopulated by them, and some parts even quite debastled from this cause. (Ibid.) The overflowing of the Euphrates, and the flagellation of the water on the adjoining desert, have always been considered as the principal causes, especially in the hottest seasons, of the fatal remitting fever of Buffon. (See Transact. of a Soc. for the Improv. of Med. and Chirur. Knowledge, vol. i.) Whence the Arabs sometimes imitate the desert, by breaking down the banks of the Euphrates, in order to be avenged on the Turks of Buffon. The fevers induced by a single inundation have been known to destroy between twelve and fourteen thousand of the inhabitants of that place. (See Wilson on Fever, vol. i. p. 152.) It is fortunate, however, that the miasmata is not, like contagion, capable of adhering to clothes, or other substances; but is diffiluted and becomes harmless in the atmo-

sphere, as we have before observed, at a short distance from its source.

It is worthy of remark, that both contagion and miasma, or, to use the words of Dr. Cullen, both "human and marsh effluvia," appear at times, to operate rather as predisposing than exciting causes; while those circumstances before enumerated, as inducing a predisposition, become in fact the exciting causes of the fever which ensues. It has been observed by Dr. Lind, and others, that persons exposed to the influence of contagion, sometimes receive it into the system, in which it remains latent, or producing only slight indisposition, such as headache, languor, &c. for a considerable time; when exposure to cold; an act of intemperance, in drinking, eating indigestible food, fatigue, wetting, or anxiety shall occur, and immediately the contagious fever is produced; which would lead us to believe that many of these persons, who remain uninfected, after considerable exposure to contagion, escape in consequence of the absence of such exciting cause. "The same cause, which gives rise to relapses," says Dr. Lind of Hoffman, "I am inclined to think does sometimes exist, or render active, an infection, before received into the body, but so slight, as of itself to produce no bad consequences. I am confirmed in this opinion by the quick and sensible effect of infection from bad fevers, when in such a degree as itself to communicate the disease. But if a person perceives no symptom of an infection, till many days after having left his place of abode, and is first taken ill of it immediately after having been wet with rain, exposed to cold or damp, or having been guilty of intemperance and excesses, it is probable that these causes have excited this dormant poison into action; and that, without their influence, it would never have affected the constitution." (Lind on Fevers and Infections, chap. ii. p. 1.) In a similar manner, the miasmata often exert no influence on the constitution, for several weeks after the person has left the febrile district, when the ague shall be immediately excited by a debauch, a quarrel, being wet or chilled, &c.

Exposure to cold is commonly mentioned among the exciting causes of fever; and it can scarcely be doubted that the simpler forms of fever do frequently originate from this cause: and as these more simple fevers are occasionally converted into the more severe or malignant species, by the confined or uncleanly situation of the patient, by improper treatment, or in consequence of some peculiar state of the constitution, so cold may justly be ranked among the common causes of fever. This notion, however, as it is popularly entertained, is carried far beyond its just extent. We have already seen that cold operates by pre-disposing the body to be acted upon by contagion and by marsh miasma; and also, secondarily, by calling into action the dormant poison of both species. In these cases, its operation is only indirect. More commonly the popular opinion ascribes from a miasma, which confides in suppuring the first symptoms, (see the shivering and sensation of cold) to be in fact the cause of the fever; these symptoms being considered as the effect of an external chill, when they are, in truth, the result of the internal condition of the circulation and nervous system, as before explained. Hence fevers have been attributed to cold, which proved to be the eruptive fever of small-pox, or measles, and, of course, originated from contagion. On the whole, exposure to cold must be considered as most commonly concurs with thenoxious effluvia, and other causes, in producing idiopathic fever, and not as alone the active agent. Thoroughs are constantly exposed to cold in this climate, in whom no fever is excited; and in the great majority of those who are affected by cold, the diseases thus occasioned are principally
the symptomatic fevers connected with local inflammation, constituting the second class of "Phlegmata" in Dr. Cullen's arrangement, as mentioned in the commencement of this article. The general effects of cold on the human body, as well as its particular effects in the production and alleviation of diseases, have been discussed at length under a former head. See Cold, in regard to its action on the living Body.

It would appear that the effluvia arising from animal, and even vegetable substances, during the process of putrefaction, have in some instances given rise to fevers of a severe and fatal kind. (See EPIDEMIC.) But under what particular combination of circumstances such fevers have been excited, it were not easy to state: it would seem, however, that animal putrefaction alone is not capable of producing these effects; since persons engaged in particular trades, in which they are much exposed to these effluvia, do not suffer from fever, as skinner, nightmen, &c.; nor are students of anatomy particularly affected by fevers from the often putrid effluvia of a dissecting room.

A redundance of bile has been supposed to be a common exciting cause of intermittent, remitting, and continued fevers, chiefly from the circumstance, that it is often thrown up from the stomach in considerable quantity, during the sick-days which occur at the onset of these fevers. But it should be observed, that vomiting, however excited, (whether by the commencement of fever, by substances taken into the stomach, or by agitation on a shipboard at sea,) if often repeated, with violent drawing, generally brings up also the contents of the duodenum, and emesis the ducts, which open into that part of the intestines. Bile, therefore, and pancreatic juice, are thrown up in the half efforts to vomit, but not in the beginning. This appearance of bile, therefore, is not an essential part of the attack of fever; it is merely accidental. "If the pancreatic juice," says Dr. Fordyce, "had been blue, and had any particular taste or smell, and the bile had been colourless, inodorous, and as much so as the pancreatic juice is, in that case, whatever has been said of the redundance of bile, as an essential part of the attack of fever, would have been said of the pancreatic juice." (First Diff. on Fever, p. 93.) Dr. Cullen remarks, that the opinion may have been partly countenanced by the fact, that intermittent and remitting fevers, being the effects of marsh effluvia, occur most frequently in the warm seasons, and the latter in warm climates, from the influence of which the bile is disposed to pass, by its secretory, in greater quantity than usual, and, perhaps, also changed in its quality; but he considers this appearance of bile, when vomiting takes place, as a circumstance accidentally concurring with the fevers, from the state of the liver in which they arise. (First Lines, § 51.)

When an exciting cause of fever has once produced its operation, the constant or repeated application of that cause is not required to keep up the disease; on the contrary, the disease will then go through its course, although the cause be entirely removed; nay, farther, it will not be increased, it is said, in degree or duration, by a subsequent application of the same cause, but will go through its course unaltered. (Fordyce, First Differt. p. 180, et seq. also in Tran. of a Soc. for the Improvement of Med. and Surg. Knowledge, vol. i. art. 1.) Thus, to adduce a palpable example, a second inoculation of small-pox adds nothing to the violence of the disease produced by the first infection of the poison: thus, also, to use the words of Dr. Fordyce, "a fever taking place from infection in the most wealthy and notified persons in the country, and treated with all attention, with regard to infection, goes through its course in the same manner as in a patient in an hospital, where there are many others afflicted with the same disease, provided that attention is paid that there shall be an equal change of the air of the atmosphere, and freedom from putrefaction." (Loc. cit. p. 189.) On the whole, this statement may be considered as begging the question, and Dr. Fordyce seems to have generalized too far, in transferring his observation respecting small-pox to idiopathic fever. For, with regard to contagious fever, we produce an equal change of the air in an hospital, as in the chambers of the rich, the contagion cannot be constantly applied in any considerable quantity. And, with respect to intermittent and remitting fevers, it is a well known fact, (even noted by Dr. Fordyce himself, though explained upon the notion of avoiding humidity,) that those fevers, although they remained oblique while the patient continued exposed to the miasma, which produced them, speedily yield to the same treatment, when the patient is removed. See the Transactions before quoted, p. 14.

Doctrines respecting the Nature or proximate Causes of Fever.—Physicians have been eager to explain the nature of fevers from the earliest dawn of medical history, and have too often quitted the laborious task of observation in pursuit of hypothetical speculations, which have tended to obscure, rather than to elucidate, the science of pathology, and to retard the progress of its improvement. Instead of accurately marking and comparing the phenomena of life, and thence deducing the laws of the animal economy, whether in health or disease, physicians have too often contented themselves with transferring the deductions of the collateral sciences to the doctrines of life, misapplying their conclusions in analogies, which existed only in their own imaginations. Hence not only the fictions of the Greek philosophy, but the principles of the more certain sciences, of mechanics, of chemistry, of magnetism, and of electricity, have been assumed in succession, as explanatory of the action of living bodies, and have each contributed not a little to confude the language and opinions of pathologists. This is more particularly obvious with respect to the doctrines relative to fever; which, from the universality of its occurrence, the striking appearances which it exhibits, and the ravages which it has committed in all ages, has always arrested the attention of mankind, and has employed the pens of the most enlightened professors of medicine for upwards of two thousand years. Nevertheless, it is at this moment a subject of discussion, and of much difference of opinion; physicians being divided in their views both of the essential nature of the disease, and respecting the seat which they ascribe to it in the body; and one of the latest practical writers on the subject, whom we have often quoted, has affirmed, that "what is the real derangement in the system is, which produces the external appearances in fever, is not at all known." Fordyce.

Although nothing absolutely satisfactory, however, is to be obtained from an investigation of the doctrines which have been promulgated relative to fever, it will be necessary to state the outlines, especially of those of modern times, which have assumed a systematic shape, and have given colour to the various modes of practice that have been pursued.

Various gratuitous hypotheses respecting morbid derangements of the fluids of the animal body, and the generation of new morbid humours, have prevailed, with occasional modifications, from the time of Hippocrates downwards; and although in the systems of Hoffmann and Cullen, and still more completely in those of Brown and Darwin, these hypotheses are rejected, and are also exploded among British practitioners.
practitioners in general, as incompatible with more correct observation, they are nevertheless the prevalent doctrines of the people at large. (See *Humoral Pathology*.) Hippocrates considered the morbid heat as the essence of fever, and upon this notion he seems to have founded his division of the varieties of the disease; as the *causa* *funebris*, or burning fever; the *leptolympha*, in which the external parts are cold, while the internal are hot; and the *epilus*, *epilepsia*, or mild fever, in which there is a simulatreous feeling of heat and cold. (See Hippoc. *lib. i. and ii.* *de medicina*, 55; *Edit Facsim.* &c. Franzi. &c.) These different forms of fever he ascribes to the superabundance of one or other of the four humours, blood, phlegm, yellow and black bile, (see *Hippocrates*), and he seems to consider the disease as the result of a conflict on the part of nature, (the preceeding principle of the animal body,) to expel the morbid humour, or to render it inert and harmless by the process of *concentration*.

Paffing by the absurd notions of Aesclapiades, respecting the motion of atoms or corpuscles, which, when it was free, constituted health, and, when obstructed, excited fevers, &c. which again differed according to the size of the corpuscles; (see Calias Aurelianus, *lib. i. cap. 14.*) and the hypotheses of other ancient physicians, which have been imperfectly transmitted to us; we come to the doctrines of Galen, which were universally received and taught, where science existed, for the space of thirteen centuries. The hypotheses of Galen were little more than an amplification of that of Hippocrates, with which he combined other hypotheses, deduced from the philosophy and science of his age, and thence, by giving a systomatic form to the doctrine, and supporting it with so much learning, he at once multiplied and perpetuated the corruptions of medical science, which the inductive and experimental philosophy of our own times has not yet exterminated. (See *Galen*.) He also considered the preternatural heat as the essence of the febile state, and enters into several plausible statements explanatory of its origin. He observes that heat is excited by motion, by putrefaction, by the direct application of heat, as of the sun or fire, or by the retention of warmth, which should be dissipated, or by the addition of a sort of ferment. Whence the exciting causes of fevers are easily understood in regard to their operation: the heat of the atmosphere, which prevails about the rising of the dog-star, increases the heat of the heart, (being taken in by breathing the hot air,) and all the heat of the arteries on the surface; over-fatigue and violence exercise occasion heat by the increase of the muscles, tendons, and joints; and much and crude aliments produce an acid and putrid humour, which excites heat; and the putrid matter in the air, during the periods of pestilence, when inspired, excite putrefaction and heat in the body, especially when the habit is already predisposed to putrefaction, from bad diet, &c. The fevers thus excited are modified by the prevalance or putrefaction of one or other of the four humours of Hippocrates: of the three kinds of intermittents, the quotidain arises from the corruption of phlegm, the tertian from that of the yellow, and quartan from that of the black bile. Wherever the heat begins, it extends to the heart, whence the general comotion of the vessels is excited: “and Nature is employed in exerting her powers, endeavouring to assimilate the good humours to the parts which are to be nourished, and to expel the bad humours. But if at any time Nature is unable to expel all the morbid humour, either from its thickness, its abundance, or its tenacity, or from some obstruction of the passages, or from her own want of power, it necerally will undergo putrefaction, if it remains long in the animal body.”

But by putrefaction Galen appears to mean any new combination or change of quality, for he includes *concentration* under that term. “Aliter autem putrefactio, quam et coctionem effe diximus, &c.” (De *Differentiis Februm*, *lib. i.* See also Van Swieten, *Com. ad Aph. 770.*

This doctrine, which became known throughout Europe on the revival of learning, kept possession of the schools until the middle of the seventeenth century, when a new light was thrown upon the subject of the animal economy by the discovery of the circulation of the blood. But in the various parts of this doctrine, afterwards variously combined with the fyltems which or, joined with the further progress of the collateral sciences, we sce the rudiments of most of the theories which the modern systematics advanced; until at length the phenomena, connected with the irritable and sensible properties of the living solids, were attentively investigated in the course of the lat century. A humoral pathology, connected with the notions of obstruction, acrimony, lector, phletora, or putrefaction in the vascular system, and of a regulating principle, nature, auctoritas, arcbus, anima medica, vis medica mater naturae, or by whatever term it may have been denominated, was found in all the systems, down to that of Boerhaave inclusive, whether among the mathematical, chemical, or mechanical facts. (See *Medicine.*) Hence various means of removing fevers were suggested, and remedies were employed by one set of physicians for correcting acrimony, for aiding putrefaction, for obviating phletora, for evacuating the morbid humour, or for diluting them; and regulations were adopted by some for supporting the operations of nature, and for removing obstructions or interferences with them; while others, considering the rational soul as the directing principle, were content to look on, and trust to its wisdom, cultivating what they called the art of medicine by expectation; which contented rather in renouncing all art, and in banishing all active remedies.

These doctrines, respecting the morbid condition of the humours in febile diseascs, and the conflict of nature in attempting to subdue their effects, to change their nature, and to expel them from the fyltem, &c. originated in ignorance of the structure and operations of the animal frame, were propagated by the bigotry of learning, which would rather err with Galen, than question his authority on matters of the smallest moment; and were strengthened by the facility with which the new discoveries in chemical and mechanical philosophy combined with them, in explaining the motions of the circulating fluids. They were counteracted also by the various discharges which accidentally occur in the crises of fevers, of which the notion of concentration, or of fermentation and desposition, deduced from a chemical analogy, afforded a plausible explanation. But we have already stated, that the inferences drawn from the appearance of these discharges were incorrect: for that the latter were the signs and effects of a favourable change in the disease, and not the causes of it. (See *Concentration*, and *Cries.*) Nor is the notion of a materia morbi, in the fluids in fever, functioned either by observation, or by the most successful plan of cure. When the discharges attended to consist of the secreted fluids, they contain nothing which is not ordinarily present, although in less quantity; when they consist of blood, it cannot be imagined that the small portion evacuated has contained all the morbid humour with which the general system was infected. But many fevers are cured without waiting for concentration, or evacuation; and the occurrence of absolute intermissions is not easily reconcilable with the existence of such morbid humour.

The:
The dawn of a more correct knowledge of the morbid actions of the animal system, of which some glimmerings had appeared in the writings of our countrymen, Willis, and of Baglivi, (in their treatises "de Pathologia Cerebrum et Nervorum," and "specimen de febra materice et morboribus") was obvious in the works of Hoffmann, before the middle of the last century. He directed the attention of physicians to the primary moving powers of the animal frame, the functions of the nervous system; functions which, had not the pernicious influence of learned authority led medical observers out of the proper train of investigation, could not have been overlooked for so many ages. The properties of the living soul were now investigated by Guassius, Haller, and others; even Boerhaave himself began to attend to them, and in the fourth edition of his Aphorisms, (see Aph. 725,) added the words, "forte et nervosi (fœl. facci) tam cerebrum quam quatern cerebelli cordi delineati inherint," (a flagellate of the nervous fluid communicated from the brain to the heart,) to the flagellate of the arterial fluids, which he had formerly flated as the proximate cause of fevers.

From this time the phenomena resulting from the sensorial functions in disease became the subject of more attentive investigation, and hence have arisen those modern systems, in which the nature of fever is explained by a reference to these functions, to the exclusion of any supposition of disease in the fluids, except as an effect of the fever. These are the theories of Cullen, of Brown, and of Darwin. The theory which Dr. Cullen promulgated, from the medical chair in the university of Edinburgh, almost rivaled that of Boerhaave in the extent of its reception; and even continues to be adopted, with slight modifications, by some later writers (See Currie, Reports on Water, p. 165, 2d edit.) It had the merit of great ingenuity, and of according more completely with the advanced state of knowledge respecting the functions of life, than the hypotheses which preceded it. The Brunonian theory of fever is not particularly prominent in the general system of its author, who reduced all diseases to two or three very simple principles, without much regard to the variety of phenomena, by which we are futfaced. That of Dr. Darwin is more complex, but much more comprehensive in its application to the varieties of fever: it is obscure, however, from the peculiar language in which it is expressed. We shall state the outlines of each of these theories.

Dr. Cullen's Theory.—The first change induced in the animal system, by the operation of the exciting causes of fever, is, in the opinion of Dr. Cullen, a "diminution of the energy of the brain," which is indicated by all the symptoms of the first stage of fever, as we have already explained. The powers of the body and the mind, the functions of sensation and motion, respiration, circulation, and secretion, all fail, or are diminished in the general debility; but after a certain time, a morbid inercean of some of these functions, especially of the circulation, takes place, with an augmentation of the heat. The three stages of debility, of cold, and of heat, which regularly succeed each other in fever, in the order just mentioned, are presumed to exist in the relation of cause and effect; the first stage being the result of the debilitative influence of contagion, marsh mistmate, and cold, which are the exciting causes. Dr. Cullen acknowledges his inability to explain satisfactorily, how the debility produces all the phenomena of the cold stage, especially the spasmodic contraction of the extreme arterial vessels, which is inferred from the suspension of the secretions, and the shrinking of parts in the cold stage, as well as from the continuance of this suspension in the hot stage, after the action of the heart and large arteries is increased. Were the contraction of the cold stage merely the result of the weakened action of the heart, it is supposed, that, on the return of its ordinary or increased action, the contraction would be removed, and the secretions restored. Here Dr. Cullen's facts to "the Vis Medicatrix Nature," so famous in the school of physic," the innate preserving power of the constitution, which has been appealed to for the solution of difficulties by all medical theorists, from Hippocrates downwards. This "pain of the extreme vessels," then, is considered as "a part of the operation of the vis medicatrix nature;" at the same time, Dr. Cullen is of opinion, that, during the whole course of fever, there is an atony existing in the extreme vessels, depending on the diminished energy of the brain, and that the relaxation of the pain requires the restoration of the tone and action of these.

To this story in the vessels of the skin, he attributes the loss of appetite, nausea, and vomiting, the stomach being affected by sympathy. The pain induced in the exterior vessels throws a load of blood upon the central parts of the circulating system, which proves a source of irritation to the heart and arteries, and excites them to a greater action, which continues till the pain is relived or overcome. The hypothesis is thus briefly recapitulated. "Upon the whole, our doctrine of fever is explicitly this. The remote causes are certain febrile powers applied to the nervous system, which, diminishing the energy of the brain, thereby produce a debility in the whole of the functions, and particularly in the action of the extreme vessels. Such, however, is, as at the same time, the nature of the animal economy, that this debility proves an indirect stimulus to the fanganeous system; whence, by the intervention of the cold stage, and pain connected with it, the action of the heart and large arteries is increased, and continues so till it has had the effect of restoring the energy of the brain, of extending this energy to the extreme vessels, of restoring therefore their action, and thereby, especially removing the pain affecting them; upon the removal of which, the excretion of sweat, and other marks of the relaxation of excitors take place." (Cullen, First Lines, § 6.)

Perfect as this hypothesis undoubtedly appears, it is liable to several objeets of criticism, partly, because it is gratuitous in some particulars, and partly, because it is not applicable to all the phenomena of fevers. In the first place, it must be remarked, that by affuming the existence of a power or agent, such as the vis medicatrix nature, we require no knowledge; and advance not a step further in our explanation of the facts, than if we flated simply that the facts occur. It is an admission, that the facts are inexplicable, that they are part of the phenomena of life, which we deem incapable of further generalization in the present state of our knowledge. This creation of imaginary agents, to account for ultimate facts, has had a pernicious influence in every department of science. What information did philosophers acquire respecting the laws of gravitation, by the sublimation of an ether; or physiologists, respecting senation and muscular motion, by the supposition of a nervous juice? Yet upon the same footing stands this autocratica, or via medicatrix, in regard to the laws of the animal economy. It is an imposition, by which we conceal from ourselves our own ignorance, and prematurely arrest the progress of inquiry. But this is for another day.

This hypothesis, however, is not only gratuitous in the assumption of a particular agent, but also in affuming the existence of a pain in the extreme vessels, and in supposing the cold stage to be the cause of all that follows. The phenomena,
Fever.

Phenomena, presented by the skin in the cold stage, may arise from the mere feebleness of the heart, which is rendered unable to distend the distant and minute vessels with blood, or from a mere inaction of the cutaneous capillaries, independently of the heart, as we believe to be the case; and not from a spasmmodic contraction of the extreme vessels. And the premonition of the continuance of that spasm, when the superficial vessels are filled and distended with blood to a preternatural degree, would appear to be inconsistent with observation; for spasm and dilatation are terms of opposite import. The same vessels, which receive little or no blood in the cold stage, and are over distended with it in the hot stage, cannot be in both cases affected with spasm.

But, it is contended, the peripharal vessels at least are spasmmodically contricted in the hot stage, for no fluid is poured out. Here, however, it should be observed, that although the poverty of language, which compels us to borrow the terms of mechanical science, in speaking of the phenomena of fever, may render the use of such a word as contraction admissible; yet it is not from a mere mechanical contraction and relaxation of the extreme arteries that the peripharal and other secrete fluids pass off. These fluids are not pre-existent in the blood, and separated as through a sieve, but are produced by new combinations, effected by an unknown and inexplicable action of the secreting extremities of the vessels; this action is interrupted by various conditions of the vessels, by their over dilatation, it would seem, as well as by their collapse; and we are ignorant of the precise form, the vein, as well as the nature and extent of its modifications.

That the supposition of spasm is equally gratuitous in both cases; and the word concretion is only to be considered as expressing, by an incorrect analogy, the non-appearance of the fluids to be discharged. The contraction of the vessels in the cold stage, and their dilatation in the hot, are equally to be considered as part of the concourse of the symptoms, and yet an essential cause of the fever.

The hypothesis, which ascribes the spasm of the extreme vessels in the cold stage, as the cause of all the following symptoms, is not merely gratuitous, however, it is also inconsistent with the various phenomena of fever. This inconvenience seems to have arisen from the assumption of a simple intermittent or ephemeral paroxysm, as the prototype of every form of fever. But in many of the forms of pyrexia, and even of idiopathic fever, there is no evidence of the existence of this spasm. The cold, it is true, generally utters in the paroxysm of an intermittent; but it is often scarcely possible, in that of a remittent, and in various cases of continued fever it does not appear at all; so that the effect occurs without its imagined cause.

Besides, there is often no proportion between the two; the cold stage may be short and slight, when the succeeding hot stage is long and severe, and vice versa. Even admitting, with Dr. Cullen and Dr. Fordey, that continued fevers are but a series of paroxysms, following each other, and generally dilatated divided by exacerbations and remissions, yet a cold stage does not occur to introduce the exacerbation, and consequentially the succeeding phenomena are not the result of a spasm or cold fit. A degree of pyrexia, marked by heat, quick pulse, oppression, languor, &c. is often produced by various stimuli, such as much heating food, or drink, exercise, &c., but the cold stage is wanting.

We may conclude, therefore, that the occurrence of the heat, and its concomitant phenomena in fever, depends upon some other principle in the animal economy, and is upon the existence of a cold stage, and its impotent spasm. As well, indeed, might we fix upon the heat as a cause of the phenomena, which, in continued fevers, succeed it; such as the delirium, prostration of strength, &c.; and in truth, the omission to notice the influence of the morbid heat upon the future progress of the symptoms constitutes, as Dr. Currie has justly remarked, an imperfection in Dr. Cullen's theory. For it is certain, that the accumulation of the heat itself is a source of much irritation to the vasaferous and nervous systems, as is proved by the relief which follows the abstraction of it by means of cool air, and the application of cold water to the skin; for as the heat is decreased, the pulse immediately becomes less frequent, head-ache and restlessness are diminished, sleep is induced, and even peripharal is excited.

We have yet to add, that the idea of a proximate cause, implies that, which being present, the disease is present, and being absent, the disease disappears. Now, the cold stage is only present during a small part of the progress of fever, which is another reason for considering it only as one in the concourse of the symptoms.

The Brunonian Theory.—We have already given a brief view of the system by which Dr. Brown attempted to explain all the phenomena of the living body, whether health or disease (see Excitability); and the various modifications of fever were of course included in that explanation. The increasing number of facts, which the proper study of the animal economy after the time of Hoffmann produced, enabled the pupil to advance a step beyond his master in generalizing those facts; and it cannot be doubted, that some of the dogmas of Brown were the result of a legitimate induction, and therefore none of his principles were more just than those of Cullen. But like most theorists, he overstepped the boundary of observation, and involved himself in hypotheses, to which he made facts bend by misrepresenting them. Fevers, like all other diseases, are attributed to debility, direct or indirect; and he affirms "that the distinctions that physicians have made about the differences of fevers are all without foundation, and that they are all the same, with no other difference but in degree, and that, unless in that respect, they do not differ from other diseases of the same form." (Elements of Medicine, § 66. note m.) But he does not attempt to explain how the various succession of symptoms results from the state of debility, or how the various modifications of the pyrexia are to be accounted for upon this principle. The only approximation to such an explanation, that we have been able to discover, resembles the one given by Dr. Cullen, inasmuch as it is little more than an enumeration of the leading changes in the symptoms, but less explicit than that of Dr. Cullen.

We are told, that "the debility during the cold stage is the greatest, that of the hot stage, and that of the sweating stage which ends in health for the time, is the least of all. Hence in a mild degree of the disease, as cold is the most hurtful power, its effect is gradually taken off by the agreeable heat of the bed or of the sun, and the strength thereby gradually drawn forth. The heart and arteries, gradually excited by the heat, acquire vigour, and, at last, having their peripharal terminations excited by the same stimulus, the most hurtful symptom is thereby removed, the heat fit produced, and afterwards the same process carried on to the breaking out of sweat." (§ 606.) We are further told that "the cause of all these diseases (i. e. fevers, from the simple and intermittent to the gallo-fever and the plague,) is the same with that of diseases not debile, to wit, debility: differing only in this, that it is the greatest debility compatible with life, and not long compatible with it." (§ 672.) It may appear strange that a theory so vague and implicit...
FEVER.

Explain should have obtained the number of admirers, which the doctrines of Brown have everywhere gained. The most rational of its advocates however, Dr. Wilson, who has striped the system of many of its errors and insufficiencies, is not content with these general terms, has stated the proximate cause of fever, according to the Brunonian principles, to be "a change in the laws of excitability, in consequence of which the same agents no longer produce the same effects." That is to say, the same external agents, food, light, exercise, &c. which is healthy produce moderate excitement, in fever produce excessive excitement. He adds, however, "how the remote causes of fever act in inducing this change, and on what cause in the living body this change in the laws of excitability depends, we neither can, nor ever shall be able perhaps to determine." (Treatise on Febrile Diseases by A. Phillips Wilson, &c. vol. i. p. 559.)

Upon this statement, it is only necessary to remark, that Dr. Wilson has fallen into the error which is common in the discussion of proximate causes, that of mistaking the symptoms for the disease itself. The change in the law of excitability is but a general expression for the change in the phenomena of the individual life, i.e. for the symptoms of the fever; whereas, the change in the living body is, in fact, the effence of the disease, i.e. the proximate cause of the symptoms, which he despairs of investigating successully.

Dr. Darwin's Theory.—In the theory of this ingenious physician, the phenomena of fever are referred to those laws of organic life, which he has deduced with great acuteness from a comprehensive view of the phenomena of the living system. His theory, indeed, is much involved in the obscurity of the language, which he has chosen to adopt; it is, occasionally perhaps, aided by fancy, where observation was deficient; and it is given by his author "rather as observations and conjectures, than as things explained and demonstrated:" but it appears to afford a glimpse of the true explanation of the concurrence of symptoms in fever, under its various forms: "a foundation and a scaffolding," to borrow the author's words again, "which may enable future industry to erect a solid and a beautiful edifice." (See Zoonomia, or the Laws of Organic Life, by Erasmus Darwin, M.D. &c. Clive &c. Supplem. ad fami.) Dr. Darwin's system is founded upon the same fundamental principles, as those of the Brunonian school (see Excitability); the inferences of which, however, he not only in a great degree avoided, but he likewise introduced a principle, which had been overlooked by Brown, namely, the principle of association, or sympathy, by which, doubtless, many of the actions of the living body are regulated. It is upon the observation of this principle, that the Darwinian theory of fever is chiefly constructed; whence the author gave it the title of the "Sympathetic Theory of Fever." Two general laws of the animal economy are flated by Darwin, as well as by Brown: 1. That all excitation or action of the living organs and functions occasions a diminution or exhaustion of their power (excitability in the language of the latter, senforial power in that of the former) according to the degree of excitation; 2. That rest, inactivity, or the abstraction of the usual stimuli, render those organs more susceptible of the action of the stimuli subsequently applied. Thus, when a small part of the capillary vessels of the skin are exposed for a short time to a cold medium, as when the hands are immersed in iced water for a minute, these capillaries become torpid or quiescent, owing to the abstraction of the stimuli of heat. The skin then becomes pale, because no blood passes through the external capillaries, and appears shrunken, because their sides are collapsed from inactivity, not contracted by freezing; the roots of the hair are left prominent from the feeding or subdigesting of the skin around them, and the pain of colds is produced. But in this situation, if the surface degree of warmth be applied, these vessels regain their activity; and, leaving now become more irritable from an accumulation of the senforial power during their quiescence, a greater action of them follows, with an increased glow of the skin, and another kind of pain, which is called the hot-ache, seizes. Here we see an epitome of simple fever beginning in the vascular system. When the same operation goes on more generally, as by immersion in the cold bath, the cold fit succeeded by the hot fit is more general, and both may be increased and prolonged by continuing in the bath, which has indeed proved fatal to some weak and delicate people, and to others who had been much exhausted by heat and exercise; the same torpor and subfrequent orgasm having extended to the heart and great vessels.

Thus far the two theories nearly accord; but beyond this point the Brunonian doctrine leaves us to a general statement of debility, altogether inadequate to account for the various forms and phenomena of fever. But Dr. Darwin appeals to other established facts in the animal economy, upon which these varieties appear to depend. From these a third general law may be deduced; namely, 3. That the functions of different parts of the system are so far connected, or associated with each other, as it were in circles, either from direct connection in structure, from the habit of acting together, or more frequently from causes at present inferable, (see Catenation,) that an increase or decrease of the action of one organ follows or accompanied by an increase or decrease of the action of another; sometimes by a similar change, that is, inerased followed by increase of activity, or decrease by decrease; but occasionally by the contrary change, that is, increase followed by decrease of activity, and vice versa in the associated parts. The former of these is termed a direct sympathy; the latter a reverse sympathy. The influences of sympathy between different parts of the animal frame are very numerous. To the medical reader it were sufficient to mention the sympathies in the functions of the stomach and brain, the stomach and skin, the stomach and heart, the brain and heart, the skin and lungs, the uterus and mammary, &c.; but for the unprofessional reader a brief illustration may be requisite.

The sympathetic action of the stomach and the brain occurs perpetually to the obervation of the physician. Thus indigestion, however induced, is frequently the cause of headache; and head-ache, dependent upon certain faties of the brain, produces los of appetite and sickness, as is hydrocephalus. We have also influences of both direct and reverse sympathy between these organs; for when the action of the vessels of the brain is languid and feeble, as in approaching syncope, nausia and loss of appetite occur in the stomach, in which case the sympathy is direct; but when the vessels of the brain are acting with increased power, as in phreny, nausia and loss of appetite are likewise induced, in which the sympathistic action is reversed. Similar sympathies occur between the stomach and skin. Thus, moistening the skin relieves thirst, as we have already stated; and a copious draught of warm liquor will often at once produce a periperation on the skin. We have seen that Dr. Cullen attributed the symptoms in the digestive functions in fever almost entirely to such a sympathy; and that Sydenham removed sickness and vomiting by exciting periperation. The stimulating influence of food on the nerves and vessels of the stomach generally excites, by direct sympathy, the

hers.
F E V E R.

erves and vessels of the skin, and produces a glow on the surface; but in certain debilitated constitutions, or states of the constitution, the same stimulus in the skin occasion, by reverie sympathy, a chilliness, even a shivering, and paleness of the skin. Exposure to a cold atmosphere (which abstracts the stimulus of heat) occasions an increase of appetite and of the digestive power, in strong habits; but the same exposure often destroys the appetite, and produces even nausea, in feeble constitutions; these may be considered as instants of direct and reverie sympathy; or perhaps both as instants of direct sympathy, the fenorial power accumulating in the strong constitution, and producing increased action of the cutaneous vessels; but not in the weak. The actions of the skin and hot and large arteries, the fever-fit becomes more complicated and dangerous. And again, when the fever commences, from the operation of other exciting causes of fever; in other organs of the body, and extends, with the subsequent organ, by direct or reverie sympathy, to the organs associated with them, other various forms and modifications of febrile disease are produced. Thus, if the skin is affected with fever, either primarily, as from the action of contagion, feverish, by the sympathy with the cutaneous capillaries, and by incrustation, or the irritation of a tissue in the kidneys, may be considered as examples of a reverie sympathy between those organs. There are many instances of the sympathy of parts connected by structure, or by the habit of acting together. Thus, the irritation of a flame upon the neck of the bladder produces an action of the lower gut, with a fruitful effort to stool, denominated tenesmus; and, vice versa, a tenesmus, as in dysenteric for instance, often excites a degree of strangury or fruitful effort to pass urine. In the same way, not only will a purgant odour, affecting the nostrils, excite tears, but the sudden impulse of strong light upon the eyes very frequently excites fasting; which may be observed daily in the streets of London, during the summer, in persons who suddenly receive the reflected light from a white pavement, as they pass from a shade. This also sympathetic pains of the mamma occur in disorders of the uterine, which organs are connected in the functions and purposes which they serve in the animal economy. See SYMPATHY, and CATATONIA.

These three laws or principles of action in the animal economy, then, 1. The exhaustion or diminution of the fenorial powers by exertion; 2. The recovery or accumulation of the same powers, during quiescence or impaired action; and, 3. The direct and reverie association of parts, by which the actions of one part give rise to actions in others, are the grounds of Dr. Darwin's explanation of the phenomena of fevers. We have seen how the cold and hot fits of simple fever are produced, from the external influence of cold; the first by the torpor of the capillary vessels, from the abstraction of the stimulus of heat; the second, by the renovative activity of the capillaries from the accumulation of fenorial power during that torpor. Dr. Darwin, however, remarks, that this renovative activity of the capillaries is not owing to the renewed action of the heart, which forces them open by the mechanical impulsion of blood; that the action of the capillaries often recommences sooner than the action of the heart, these vessels having a greater mobility than the heart and large arteries, as appears in the sudden blush of shame; and that, in low fevers, the capillaries acquire increased strength, as is evinced by the flush and heat of the skin, while the pulsations of the heart and arteries remain feeble. Hence simple fever is of two kinds; in one the pulse is strong, in the other weak; in the fever with strong pulse, not only the cutaneous capillaries, but also the heart and arteries readily acquire a greater activity by the accumulation of fenorial power during the torpid state, which last is further increased by direct sympathy with the increased activity of the capillaries; this happens in strong fevers, and is often seen in small intermittents; in the fever with weak pulse, on the contrary, the heart and arteries do not acquire much increase of fenorial power, but continue in some degree in their state of torpor, while the organ of the capillaries is produced, whence there is a hot fit, with feeble pulse. But when the sympathies of other parts of the system are called into action, together with this torpor and organ of the cutaneous vessels, and of the heart and large arteries, the fever-fit becomes more complicated and dangerous.

And again, when the fever commences, from the operation of other exciting causes of fever; in other organs of the body, and extends, with the subsequent organ, by direct or reverie sympathy, to the organs associated with them, other various forms and modifications of febrile disease are produced. Thus, if the skin is affected with fever, either primarily, as from the action of contagion, feverish, by the sympathy with the cutaneous capillaries, and by incrustation, or the irritation of a tissue in the kidneys, may be considered as examples of a reverie sympathy between those organs. There are many instances of the sympathy of parts connected by structure, or by the habit of acting together. Thus, the irritation of a flame upon the neck of the bladder produces an action of the lower gut, with a fruitful effort to stool, denominated tenesmus; and, vice versa, a tenesmus, as in dysenteric for instance, often excites a degree of strangury or fruitful effort to pass urine. In the same way, not only will a purgant odour, affecting the nostrils, excite tears, but the sudden impulse of strong light upon the eyes very frequently excites fasting; which may be observed daily in the streets of London, during the summer, in persons who suddenly receive the reflected light from a white pavement, as they pass from a shade. This also sympathetic pains of the mamma occur in disorders of the uterine, which organs are connected in the functions and purposes which they serve in the animal economy. See SYMPATHY, and CATATONIA.

These three laws or principles of action in the animal economy, then, 1. The exhaustion or diminution of the fenorial powers by exertion; 2. The recovery or accumulation of the same powers, during quiescence or impaired action; and, 3. The direct and reverie association of parts, by which the actions of one part give rise to actions in others, are the grounds of Dr. Darwin's explanation of the phenomena of fevers. We have seen how the cold and hot fits of simple fever are produced, from the external influence of cold; the first by the torpor of the capillary vessels, from the abstraction of the stimulus of heat; the second, by the renovative activity of the capillaries from the accumulation of fenorial power during that torpor. Dr. Darwin, however, remarks, that this renovative activity of the capillaries is not owing to the renewed action of the heart, which forces them open by the mechanical impulsion of blood; that the action of the capillaries often recommences sooner than the action of the heart, these vessels having a greater mobility than the heart and large arteries, as appears in the sudden blush of shame; and that, in low fevers, the capillaries acquire increased strength, as is evinced by the flush and heat of the skin, while the pulsations of the heart and arteries remain feeble. Hence simple fever is of two kinds; in one
fenoral powers of the stomac, heart, and brain, are pri-

marily exhausted by narcotic poisons, as by digitalis, to-
bacco, and contagion, (which both Brown and Darwin
consider, perhaps erroneously, as exhausting by excess
of stimulus,) these organs are longer in recovering their exi-
tability, than when they suffer from defect of stimulus, or
secondarily, from sympathy with the capillaries of the
skin, or of some other organ. From either species of ex-
haustion the fenoral power in voluntary or involuntary
muscles might be removed by a short quiescence; but with
the heart to rest is death: whence that organ recovers more
slowly, and thus produces fever with weak pulse. The
organs which are in perpetual action, indeed, being en-
dowed with a greater abundance of vitality, recover their
fenoral powers in the same proportion more readily; other-
wise life could not continue. As the fenoral power accum-
ulates, the actions of those organs increase; whence a de-
gree of inflammation often occurs in the brain and its mem-
brane, accompanied with flushed countenance, redness of
the eyes, and delirium, sometimes followed by stupor; or
a similar inflammatory action occurs in the stomac, or in-
testines, or in the lungs, or the heart. Thus, however,
are generally secondary effects of low fever, but death is
f seldom produced without such an occurrence in none of
those vicera. Dr. Darwin judiciously considers the painful
or uneasy feelings, or (to use his language, the fenoral power
of sensation,) excited especially when inflammation takes
place, as contributing farther to augment the actions of the
heart and arteries, and of all the moving sytem along with
them; whence the pulse, under such circumstances, ac-
quires a degree of sharpness in its stroke, unobserved in
health.

When the stomac is secondarily affected, and the torpor
is primarily produced in some other vicera, the actions of
which, on the restoration of the fenoral power, are aug-
mented to the degree constituting inflammation, and of
course pain, or the fenoral power of sensation is also ex-
cited; as in pleurisy or perипneumony, the heart and arteries,
not having been exhausted by a narcotic power, as by con-
tagion, soon resume a strong action, the pulse becomes
hard, and the disease is termed an inflammatory fever, or
plegmania. "Thus," says Dr. Darwin, "the perипneu-
mony is generally induced by the patient respiring very cold
air, and this especially after being long confined to warm
air, or after being much fatigued and heated by excessive
labour or exercise. For we can cover the skin with more
clothes, when we feel cold; but the lungs, not having the
perception of cold, we do not think of covering them, nor
have we the power of covering them, if we defined it; and
the torpor thus produced is greater, or of longer duration,
in proportion to the previous expenditure of fenoral power
by heat or exercise. This torpor of the lungs affects the
skin with shuddering, and the stomac is also secondarily af-
ected; next follows the violent action of the lungs from
the accumulation of the power of irritation, and an inflam-
mation of them follows this violent action, &c." (Loc.
cit. Suppln. 2. § 16. 7.)

The theory, of which we have thus given an imperfect
account, stripped of the peculiar phraseology of the author,
appears to us incomplete, as it confecutively is, to afford an
approximation to at least a more comprehensive and more
confident doctrine of febrile disease, than any that has yet
been promulgated: more comprehensie, because it not
only includes the varieties of idiotopathic, but also of sympto-
matic fevers; while other hypotheces scarcely embrace more
than one form of the first, namely, the ephemeral, or in-
termittent paroxynm, and have dwelt too much upon some
particular symptom, as the cause of the whole disease, such
as the heat, the cold fit, or the quick pulse; and more con-
flident, because it is derived from those laws of the animal
economy, which have been deduced from the observation
of the general operations of life, both in health and disease.

To the language, however, many objections arise, as well
as to several collateral statements, which are employed in
filling up the outline, which we have drawn: such as the
notion of a retrograde action of the animal, of the ab-
fortion action of the capillary veins, of the excessive stimu-
lus of digitalis, and the matter of contagion, &c. are not essential parts of the doctrine. We shall now pro-
ceed to state briefly the principal points of another
theory of fever, lately published, which, from the erudition
and practical knowledge with which it has been maintained,
is entitled to consideration. We allude to

Dr. Clutterbuck's Theory.—Fever has usually been called
a general disease, affecting all the functions, in contra-
distinction from local diseases, in which some particular
organ is the primary seat of the disorder, and the affections
of the other functions are secondary, or symptomatic. But
Dr. Clutterbuck denies the existence of general disease,
and maintains that all general or extensive derangement of
the animal sytem is referrible to local derangement, in some
one organ. "The organ universally affected in all the
varieties of idiopathic fever which differ but in degree,
as well as in those which arise from specific contagion, as
malignant fore throat, scarlet-fever, small-pox, &c. is, in
the author's opinion, the brain. This is manifest, he contends,
from the symptoms as the expulsion of the strength, and other derangement of the animal functions, the
delirium, the tremors, failure of vision, &c. It is manifest
from the nature of the remote causes which act chiefly
on the brain and nervous sytem, as intoxication, fear, grief,
and other passions, external irritation, not to mention malad-
ies and contagion, of the operation of which we are igno-
rant; as well as from the predisposing causes, which probably
confer in a deficiency of sensibility, as in idiots, negroes,
old people, and infants: but it is more particularly mani-
fested from the consequences of fever whether after recovery,
or after death, ascertained in the latter case by dissection.
Among the consequences of fever, which are not uncommon
after recovery, are an impaired condition of the senses; such
as deafness, imperfect vision, deprived talk: paralytic efeeti-
ons, or convulsive contusions, as epilepsy and chorea; derange-
ment or loss of the mental powers, such as melancholy,
great irritability of mind, loss of memory, or even complete
fatuity. The consequences, observed by dissection after
death occasioned by fever, are frequently visible disease
of the brain, of which several examples are quoted by
the author. He then proceeds to shew, that the local af-
fecition of the brain, thus manifest, is in fact inflamation
of that organ; or that fever, therefore, "is nothing less than
a species of phrenitis, or topical inflamation of the brain,"
and should be arranged in the order of Plegmanias, with
pleurisy, enteritis, and other symptomatic fevers: but as
phrenitis has been generally applied to a particular form
of inflamation of the brain, and implies delirium, which does
not always occur in fever, although it is a frequent sym-
ptom, Dr. Clutterbuck proposes the term Encephalitis
as the denomination for fever. The arguments adduced in
proof of the notion that the topial affection of the brain,
in fever, is inflamation, are, 1. The analogy
between the symptoms of fever and those of inflamation,
eis. pain, heat, throbbing, acute sensibility, &c. being
common to both; 2. The occasional bull of the blood in
both; 3. The similitude of several of the exciting causes of
both;
both; 4. The occasional alternation of fever with inflammation; 5. The analogy in regard to the cure of the two diseases generally, as by means of blood-letting, vomiting, sweateing, purging, blistering, and the application of cold; 6. The symptoms of fever not being distinguishable, on the whole, from those which belong to phrenitis, as described by authors; 7. That the morbid condition of the brain, discovered by dilatation, is such as implied previous inflammation. (See an Inquiry into the Sent and Nature of Fever, &c. by Henry Clutterbuck, M. D. 1807.) The author has illustrated these arguments at considerable length, with great peripeties; and with an ample collection of facts and observations, compiled from the records of medicine, but our limits confine us to a mere sketch of the general doctrine, and to a few observations relative to its apparent solidity and truth.

In the first place, Dr. Clutterbuck, like other theorists enamoured of a favourite doctrine, appears to have laid too great stress upon those phenomena which support that doctrine, and to have concealed facts to opposing facts, than they are entitled to claim. Hence, in retracing the delineations of fever, in the words of the most creditable writers, he has distinguished by italy all those signs which indicate derangement of the encephalon, by which they are made to stand the most prominent features in the picture. Hence, also, he has assumed the position, that the derangements of the natural and vital functions, which are nearly, if not altogether, as universal concomitants of fever, as the disorders of the animal functions, are, nevertheless, in all cases, secondary symptoms, originating from the primary affection of the brain. Thus then the vomit, the total loss of appetite, and of the digestive power, are believed to be always sympthetetic of the affection of that organ; so likewise is the quickened action of the heart and arteries, and of the respiration. That this, however, is a gratuitous assumption may be shown, 1. By attending to the very histories which Dr. Clutterbuck has quoted, in which the occurrence of the deranged condition of the stomach is as constantly mentioned, as that of the disorder of the encephalon; 2. By observing, that the sympathy between the brain and the stomach is perfectly reciprocal; so that the brain suffers in sympathy with the stomach, not less manifestly than the stomach with the brain; and, 3. By remarking, that the symptoms of disorder in stomach are capable of being relieved or removed, while the supputed cause (affection of the brain) remains; the thrill being allayed, and the sickness removed, by changing the state of the skin only, the former by moistening it with water, the latter by exciting sweat, as observed by Sydenham. Whence Drs. Cullen and Darwin seem to be rather justified in attributing the derangement of the stomach, when it is affected secondarily, more frequently to its sympathy with the state of the skin, than of the brain.

Further, the connection of many of the leading symptoms with some disorder of the brain, or common febrorum, is admitted by all, and equally favours the hypothesis of the other authors, as well as that of Dr. Clutterbuck; since whether the brain be primarily or secondarily affected, certain phenomena in the nervous system must necessarily ensue. We have just stated some reasons for believing that it is often thus secondarily affected; and it now remains to offer those reasons for supposing that inflammation of the brain, when it occurs in fever, (to which we cannot consider it essential,) is commonly secondary likewise.

The first symptoms of the affection of the brain are by no means those which indicate inflammation or weal excitement of the menaphron; on the contrary, they are such as indicate an opposite state, which Dr. Cullen has termed ataxy and collapse, and Dr. Darwin torpor: the head-ache itself, according to the observation of Dr. Fordyce, is altogether distinct from the head-ache of inflammatory excitement, or of the hot flag. Any symptoms that can be interpreted as indications of local inflammations, such as redness of the eyes, protrusion of the features, flushed countenance, throbbing of the arteries, and even delirium, are the appearances belonging to a sublunary period of the fever. But at this sublunar period, inflammatory congements are liable to occur in the other viscera, if not frequently, at least, not unfrequently; as in the stomach, for example, the intestines, the lungs, and other organs. This fact has been noticed by many physicians of accurate observation. Riverius long ago remarked that acute and malignant fevers fearely ever occur unaccompanied by inflammation in some one of the viscera; and he has stated in another place, in most difficult cases, that we ought affiduously to recollect, that all those fevers, with which local inflammation is conjoined, are not symptomatic, but often idiopathic, and that the inflammation supervenes, not being the cause, but the consequence of the fever; "qua febrem istam non efficat, sed illi potius sequaxit aet. Thus, he adds, "we frequently observe, in practice, that patients labour under continued fever for a day or two before pain of the side and other symptoms of pleurisy appear; and thus many persons on the third or fourth day of fever fall into inflammation of the brain, &c." " Sic nobis frequenter in usu practico videre licet aegrotantes, ab initio febri continua laborantes per unam aut alteram diem, antequam dolor lateris et alia pleuritis signa appearant: sic multi tertia vel quartae febris dies in phrenicidem incident, &c." (See River, Prax. Med. lib. xvi, cap. 1.) Dr. Donald Monroe, whose testimony on subjects of morbid anatomy is of considerable weight, with Dr. Clutterbuck, remarks, when speaking of malignant fever, that this fever occasions in general a more or less redness (I do not know that we can properly call it true acute inflammation) of the membranes; and the febile matter is apt to fall on particular parts, and there to create abscesses, particularly in the brain, the lungs, and the glandular organs." (See his Treatise on Military Hosp. vol. i. p. 237, and Dr. Cullerbuck's Treatise, p. 172.) Observations to this effect might be easily multiplied, and we have already enumerated several in a former part of this article. It is somewhat singular, that Dr. Clutterbuck, who quotes the remark of Dr. Monroe, should deem it favourable to his hypothesis of exclusive inflammation of the brain; since it obviously proves an equal liability to inflammation in other organs, if it proves anything. Now, it must be admitted, that, if fever depends upon inflammation of the brain, and is merely symptomatic of such a state, this state must be always present, when the symptoms of fever occur; one clear negative example is fairly fatal to the theory. Dr. Beddoes collected a considerable quantity of evidence from the histories of diseases, made during the prevalence of several epidemic fevers on the continent, from which it is proved, indeed, that congestion, or some other morbid appearance was frequently observed in the brain or its membranes; but it is also shewing that abscesses, gangrene, or other marks of inflammation, were not less frequently found in the viscera of the thorax and of the abdomen, especially in the stomach and liver. These facts we have detailed, when speaking of the consequences of fatal fevers, as discovered by dilatation, and it is unnecessary to repeat them here. Dr. Beddoes is fairly led (supposing the facts accurately reprented) to this inference, that in idiopathic fever, the stomach and contiguous parts have been found more constantly and more deeply affected with
F E V E R.

(ACUTE, AGUE, and REMITTENT.) In the syphochna, or inflammatory fever, this is the principal indication to be followed; in the syphochois, or sub-inflammatory fever, it is the rule of practice in the greater part of the disease; and even in typhus, originating from contagion, it is equally necessary to be kept in view in the first days of the complaint, and partially for a longer period. We are not in possession of any means, by which we can with safety effect a direct diminution of the actions of the animal system in fever: our measures, therefore, are limited to a negative or indirect reduction of excitement, by withdrawing or diminishing those irritations or stimuli, which are constantly applied to the body, in one degree or other, and actually excite the actions of life, (see Excitability,) or which are more particularly the consequence of the febrile state. Of the irritable of these irritations, the ordinary impressions made upon our senses, the exercise of the body and mind, the use of food and drink of various qualities, are examples; of the latter, the excessive heat, the thirst, and the various painful sensations, &c. The system of avoiding these as much as possible, or of moderating their force, when that is impracticable, constitutes what has been called the antiphlogistic regimen, which it is requisite to pursue in almost every continued fever. Although the latter is generally regarded as the more dangerous, yet it is by no means falutary, and support the activity of the living body; yet, in the febrile state, when the body is more capable of the operation of stimuli, on the one hand, and more feeble, (in typhus at least,) and therefore less capable of bearing their action, without suffering exhaustion, on the other, they become exceedingly prejudicial.

1. In the hot stage of fever, the senses are generally more acute, and the ordinary impulses excite a painful irritation, and thus contribute to augment the vascular action, and to increase head-ache, repletion, &c. Hence the obstruction of too much light is to be prevented, all noises are to be excluded, and such covering, or bed, to be employed as is least uneasy to the body of the patient. In large towns, fluffing the ears with cotton may perhaps more effectually lessen the effect of noise than laying straw in the street. But no impression is to be more carefully guarded against than that of external heat; while at the same time every other means of increasing the heat of the body is to be shunned. Both these precautions are to be observed as soon as a hot stage is formed, and the patient is hourly commencing. In this state, the more the morbid heat is augmented, the more necessary this attention becomes, since the uneasy sensations connected with it are the constant cause of increase to all the other symptoms. This is not less evident, than the general and speedy relief which follows the abatement of this morbid irritation, i.e., in the common phrase, the application of cold. Yet it was formerly a universal practice, to augment the heat in the early stages of fever, in spite of the instinctive feelings of the patient; partly under a notion, that sweating might thus be produced, and a crisis accomplished; and partly from an hypothetical opinion, that heat contributed to accelerate the process of concoction, and therefore to shorten the fever. Our countryman, Sydenham, was one of the first to point out the advantages of a contrary practice, which he adopted when the rest of European physicians were pursuing the hot regimen. The fame notion of the humorists, and with others, the fear of the subfequent debility and prostration of strength, which occur in the latter periods of typhous fever, and the doctrine that debility is the proximate cause of the disease, have also contributed to conjoin with this a stimulating mode of treatment, in fevers of this character; so that some practitioners no sooner hear the name of fever, especially when the epithets putrid, contagious, malignant, &c., are connected with it, than they immediately ply the patient with wine, Peruvian bark, and other stimulants and cordials, whatever be the period or circumstances of the disease, for the purpose of obviating or anticipating the consequences of debility. This the experience of all enlightened and unprejudiced physicians of the present day, condemns as a pernicious error, in the early stages of fever, when there is a dry heat on the surface of the body. For not only is the general vascular action, and with it the head ache, delirium, thirst, repletion, &c., directly augmented, but they are also indirectly increased by the increase of the irritation of superficial heat; and the very debility, which is intended to be prevented, is, therefore, actually accelerated and augmented, in consequence of the exhaustion which over-excitement induces. Thus petechiae, and other signs of putrefaction (as they have been termed,) were common results of the hot regimen; which, on the other hand, was inadequate to produce a crisis by sweating, or to shorten the febrile state by concoction, as we shall presently state.

The reduction of the morbid heat, then, constitutes an important part of the system of avoiding irritation. It is accomplished by external and internal means, by the external cooling of the application of cool air, or of cold or tepid water to the surface of the body, and by surrounding the patient with light clothing, by which the animal heat is not accumulated; and the internal, of cold drink; and perhaps of what have been denominated refrigerant medicines. The human body evolves a sufficient quantity of heat to preserve its regular and agreeable temperature, in so rare a medium as the air, when the temperature of this is not under 62° of Fahrenheit's thermometer, or unless it contain moisture; and in air at 62°, the caloric disengaged from the body is neither carried off, nor permitted to accumulate so as to become unpleasant. But if more caloric be disengaged than in health, a lower temperature will be required for its due ablation, in proportion to the greater heat and strength of the patient. A temperature of the air in his apartment of between 45 and 55 degrees will be the most grateful, perhaps, in the ordinary forms of typhus. In the syphochna, in which the temperature of the body is higher, the patient's bed-room may be kept as low as 45° or 50° with advantage. In this country, the former temperature is very commonly attainable; if the heat of the atmosphere be higher, the evaporation of watery fluids, sprinkled upon the floor or other parts of the bed-room, especially such as are impregnated with the essential oil of aromatic plants, contributes somewhat to reduce the temperature, and feels refreshing to the patient. The free admission of pure air is at all times necessary, not only as producing evaporation and consequent coolness, but as carrying off the morbid effluvia arising from the body, and affording a pure pabulum for respiration; of which we shall have occasion to speak hereafter. The late Dr. Gregory, father of the present professor at Edinburgh, used to remark, when he had been visiting one of the richer classes of people in fever, that if he had the patient in a cool ward of the infirmary, he could ensure his recovery; whereas, from the mere circumstance of the heat and depression of the apartment, which he could not regulate according to his wishes, he would in all probability, find the symptoms of the fever increased at his next visit. The writer of this article has frequently experienced the great and obvious benefits of a cool and well ventilated room, independently of medicine. He has visited patients, who had applied for admission into the House of
Recovery, in their own close and suffocating apartments, and found them in a state of delirium, with dry black tongue, great heat, and other bad symptoms; having directed them to be removed to the House, he has found them cool and perfectly collected, with other symptoms of equal amendment, on the following morning, from the mere influence of a cool bed, and an airy apartment.

Another mode of reducing the morbid heat is the application of cold or tepid water to the skin. As the fever is now supposed to have advanced beyond the fourth day, after which period a complete solution of it is not to be expected, either the cold infusion may be employed, or the surface of the body may be washed, by means of a sponge, with cold or tepid water, or tepid water may be used in the way of application. The same precautionary rules, as we have already stated, are to be observed in regard to all these modes of the external application of cold water. The tepid infusion (i.e. of water heated to that degree which is warm, but not hot to the sensibilities, or from 87° to 97° of the scale of Fahrenheit) produces a cooling effect, equal to that of cold infusion, partly in consequence of a more speedy evaporation, and partly because it gives a cool, or re-acting, as it has been called, does not succeed. "Where the object is to diminish heat," Dr. Currie observes, (Reports on Water, vol. i. p 69. chap. x. 2d edit.) "that may be obtained with great certainty by the repeated use of the tepid infusion, suffusing the surface of the body to be exposed in the interval to the external air; and if the beams of the sun be excluded, and a stream of wind blows over it, the heat may be thus reduced where cold water cannot be procured, even in the warmest regions of the earth, on the plains of Bengal, or the sands of Arabia."

The effects of the infusion of tepid water on the skin are thus enumerated. "It very generally produces a considerable diminution of heat, a diminished frequency of the pulse and respiration, and a tendency to repose and sleep. I have also used it in feverish disorders of various kinds where the lungs are oppressed, and the respiration laborious, and where of course the oppression might be dangerously augmented by the sudden influx of the cold infusion. It is also applicable to every case of fever, in which the cold infusion is recommended, and those may receive much benefit from it whose fears or whose feeblestheens deter them from that energetic remedy. I have not, however, found its effects so permanent as those of the cold infusion, and I have never seen it followed by the total cessation of regular fever, as often occurs after the cold infusion." (Currie, loc. cit.)

Where the infusion of cold or tepid water is not employed in fever, benefit may be derived, though in an inferior degree, by plunging or wetting the body with cold or warm water, or vinegar and water. According to Dr. Currie's experience, however, it is not only less effectual, but in many cafes less safe; for the fyllem will often bear a sudden, a general, and a stimulating application of cold, when it shrinks from its flow and successive application. In the House of Recovery belonging to the Fever Insitution of London, all these measures have been constantly employed according to the circumstances of the patient, as pointed out by Dr. Currie, and relief has been invariably the result; no individual remedy, to which we have referred, has appeared to produce so prompt and decided a diminution of the febrile symptoms; which, though often temporary only, is in many cases permanent, and renders the future course of the disease apparently milder and shorter, than it would otherwise be.

The fation of thirst is another irritation, which is often very distressing in fever. In this instance, as in that of extreme heat, the instinctive feelings of the patient direct him to the source of relief; to sipple diluent drink in the one case, as to exposure to cool air, or immersion in water, in the other. Had not the rage for hypothesis for ages, blinded the practitioners of medicine, the obvious proprieties of the constitution could not have been so long and so obstinately thwarted, nor the gross inconsistency have been committed, of acknowledging the superintendence of nature, her salutary and healing exertions, her vis medicatrix, yet of counteracting her instinctive dispositions and operations with so much industry. Thus, drink, as well as cool air, has been denied to patients in fever by some physicians, and, when allowed, was directed to be given warm, notwithstanding their desire for it cold. The ancient physicians, indeed, with whom observation on the whole was paramount to hypothesis, generally admitted of a free use of cold drink: Galen considered it as a most important remedy in fever; and Avicen, Rhazes, and others of the Arabian physicians, were more indulgent in this respect than the Greeks. Nevertheless, Aetius recommended total abstinence from liquids until the thirst was greatly augmented, and then to allow it to be fully gratified by copious draughts of cold drink. Celsus also recommends the use of copious cold drink in the height of the fever, "but not before the fourth day, and after great thirst." (De Medicina, lib. iii. cap. 7.) "In the article of drink," he says, in another place, "the struggle is great, and that in proportion to the severity of the fever; for this inflames the thirst, and demands water most importantly, when it is most dangerous." (Lib. iii. cap. 6.) After the revival of learning, when the Galenical hypothesis of concoction was universally adopted, cold drink was generally prohibited until the fever had attained its acme, under the notion that it increased the cruelty of the fluids, and prevented the progress of concoction; "verum materiam morbi incassando, atque istus includendo," says Lommius, "longe facere coetiones rebelliorum, itemque measus, quibus ea tandem vacuari debet, obtinuere." (Lommi. de Febris contin. curandis, sect. iii. cap. 2.)

The conclusion, however, which common sense would deduce from a consideration of the instinctive proprieties of the constitution, is fortunately corroborated by observation and experience. Dr. Fordyce, after rejecting some arguments and slating some facts, upon this point, adds this remark: "the author, therefore, concludes, that as it is of no use to restrain the patient from drinking, as much as he pleases, or to compel him to drink more than he chooses, so it is of no use to prevent him from drinking; it of the degree of heat that he likes best." (Third Dissertat. p. i. 211.) The absurd opposition to the intimations of nature, which many practitioners have been led to maintain by equally absurd reasoning, almost justifies a sarcasm of the late Dr. More, who said, that "between a good physician and a bad one, there was a wide difference; but between a good physician and none at all, the difference was very little." At present, however, the observation is not applicable, since the abstractions of former physicians are now adopted by the people at large, and one of the greatest difficulties which a practitioner has to encounter at present, is to prevent the mischief of popular interference, and to defend the operations of the constitution from popular interruption.

With respect to the use of cold drink in fevers, Dr. Currie ascertained that its safety and utility are dependent on the same principles, and that its administration is to be regulated by the same rules, as the external application of cold; namely, that when there is a steady heat of the surface,
FEVER.

face, without any feafe of chillines, or a general perforation, it is safe and falutary, and attended by similar eftects, though generally left in degree, than thofe of the cold wafting. This principle was, indeed, long ago pointed out by Galen and others, though with lefs precision. The degree of corporal heat, the strength of the patient, the fummer fealor, &c. are flated by Lommius, from the ancients, as indicating the safety of cold drink. "Fidicem addunt, febris admodum ures, atas juvenilis, corpus boni habitus, firmorumque vicercum, atque his (ut fere fit) juncta vires, atas media, confuctudo. Ingens febris ardo riae noxia frigide impetum fulficet, &c." (Loc. cit.) The effects of cold drink, when copiously taken in the hot flage, as defcribed by the ancients, as by Actius, Cellus, &c. are sweating, a defipition to found sleep, and relief from the fever. "Poft que," fays the author juft quoted, after having mentioned the quantity of cold water drank (three or four pints), and occafional vomiting or diarrhoea produced by it, "reclinæ ac probe operti, max uberrimus ludoribus totas noticès vel etiam altimine dormientes, deliquerunt, quibus finitus, omnem in poterum aniferunt febridicationem." Cold drink is seldom employed, at prefent, to this extent; but a treatife was published in health, fome years ago, by the reverend Dr. Harney, of St. Stephen's, Walbrook, entituled "Fæbrifugum Magnum, or common water a cure for all fevers," in which he flates, that very copious draughts of cold water, drank at bed-time, at the beginning of fevers, invariably produced copious sweating, and a folution of the difeafe, in feveral cafes, which he has related. He was not, however, aware, that fuch a practice was only safe after the hot flage was completely formed.

2. Another irritation, which it is requisite to avoid in fever, is motion, efpecially that which requires the exerfice of the muclcles; and it muft be obferved, that every motion of the body is more fumilant and exhauting in proportion as the body is weaker. Hence that poffite is to be chosen which employs the fewelt muclcles, and which keeps none of them long in a state of contraction. In the horizontal poftion, the patient is supported in every part by the bed, and he is not obliged to exert many of his muclcles to maintain an equilibrium, as when in the erect pofture. Some muclcular exerfion is, however, required to be on one fide or the other, although it be imperceptible in health; there is further, in the extreme proflration of strength, in the left flage of fever, the patient invariably fides upon his back. Speaking, which as it also tends to accelerate reflation, fhould be particularly refrained from.

3. The exerfice of the mind add much to the ex- citemen of the body, more efpicially when there is con- siderable debility, as in fever, and when, therefore, the exerfice of the mental powers requires more exerfion on the part of the patient. Hence as foon as a febrile attack has come on, every circumstance that can lead to thought, and efpicially to fuch as is connected with anxiety, or may tend to excite passion or emotion, is to be carefully fhunned. It is fearely neceffary to warn the practitioner againft exciting anxiety in the mind of the patient about his difeafe, by making it the fubjeft of converfation in his preffen; but it fhould be inculcated to nurses and friends, and all unneceffary attendants and visitors fhould be excluded, that the fubjeft of buffines, and all other interefling converfation may be avoided.

4. A very important part of the antiphlogiftic regimen relates to the nature and qualities of the food and drink to be given to perons labouring under fever, particularly in the early periods of it. The prefence of recent aliment in the flomach always proves stimulant to the ftylum, and the more f0 in proportion to the quantity received, to the folidity of its texture, and therefore the difficulty of its digestion, &c.; in all these points the irritation ought to be moderated as much as poifible, confidently with the safety of the patient. In the beginning of continued fever no great quantity of nourifhment is immediately required, the fytem being able to support itself for a time, without any thing being thrown in to be formed into chyle and blood. Total abfolute from food, for the firft few days of continued fever, was much practiced by the ancients, who have left us a great many precepts respecting the regulation of the diet in febrile difeafes. A coniderable degree of abfolute in fact is rendered absolutely neceffary by the loss of appetite, and even avifion to food, which prevail through the greater part of the course of fever; but fome aliment be- comes requisite to prevent the patient from finking under the exhaustion of the difeafe. In the firft place, however, no principal meafure fhould be employed under thefe circum- fances, even were the organs of digestion capable of retaining a large quantity of food, or of converting it into chyle, on account of the irritation which it would induce: small quantities, therefore, fhould be given, and repeated more frequently than in health. In the fefcond place, no folid aliment ought to be given during the firft days of continued fever; however light. The eftect of fuch food, when taken, if the flomach do not altogether reject it, is to increafe the heat of the patient, not only to his own ten- fions, but ftil more to the feel of the by-fander, and fre- quently, though not always, to the thermometer; to increafe the frequency of the pulf and reflation; to excite great refleflleness and a fefte of nauseas, and to augment the deftility of strength, during the time that it remains in the flomach and intenines. In short, it totally deranges the fever, and often produces the appearance of a fresh paroxym. (Fordyce.) If the fame kind of food be per- fifted in, it increafes the evening exacerbations extremely, brings on delirium much more rapidly, and to a much greater degree than it would otherwife arife, and in very way aggravates the danger of the difeafe. Dr. Fordyce prides a farther caution strongly upon the attention of his readers: "even after the difeafe has been terminated by a crift," he fays, "animal food, in a folid form, fhould be rejected, there being no caufe which has produced relapfes, as far as the author has been able to judge, during the early days of continued fever. Only when the patient is using folid animal food too foon," from a notion that it would speedily reftrange the strength of the patient. And he properly fuggexts that under fuch circumfiances, the fever being gone, the deftility of strength no longer exist- ing, and no further caufe of weaknes remaining, "the patient, with very moderate nourifhment, and the feep and ref which are fo apt to cafe after the fever has been com- pletely carried off, will have his strength refored in a very fhort time, without using any thing that fhall run any risk of reproducing the difeafe." (Third Diflert. part i. p.184.) The moft proper nourifhment in fever, then, confifts of light, fluid, vegetable matters; efpecially the farinous furbances, coagulated by heat. Difterions of barley have been employed for this purpofe, as the simplest nourifhment, from the earliet ages; and the feeds of oats, or other fari- naceous grain, with the hulks removed, afford similar food by decoction in water. The various forts of vegetable flarch, which are prepared under the names of fago, tapioca, arrow-root, &c. under the fame purpofe of furnifhing aliment, which gives the heat definuent to the organs of digestion. The polenta of the ancients, which was compofed of a decoction of baked flour, or of bread twice baked, which we call rufles, was much recommended in acute difeafes. All vegetable furbances, however, are not to be employed indiscriminately as food, in fevers. Even the farinous
Fever.

Farinaeous substances, if dissolved in water, without being coagulated by heat or otherwise, afford a very viscid fluid, which is not easily digestible, and disturbs the stomach and the constitution at large: all such vegetables as cabbage, lettuce, green pea-fe, and the like, are to be rejected, on account of their disposition to run into the visous and aceto-us fermentations, which the stomach, having its powers depressed, is not strong enough to counteract; whence a considerable quantity of vapour is extricated, which diverts the stomach and intestines, and produces partial epiplectic contractions in them. All kind of food which is adhesive to the stomach produces irritation in the fylfe, such as strong solutions of gum Arabic, jellies, formed from the fle& of young animals, or from the membraneous parts, which should therefore be avoided. The fruits, especially the subacid or summer fruits, or such of them as, from containing less mucilage, are not so prone to fermentation, (Fordyce;) afford a light and agreeable nourishment, as grapes, &c.; those which consist of much acid, and little sugar, although agreeable in small quantities, do not contain sufficient nourishment to be depended upon, such as lemons. Another class of fruits, which contain, besides native vegetable acid, a visous mucilage, sugar, and a quantity of farinaeous matter, such as apples, pears, apricots, peaches, &c. should have their mucilage coagulated by heat, when given to patients in fever: baked, boiled, or roasted, they constitute a light and nutritious food. If animal food be employed at all during the progress of continued fever, (and the prejudice in favour of it in this country is so strong, that it is almost impossible to prevent the attendants on the sick from giving it, or to convince them that the patient can be sustained through the fever without it:) it should be used only in solution in water, and solutious only of the muscular parts of full grown animals. These afford a less viscid fluid than the flesh of young animals, or than the membraneous, tenacious, or faumentous parts: the fat or oily part should be removed by cooling and skimming it off, before the solution be given to the sick.

5. The nature of the drink which is proper to be given to persons laboring under fever requires some consideration. We have already observed, that, with respect to quantity, it is useless either to force the patient to drink more than his thirst requires, or to debar him from drinking as much as it urges him to take; and also, with respect to its temperature, that it may be taken cold, even in large quantities, under the same circumstances as the application of cold externally; namely, when the patient is in a febile heat, without any feve of chilliness, on the one hand, or prejudice against general perspiration on the other. In regard to the quality of his drink, the principle of avoiding irritation or excitement of the arterial action is to be constantly kept in view, at least in the early stages of fever. When there is considerable heat of the body, water from the spring is generally most grateful to the palate of the patient, and is not, perhaps, to be excelled in wholesome qualities by any combination of art. The light empyreumatic flavour given to it by toasted bread, or the imprigation of it with a small quantity of the essentia oil of the plants of the class *Dicyanum* of Linnaeus, such as sage, balm, &c. must be deemed altogether indifferent in their effects on the digestive, and may be employed or not, according to the ingestion of the palate of the patient. All fermented and spirituous liquors, as directly irritant to the fylfe, should be interdicted during the early and middle stages of continued fever, of whatsoever denomination. Dr. Fordyce, milled by a piece of hypothecus reflecting the procies of digestion, and misconstruing the meaning of the word *fermentation*, has recommended "weak vinous fluids" as drink in fevers. As these are "in a state of fermentation, he says, "and as substances in a state of fermentation are apt to excite any other fermentation that the same substances are capable of, are perhaps useful to excite in the stomach the fermentations by which the food is converted into chyle; they are, therefore, foul, perhaps, better than pure water." (Third Differt. part i. p. 216.) But this is an abuse of terms; for there is no analogy between the processes of visous fermentation in vegetables, and that of animal digestion; and the former author had already cautioned his readers against the use of the vegetable substances, as food, which were prone to fermentation, on account of the ill consequences which such fermentation produces. A more free use of vinous liquors is referred to, with great discretion to the patient, by some practitioners, who suppose that fever is a disease of mere debility, and therefore think of stimulating from the moment the idea of fever occurs: and the same pernicious practice is pursued by the people in general, at least the uninformed part of them, from the truly English prejudice, that if a person cannot eat, (i.e. cannot take solid food,) he cannot live; and that wine and spirits are therefore requisite to sustain him. These notions are so general among the uninformed, whether in or out of the profession, that it requires the constant vigilance of the practitioner to prevent the practical mischief resulting from them: we have hence thought it necessary to speak strongly upon this point; and regret that Dr. Fordyce, whose opinion is by some deemed little less than omnipotent on this subject, allowed himself to be misguided by an hypothesis, so as to give any countenance to the practice. While the indication of avoiding irritation is to be pursued, fermented liquors, even of the lowest quality, such as small beer, are scarcely admissible, unless the febile excitement be very moderate.

6. There are other irritating powers which are occasionally applied, and require to be removed in fevers; these are especially a collection of crude and undigested food in the stomach, and of feces in the intestines. If food had been taken a short time previous to the attack of fever, it must remain undigested, and therefore tend to aggravate several of the symptoms, especially the uneasines about the praecordia, the headache, the heat, and the velocity of the circulation and respiration. This, therefore, is another reason for the administration of an emetic, as well as for the use of diluting liquids. And the filmus of retained feces in the bowels equally suggests the propriety of laxative medicines or glyders, by which they may be removed; for, while present, they occasion a sense of fulness and weight in the abdomen, and of uneasines and restlessness in every part of the body, and augment the fever considerably. Of the effect of purgatives, as a general evacuant remedy, we shall have occasion to speak immediately. "The avoiding of irritation in all these particulars," Dr. Cullen observes, after a brief enumeration of the same circumstances, "constitutes the antiphlogistic regimen, absolutely necessary for moderating the violence of re-action; and, if I mistake not, it proper in almost every circumstance of continued fever." (Tifill Lines, § 132.)

To enable us to fulfill the first indication of "diminishing excit|ive action" in the fylfeum, several remedies are commonly used in aid of the antiphlogistic regimen; these are chiefly such as produce an evacuation of the circulating fluids directly, or of the secretions from them through their respective canals: for, as it is believed that the activity of the fylfeum depends, in a great measure, upon the summation of
of the fluids diffusing the vessels through which they circulate, it is inferred, that the diminution of the quantity of the fluids must diminish the activity of the fanguous system. The fact is proved by experience, whatever explanation may be adopted.

**Blood-letting**, by opening a vein in the arm, or any other part of the body, is the most direct means of diminishing the quantity of fluids in the system, and has been reported from very ancient times; its effects have been explained by various hypotheses, which it is not necessary to enumerate or discuss. To abstract that fluid, which is the immediate province of life, cannot, it is obvious, be a matter of indifference to the constitution; if it be the most powerful means of influencing the variations, so it is the most dangerous when improperly employed; if the most effectual mode of diminishing excitement, it is consequentially the most apt to induce extreme debility. A cautious consideration of many circumstances is, therefore, requisite in determining on the propriety of blood-letting in fever. Dr. Fordyce affirms, speaking of fever in the feafe in which we have defined it, (as distinct from the *phlegmasiae*, or local inflammations,) that, "the taking blood from a large vein, in any part of the body indiscriminately, never diminished, shortened, nor carried off a fever, in any case he has seen, nor has he found any upon record in which it had this effect." (Differt. Third, part ii. p. 4.) A statement which may, perhaps, render the extent of his reading very questionable; but which, as it relates to the fevers of this country, we are disposed to consider as correct. A pure inflammatory fever, or *fynocha*, is never seen, we believe, in this country; patients are seldom destroyed by a more general excitement, without topical congestion; but commonly by the subfequent exhaustion, together with local injury of some particular organ. In the fevers which we are acquainted with in this climate, then, blood-letting is generally to be avoided, on account of the danger of the subfequent debility which it occasions; more especially when we consider that this debility is to be expected, at all events, to ensue, in consequence of the failure of the digestive powers which support the health of the body; of the loss of pure necessary to reconstitute the vital energy; and of the concomitant over-action of the whole system, which is followed by proportionate exhaustion. In typhus, under all its modifications, these obervations demand attention; and it is now generally admitted that blood-letting is a pernicious practice in that form of fevers. It were not easy, indeed, to comprehend how the practice in low fevers could have been so generally and so long pursued, did we not know the influence of authority in perverting observation. While the precepts of Galen and Celsus were followed by Sydenham, Huxham, and others, these sagacious observers did not fail to remark the occasional injuries which the practice produced; (see Wilfon on Febrile Difeases, vol. i. p. 671, &c.) yet they did not escape from the trammels of authority, but repeated the practice, expressing "great concern and alackment" at the failure and mischief, which were often most evident. (See Huxham on Fevers.)

As the employment of blood-letting, in idiopathic fevers, requires much caution and discernment, the following circumstances were suggested for the consideration and guidance of the practitioner by Dr. Colles: 1. The nature of the prevailing symptom; from which we learn the nature of the symptoms which are to be expected, as well as the influence of different remedies. 2. The nature of the remote cause; all fevers arising from contagion, whatever be the state of the patient, or the appearances of the disease in the commencement, will soon assume the form of typhus, and therefore blood-letting is seldom admissible, although the excitement in the beginning be considerable. 3. The season and climate in which the fever occurs; for the symptoms are much more violent, and the changes more sudden in sultry than in temperate climates, in the autumn than in the spring. The practitioners in hot climates have been divided in their opinions respecting blood-letting; but in this, as in most other cases, the extremes are to be avoided; and it seems probable, that blood-letting is only to be employed in tropical climates, when the violence of the excitement threatens to prove speedily fatal, or to induce extreme debility, and then only to push it to that extent, which the urgency of the symptoms absolutely requires. (See *Fever, yellow*. 4. The degree of phlogistic diathesis, or of high excitement; which, however, it is difficult to define. The same degree of excitement, which warrants blood-letting in an epidemic, which partakes much of the *fynocha*, or inflammatory character, or in a fever from cold, violent excition, or rage, does not warrant it in a typhoid epidemic, nor in fever from contagion. 5. The period of the disease. In the most ardent fevers, as soon as the symptoms shew any tendency to decline, the proper period for blood-letting is past. Even Huxham, prejudiced as he and most of his contemporaries were in favour of this remedy, admits that "bleeding, unless in the beginning, seldom did service." 6. The age, vigour, and plethoric state of the patient. 7. The patient's former diseases, and habitudes of blood-letting; if he has been subject to inflammatory complaints, more vigorous remedies may be employed; and if he has been in the habit of losing blood, he bears the loss of it better, as habitual blood-letting produces habitual plethora. 8. The appearances of the blood drawn; which are chiefly the firmness or loose consistence of the coagulum, the presence or absence of the *buffy coat*, the proportion of leumen to the coagulum, &c. (See Blood, morbid alterations of the.) 9. And, lastly, the effects of the blood-letting that may have been already practised; namely, the continuance or alleviation of the symptoms, the occurrence of debility, &c. (See Colles, loc. cit. § 142, and Wilson on Fevers, vol. i. pp. 648, and 668, where this subject is fully and ably discussed.) On the whole, however, few cases of fever in this country require venesection, and in no case, perhaps, under any circumstances, is this remedy admissible after the first five days of the disease.

But the use of local blood-letting, by means of leeches, or cupping, is often of great advantage in certain conditions of fever, more especially in relieving local congections of blood in the head, and the symptoms thence resulting. Thus, when there is much head-ache, or delirium, accompanied by flushing of the countenance, and redness of the eyes, the application of a few leeches to the temples, or the scarificator and cupping-glasses to the same part, or to the nose of the neck, or even taking four or five ounces of blood from the jugular vein, has often diminished these symptoms considerably, sometimes carried them off entirely, and with them the whole fever. Under the same circumstances bleeding from a part distant from the head has been of no manner of use. If the strength of the patient be much diminished by the fever, or otherwise, the application of one leech to each temple is often of considerable benefit. (Fordyce.) We are disposed to believe, that the local evacuation of blood is a remedy too much neglected in the general practice in fever.

**Sweating** is another mode of diminishing excessive vascour action in fevers. The observation, however, that a free sweating commonly takes place in the crises of intermittent fevers, and in those which occasionally occur in continued fevers,
Fever.

F e v e r.

Fever, has led to much absurd and pernicious practice, for the purpose of forcing perpiration. Practitioners millook one of the symptoms of the cessation of fever for the cause of that cessation. But neither does sweating certainly carry off fever, (for it frequently takes place without even producing any alleviation,) nor is it alone a symptom of its cessation. Under such circumstances there is a general increase of all the secretions, the saliva, urine, &c.; and the tongue becomes moist, the skin soft, and so on. But when sweating is excited by the hot regimen, by stimulant alexipharmic medicines, a load of bed-clothes, and a heated atmosphere, these beneficial accompaniments do not take place; on the contrary, the heat of the body, the thirst, and general excitement are increased, as well as the head-ache, anxiety, and difficulty of breathing; and the very reverse of the indication of "removing irritation, and diminishing excessive action," is accomplished. This artificial excitement, supported by the hot regimen, perhaps, will enable us to account for the appearance of relief often produced by blood-letting, and for the perverence of our ancestors in the use of that remedy. More accurate observation, however, has decided, that in general, the most advantageous perpiration is produced by the opposite plan, viz. cooling the body, and diminishing excitement; in which case it is an indirect confluence of the treatment, and approaches more to the spontaneous sweating, which accompanies the natural sulation of fever. On the whole, therefore, the use of diaphoretic medicines is to be considered rather as auxiliary, than as an essential part of the treatment of fever.

The principal medicines now employed for the purpose of exciting perpiration are the neutral salts, especially those composed of an alkali with the vegetable acids, and the preparations of antimony. The neutral salts possess a very feeble power, which is supposed to be refrigerant; a term which is not very intelligible, and perhaps originated from the cold produced during their solution; the combination of potash or ammonia with vinegar, or lemon juice, are chiefly employed. But antimonials are more certain in their operation upon the skin. Of these the secret preparation of Dr. James, commonly called James's powder, the pubeis antimonialis of the London pharmacopoeia, which is probably the fame as the former, and the tartarized antimony, or emetic tartar, are principally used. They are all somewhat uncertain in their operation, and none of them possesses of any specific febrifugal quality; the two former, consisting of the simple oxyd, and therefore being liable to be combined with any acid in the first passages, and thus to be rendered more or less active, according to the quantity of acid which may be accidentally found there, are more uncertain in their action, than the emetic tartar, in which the antimony is already saturated with an acid. The moderate use of dilute drinks tends to aid the operation of diaphoretic medicines, partly by the sympathy of the skin with the stomach, and partly, perhaps, by supplying an increase of the thinner parts of the blood. The use of diluents was carried to a great extent by the Spanish and Italian physicians, in what they called the dista aqua, which consisted of abstraining every other kind of aliment and drink, and giving, in divided portions every day, for several days together, six or eight pints of plain water, generally cold, but sometimes warm. (See Philosoph. Transact. vol. xxix.) But this drudgery has not been frequently countenanced either by reason or experience. The use of dilute drinks has been supposed to be advantageous by diminishing the acrimony of the blood, and consequently its stimulating quality, in fevers; but the existence of this state of acrimony has never been proved, and we are not acquainted with any evidence that renders its existence probable.

Purging, so far as to empty the bowels of undigested aliment, or feculent matters remaining in consequence of the weakened peristaltic motion, we have already said, is useful, by removing a troublesome source of irritation. Dr. Cullen, Dr. Fordyce, and others have considered this as the only advantage derived from emptying the intestines, and believed that it merely obviated the mischief, which would ensue from the retention of those matters. Dr. Fordyce, indeed, affirms that all evacuation beyond this is detrimental, as producing debility, and that simple evacuation from any of the glands, as tending also to weaken, is detrimental instead of being useful. Many other physicians have expressed similar opinions, and rather diffused us from the use of purgatives, among whom are De Haen, Werlhoff, &c. Dr. Cullen, considers it "sufficient to prevent colic virescens by almost daily clysters, if the patient had not otherwise regular rooks." (Pringle, Difefases of the Army. p. iii. cap. i. See also Cullen, loc. cit. § 149, &c.) Dr. Cullen considers purging as injurious, both from producing debility, and from taking off the determination to the skin, and thus preventing perpiration; but this, in the active state of fever, is not, we believe, the result of its operation; since, as we have shown, with regard to the diminution of the febrile heat by cold water, whatever tends to alay the excessive action of the cutaneous vssels, tends to produce a flow of perpiration. The necessity of preventing any accumulation in the bowels, however, whether by repeated clysters, or gentle laxatives by the mouth, is universally admitted.

But since the prejudices of lytten and of particular schools have been somewhat laid aside, it has been observed by several intelligent practitioners, that a more active employment of purgative medicines is frequently beneficial in fever; and that not only in inflammatory fever, but in typhus. Dr. Hamilton has recently called the attention of the medical world to this important subject; and he affirms that he has for many years given up the use of emetics and clysters in typhus; and that he finds all the advantages of these medicines obtained in a more effectual manner by cathartics given internally. (See his Observations on the Utility of Purgative Medicines.) With this view he chiefly employs a combination of the sub-muriate of mercury, or calomel, with a few grains of jalap or rhubarb. He considers, that if fever does not originate in many instances from an accumulation and corruption of the contents of the alimentary canal, it is generally connected with, or productive of, such a state; and he affirms, that the removal of the dark and offensive matter which purging, under such circumstances, generally effects, is a most important step in the cure of fevers. The presence of these matters in the canal is a source of augmentation to the general fever; and we have in several cases been delirium removed, the head-ache diminished, and the state of the skin, tongue, and circulation, proportionally alleviated by the operation of a moderate cathartic; in some instances, in which the fever had been preceded by considerable contipation, a brisk cathartic or two have appeared to remove the symptoms altogether. In the early stage of fever, then, cathartics are advisable, both as removing a great source of irritation, and as exciting the glands which open into the bowels, and the mucous follicles and chalazent arteries in their course, to pour out an increased quantity of fluids, by which the general excitement is diminished; although in a considerably lefs degree than by blood-letting. (See Cathartic) The first operation, of removing irritating fords, is afterwards...
wards necessary during the whole progress of the fever; and in
the weak-est condition the use of a calomel may be re-
ferred to. The second operation, with a view of emulsifying
the bilious ducts, and of evacuating the morbid secretion
of the liver, and of the other glands, and clearing the
whole canal, is often required during the continuance of the
disease. This is indicated, 1. By the appearance of the
floods, whether they are of a highly bilious colour, which
implies a copious excretion of bile from the liver; or of
a dark brown or green hue, and very offensive odour, which
implies a morbid state of the secretion; 2. By pains in the
abdomen, especially when there is at the same time a degree
of fullness and tension in the epigastric and hypochondriac
regions, and a tenderness perceived on pressing the abdo-
men; or when there is also a degree of hepatica, or frequent
dehis to go to stool. 3. When, together with these symptoms,
the tongue is much loaded and parched, or sometimes when
there is a considerable spitting, when the countenance is of
a dirty or leaden hue, and the breathing much oppressed
than the state of the circulation would lead us to expect.
Sometimes with this state of the abdomen and countenance
a great Laurent takes place, even to fainting, al-
though there are no other symptoms of extreme prostration
of strength, and the pulse, though quick, is not equally
languid; under such circumstances we have seen the la-
enguor speedily removed by a copious evacuation from the
bowels. A degree of dysenteric affection is not un-
frequently seen in the advanced periods of fever; that is, a
frequent discharge of loose or slimy fluids, with some griping
and tenesmus; this is most effectually relieved by purga-
tives with which opiates are combined, in order to obviate
the irritation and exhaustion which the operation of the
cathartics might induce. Calomel and opium combined in small
doses seem to answer this purpose very effectually. Where
the mere emptying of the bowels is the object of the medi-
cine, and especially where extreme weakness has already
come on, or is to be speedily removed, the milder neutral
fats, as the sulphate of magnesia, the Cheltenham, or Ro-
chelle salts, castor oil, maguey and rhubarb, &c. are the
most proper remedies; but the more active agents, as calomel,
and jalap, in moderate doses, (Dr. Hamilton's formula
confists of three or four grains of the former, with six,
eight, or ten of the latter,) are requisite; and these, in-
deed, may almost supersede all other laxatives; or senna,
Jlbharb, &c. may be given with the calomel. It is not
very important to dilate on the different remedies; for when
the indication is understood, the means of fulfilling it will
readily appear. An active purgative, during a state of ex-
ternal cold, may be productive of great mischief; and in
the last stages of contagious typhus such a medicine is to be
obtained from altogether: even the mildest cathartic op-
eration has, at such times, occasionally produced a dan-
gerous linking of the vital powers. But from this fact it were
an error to infer, that active purgatives are to be discarded al-
together from our practice in typhus, as the Brunonians
have affected.

The humoral pathologists, from a hypothetical notion
of the remains of the mediates mortis being retained in the
constitution after the ceasation of fever, have directed the
administration of cathartics to carry them off, and to pre-
serve the convalescent from their future influence; and Dr
John Pringle has suggested the propriety of using them,
during the state of convalescence, with a view to prevent
a too haftiy repeation, which an indulgence of the appetite
is sometimes apt to produce; but, he observes, cathartics
at that time seem otherwise necessary. But Dr. Forley
remarks, that he has observed more relapses to take place
when purgatives have been used after the cessation of fever,
than when they have not been employed. Indeed, the no-
tion of the humors, that by partial evacuations, whether
by bleeding or purging, the remaining fluids could be de-
prived of the noxious matter, supposed to be diffused in
them, is too absurd to require a serious refutation. Never-
theless, this practice of purging, "to carry off the dregs"
of fever, small pox, &c. is still generally prevalent among
the ignorant, both in and out of the profession.

Fever.

When the skin has been refers to as a remedy in
fever, upon two very different principles, which are scarcely
confident with each other, and neither of them, perhaps, is
much entitled to our confidence. Inflammation, and fu-
puration, or some other discharge, having been observed to
precede the cessation of fever in certain cases, the proc-
eds was attempted to be imitated by the application of blisters
or irritants, composed of caustic, Dr. L. of the Haflar hospita,
whole experience and abilities are entitled to the highest regard.
"I do not know a more certain proof," says this respectable author, "of a prevailing
infectious fever, than that of twenty patients in fevers
blistered at night, sixteen will next morning be entirely free
from heat, head-ache, pain, and fever." (Loc. cit. chap. ii.
sect. 1.) And he denies the dissolving effect of blisters in
contagious fevers, and affirms that, "acc ording to the
nurses' phrase, the patient generally received a cool from the
blister," (ibid.) These encomiums, however, are very far
from being corroborated by general experience, or by the
authority of many able physicians; and on the contrary,
the testimony of the majority tends to prove, that little is to be
expected from blisters in fevers unaccompanied by local
affections. We have seen numerous instances in which
large blisters had been applied between the shoulders in
the early periods of fever: but we never witnessed any
marked effect, either good or bad, in those cases. Like
the local blood-letting, however, they are decidedly benefit-
ful in relieving local pains and contusions; and every
practitioner has experienced their utility, when the brain,
locomot, lungs, &c. have been thus affected. Sir John
Pringle observes, that blisters were only of service in the
good fever, when the patient was threatened with an inflam-
ation of the brain. "Blisters, before used, became then of
service;" and in the synocha, or inflammatory fever, he
was led by experience to confine their use to those cases
where the head-ache was considerable, which they seldom
failed to relieve. In fevers attended with coma or delirium
they are often employed with advantage. They are applied
over the blenned scalp; for the nearer they are applied to the part
affected, they are the more powerful in giving relief, like all
other local remedies.

Dr. Cullen was likewise a strong advocate for the use of
blisters in fevers; but he considered them as most benecial
in the advanced periods of the disease, "when the re-action
being weaker, all ambiguity from the stimulant power of
blistering is removed." We are disposed to believe, how-
over,
ever, that the stimulus of a blister is productive rather of irritation, than of support to the linking system; and the inflammation thus occasioned, when the vital powers are low, is liable to terminate in gangrene. Rubefacients are safer than blisters in this state of the system, but do not seem to be of much benefit where there is no local affection. Sinapisms, or mustard poultices, are sometimes applied to the feet, especially where there is coma, or great failure of the *viv aet: this, like the old practice of bleeding from the feet, probably originated in the obsolete doctrine of revulsion, and would be more efficacious, if the sinapisms were applied to the region of the stomach, or to the head.

The second indication is, "to increase the actions that are defective." It has been seen, in tracing the history of the progress of fever, that the symptoms, which occur in the former stages of the disease, are principally the result of a general failure of the vital power, or nervous energy; and that such a failure is the necessary result of the previous over-excitation, and the privation of the ordinary means of support, from aliment, sleep, &c. Hence, then, the means of preventing this failure of life consist partly in fulfilling the first indication, or diminishing the over-excitation, and partly in using those remedies which tend to support and increase the vital actions, when the symptoms of their failure appear. It must also be obvious, therefore, that the early employment of stimulants, cordials, and tonics, which was referred to by the humoral pathologists, in order to accelerate the conclusion of the morbid matter; by the disciples of Brown, with a view to obviate debility, and by others to prevent putrefaction, must be extremely pernicious. It is a practice founded on the same grounds as the vulgar error of the people in forcing food upon a person in fever. They forget that, in order to nourish the body, the food must be digested, converted into chyle, and assimilated; but that, while the system is incapable of performing these functions, the food introduced tends but to increase the weakness, by increasing its cause, the febrile state. In like manner, the practitioners no sooner hear the name of fever, than they immediately ply the patient with wine, Peruvian bark, and various cordials, regardless of the period and circumstances of the disease, and thus accelerate the debility, the consequences of which they are most anxious to avoid. This treatment cannot be too strongly reprobated; especially as it is still adopted by many in the profession, who practise by rote, notwithstanding the proofs of its uneffectiveness, which experience has so plainly averted. And it is most particularly to be condemned, when there are symptoms of considerable local congestion, especially in the head.

When, however, the means of moderating the excitement, in the former stages of the fever, have been omitted, or have failed to terminate the disease, and the symptoms of exhaustion and defective action begin to appear, it then becomes requisite to administer those remedies which poffefs a stimulant power over the actions of the arterial and nervous systems. Of the medicines which support and increase the actions of the animal body, those which are poifoffed of strong favourable qualities, and excite an obvious and immediate action, are denominated stimulants; and those which flow, and by repeated exhibition, increase the power and force of these actions, or the tone of the moving parts, have been called tonics. Of the former class are wine, spirits, volatile alkali, the ethers, &c.; of the latter are the bark of cinchona, cæfarilla, and other vegetable bitters, the metallic salts, and oxys of iron and zinc, &c. Now, as the operation of the latter is comparatively slow, they are less useful in the late stages of continued fever than the articles of the former class. The principal tonic medicine that has been employed in continued fever is the cinchona, or Peruvian bark; which has probably been given in these fevers, in consequence of its success when administered in the intervals between the paroxysms of intermittent fever. Between this operation, however, and the cure of a continued febrile state, it is obvious that there is not much analogy; and experience has evinced accordingly, that the practice is not beneficial; but that, on the contrary, it more frequently increases the symptoms of continued fever, and that its use is most likely to be detrimental, especially when the tongue remains foul, the pulse frequent, and the skin not yet become lees, cool, and moist. Dr. Fordyce has accurately described the consequences which we have occasionally witnessed from the exhibition of the bark, even when the favourable remission of the symptoms seemed to justify its use. "The relaxations which began to take place in the disease have been much diminished, the pulse has become more frequent in the morning, the headache more considerable, the skin drier, the tongue covered with a thicker fur, the colic vesicles greater, if the patient was not thrown into a purging, the oppression upon the precordial greater, and likewise the difficulty of respiration greater. On the following evening the head has been also much more affected, that is, the conjunctiva and delirium have been much more considerable, and the patient altogether worse than he probably would have been, if no remedy whatever had been exhibited, and there has been less chance of cure in the fever, and it has been longer of being worn out." (Third Differt. part ii. p. 148.) Where there are marks of congestion in the head, lungs, or other viscera, the administration of bark is at all times to be deprecated. In a word, the most accurate experience has taught us, that the cinchona, especially in subhance, is seldom beneficial, and often injurious, in continued fever of any kind; and that it is most useful in reining the strength in the convalescent state, when the symptoms of fever have altogether disappeared. The only cases in which we have seen any advantage from it, are those in which there is an obvious remission and exacerbation, especially at tertian periods; a form which we have sometimes observed the continued fever of this country to assume. A great variety of stimulant remedies have been employed for the purpose of obtaining debility in the late periods of continued fever; of these cinchona is generally the most grateful, and not less efficacious than most of those which have been recommended. But this, we believe with Dr. Gregory, has been often given in too large quantities, to the amount of two or three bottles in the day. We have certainly seen the strength robed by powerful stimulants in great quantity; but we have also seen this new excitement immediately followed by a fatal inflammatory condition of the brain. Perhaps a pint in the day may be generally sufficient. When wine cannot be procured, either, porter, or spirits diluted with water, sweetened and acidulated, are valuable substitutes. Dr. Cullen was of opinion that the most mentioned compound and opium produced all the effects of wine; but opinion does not appear to support the popular like wine. With respect to opium, it is generally safe while any considerable excitement exists, and especially when the skin is hot and dry, the tongue very foul, the bowels bound, and marks of congestion in the head, or elsewhere, appear; under these circumstances it neither diminishes relapses, nor tends to induce sleep; but, on the contrary, it creates the watchfulness, and disturbs the mind with excessive and frightful dreaming, increaseth the delirium, and the torpid
heat and thirst. When the skin is moist and cool, and the head but slightly affected; when the tremors,subfits, and the whole person are affected; when the bowels are excessively relaxed, and the evacuations watery; opium may be usefully employed. Under the same circumstances camphor is frequently administered as a stimulant: but it may be judiciously, as Dr. Fordyce has observed, whether the very small dose contained in what is called the camphor mixture, usually given, produces any decided effect: since much larger quantities have been given without any sensible influence. Musks, caftors, and other substances of powerful odor, have been often given in the last stage of fever; but the effects have been differently represented by different practitioners, some believing them to be very effectual stimulants, while others have deemed them almost inert. Dr. Gregory considers them as no farther active, than by their strong impression on the senses, and much, less efficacious antipathetics than wine and opium. The ferpertinaria, or snake-root, antiperite, and other cordials and aromatic vegetable substances are often administered with advantage. It must be remembered, however, that there are marks of considerable congestion of the brain, all powerful stimulants, which will tend to augment that condition, will ultimately fail to produce strength; but, on the contrary, will increase the most dangerous symptoms of the disease.

Much has been said relative to the prevention of putrefactive in the last stages of infectious fevers. This, however, as chiefly the result of extreme prostration of strength, is principally obviated by the means of support already pointed out. These marks of putrefactive changes exist principally in the excretions of the patient; which is important to remove, as their presence seems to augment the depuration of the vital powers: hence the utmost attention to cleanliness is requisite, and clean air, if we may so speak, or air free from the noxious exhalations, admitted by a constant ventilation, contributes to support the patient. The putrid fœces contained in the bowels or bowels are often evacuated with great advantage, and may be effected by gentle means, which do not contribute to further exhaustion. With view to correct the putrefactive of these contents of the alimentary canal, various antifeptics have been recommended, especially the mineral acids. That these acids, especially the vivric acid or phosphoric acid, which has been principally employed, are sometimes useful, cannot perhaps be questioned; but it is probable that their administration was suggested upon the principle of being chemically antifeptics to dead animal matter. A chemical explanation of the operation of a medicine on the living body is somewhat ambiguous; and Dr. Fordyce has remarked, that no antifepic can be applied in that proportion to the living solid, as would be requisite to prevent putrefaction in dead animal matter. (Loc. cit. part ii. page 171.) These acids, however, tend to quench thirst, and to settle the bowels, and are grateful to the patient.

Dr. Gregory is in the habit of concluding his lectures on the subject of fever by strongly cautioning his pupils not to do too much to patients labouring under the disease; for he justly averred, that in many cases, little more would be requisite, after the proper evacuations at the commencement, than cool drinks, and the antiphlogistic regimen already pointed out. And this is unquestionably true of fevers not occasioned by a virulent contagion, and where no considerable local congestion occurs; in which case it becomes us to watch rather than to be active. This, however, will seldom satisfy a patient, or his friends; and hence the building mischievous empiric is often preferred to the experience of the physician, as Sydenham, who attributes fame of the worst symptoms occasionally to the "nimia medicorum diligentia," feelingly laments. "Sed, quod dolendum omnino est, zegorum quam parimenti, habu suis quoque, quandoque is nihil agere, atque atque tempore efficacissima adhibere remedia, probatis atque fideli fructum hunc capere nolunt, sed vel negligentia vel ignorantia id imputant, cum empiricorum inulisllimums quibusc medicamenti medicamentis adiicere ac voluit, ac folis magis quam medicorum prudentissimus." (Sydenham, Opera, fec. i. cap. 6.)

Division of Fevers. — Having discussed the nature, causes, and cure of fever in general, it remains for us to notice the various forms of the disease, which have been distinguished by particular appellations. From the earliest periods of medical history, a great number of names have been applied to the varieties of febrile disease, which, as they were often deduced from hypothetical notions, respecting the nature and cause of the fever, often more indications of the violence or absence of particular symptoms, and often very vague in their signification, have tended to introduce much confusion into the writings of physicians on this subject. The majority of the names, which have been thus invented, are applicable to the same fever; at least to a fever arising from one and the same source; whence, it has been justly remarked by Dr. Lind, that physicians, who have had the most frequent opportunities of seeing numerous patients in fevers, have always found great difficulty in arranging their cases under the common appellations, and that the attempt has frequently led them into absurdities. (On Fevers and Infections, chap. ii. fec. 2.) For the same fever the term putrid, petechial, malignant, inflamed, nervous, bilious, typhous, verminous, &c. are often equally applicable. It is obvious, however, that accidental symptoms of local affection, or the accidental violence or mildness of any particular symptom, do not mark a fundamental change in the nature of the disease, and are therefore not the proper grounds for multiplying names, which tend to confound disorders that are essentially the same, and therefore to mislead us in our practice.

The least ambiguous division, which is now generally adopted, is into three orders, of intermitting, remitting, and continued fevers; which are again distinguished by their leading symptoms. The intermitting fevers are those which occur in distinct paroxysms, or fits, in the intervals between which there is a complete apoplexy, or absence of all febrile symptoms; this is termed an intermission. In the remitting fevers, which also consist of repeated paroxysms, there is no entire intermission between the paroxysms, but only a considerable abatement or remission of their violence; the return of a new paroxysm, however, being generally marked by chilliness, and some other symptoms of a cold stage. By continued fever is understood a fever which goes on day after day, without any intermission or decided remission of the symptoms; not in an uniform progress, however, but with an obvious aggravation or exacerbation of the symptoms of a hot stage, once in the twenty-four hours, and generally in the evening. Many of the ancient and modern writers, indeed, down to the time of De Lancy and Cullen, have described a continued fever, proceeding in one uniform and unvarying tenor, without exacerbation or abatement of any symptom, in a word, confining of one lengthened paroxysm: this they denominated a continued fever, in contradistinction from the intermitting fever, just described. By the Latin writers the former is called febris continuas; the latter febris continua; by the Greeks the former was denominated τερτας συνέχεις, συνεχόμενος; the latter τερτας συνέχεις, συνεχόμενος.
FEVER.

By some writers, again, the 
continent fever is called continued, and what we now understand by continued fever is called continued-remittent. 
Our countryman, Morton, whether through mistake or 
design is not evident, has revered the common acceptance 
of the terms, (as has been justly remarked by Burfeius, 
Infl. vol. i. § 194. and by Selle, in his Rudim. Pyroto-
logy,) and describes the continent fevers, or 
suppes, as remittent. 
(See Morton, Pyroto logia.) De Haen, how-
ever, and Cullen, denied altogether the existence of a 
continent fever, without periodical exacerbation, as it never 
occurred to them in the course of a long experience; and 
their opinion is now generally admitted as correct. Burfe-
lius and Selle maintain the ancient doctrine. 

The confusion which has enveloped this subject does 
not, however, end here. For Dr. Cullen, Burfeius, and 
others, who have still farther reduced the orders of fevers 
to two only, viz. intermittent, and continued, (deeming the 
remittent fevers different only in degree,) have never-
theless widely disagreed in their arrangement of the latter. 
Cullen has chaffed the remittents with the intermittent fevers, 
considering the remission as a lesser intermission; 
while Burfeius has placed them with the continued fevers, 
considering it as a greater exacerbation and abatement: so 
that we find the same identical diseases among the continued 
fevers in the writings of Burfeius, which are placed among 
the intermitten ts of Dr. Cullen. The arrangement of Dr. 
Cullen, however, would seem to be the most correct; first, 
because the intermission and remission more nearly accord in 
their phenomena; and, secondly, because both these fevers 
are in general from the influence of marsh effluvia. 

We shall here proceed to enumerate the principal 
appellations of fever which are to be found in the writings 
of phyficians; referring for the full explanation of the majority 
of them to their places in the alphabet, as more conftant 
with the nature of a dictionary. See also FEVERIS; where 
the Latin and Greek names, for which we have no corre-
sponding English terms, are enumerated. 

Fever, Acute, a term of indefinite application; some-
times used to denote idiopathic fever, and sometimes indi-
cating a fever with violent symptoms, whether idiopathic, 
or symptomatic of local inflammation. 

Fever, Ardent, Febris ardens of the Latins, the fame 
with the caninus, κανίνος, of the Greeks, signifying those 
forms of fever in which the heat in the early stage is exce-
five. The words are from ardor, and κάνος, I burn. 
The terms have been variously applied to intermittent, remittent, 
and continued fevers, in which this symptom prevailed. 
The yellow fever of hot climates is the most ardent fever 
with which we are acquainted. (See FEVER.) The 
word ardent is nearly synonymous with inflammatory. See 
Sennertus de Febribus, lib. ii. cap. 12. 

Fever, Bilious, a term applied to the habitual fevers, 
whether idiopathic, as the remitting or continued, and those 
continued fevers in which there is a considerable discharge 
of bile, or to cholera, and dysentery. (See Pringle on 
Diseases of the Army, part ii. chap. 1. and part iii. 
chap. 4.) Hippocrates considered all habitual epidemics 
as originating from a corruption of the bile, and the term 
has been often used, perhaps, upon his authority, without 
any evidence of a morbid flat of this fluid. In hot 
climates and seafons, however, there is generally a tendency 
to superabundance of the bilious secretion: and the yellow 
fever, which is so named on account of the bilious tinge of 
the surface, may be considered as an example of Bilious 
fever in its most violent form. 

Fever, Catarrhal. See CATARRH.
clumsy, gen. 4) Under this definition it corresponds with the 
*yrica non patriis, and continua a patriida, of several authors, and 
the (aburdly named) *phima^ pluman die-
rum, or daily fever of feral days, of others. (See Sen-
nert, Dr. Febril. 1 b. c. 6. Boeckhues, 728.) Such 
divisions, however, cannot be regarded as accurate, or as 
differentiating forms of fever essentially different in their na-
ture; for, in fact, the puré *ynocha, or fever with no other 
but inflammatory symptoms, is scarcely ever met with, as 
we have already remarked; nor is a purely opposite, or 
typus fever, which is characterized only by symptoms of 
proliferation of strength: almost every continued fever being 
inflammatory, or marked by some degree of excitement in 
the beginning, and nervous or typhoid, i.e. marked by de-
bility in the latter stages. This constitutes an intermediate 
genus, which Dr. Cullen has called *ynocha. Thus the 
•ynocha, or fabric oradus, and the yellow fever 
of modern times, is characterized by the highest excitement in 
itself total, but is perfectly typhoidal in the left.

The symptoms of the *ynocha, or inflammatory fever, as 
it is commonly described, are as follows. The depression 
of strength, which precedes and accompanies the attack, is not 
so great as in contagious fever, and the cold stage is more 
frequently absent, and lasts marked. The pulse, even in the 
cold stage, is seldom small or very frequent; after the heat 
commences it becomes full, rapid, and, as it has been 
termed, florid; still, however, its frequency is less than 
in those fevers in which debility prevails. The respiration is 
frequent, hurried, generally suppressed, and attended with 
a dry cough. The heat is greater than in other continued 
fears, and although burning to the feeling of a flatter, it does not excite that pungent or acrid sensation 
which is observed in the feverous cases of typhus. Dr. Moore 
remarks, speaking of the latter, **on pressing the skin of 
the patient a sensation of a peculiar penetrating heat 
remains on the hand for some minutes after; whereas, the heat 
communicated by the skin of a patient in the inflammatory 
fever is more transient. (See his Medical Sketches.) Dr. 
Huxham, as well as Pringle, and others, has remarked 
the peculiar biting heat in malignant fevers, and observes 
that Quetelet calls it la chaleur d’un enceinte,** and very judiciously 
distinguishes it from la chaleur d’inflammation. The fea-
tion in truth is as different as touching a very hot piece of 
dry wood, and dipping your finger into tepid spirit of hart-
florn. The head-ache in inflammatory fever is generally 
considerable, accompanied with throbbing of the temples, 
and seems, in the earlier stages, to be calm and florid, and the 
eyes inflamed, and incapable of bearing the light. The de-
pravation of the senses, however, is less frequent than in 
fears with debility, nor is delirium a common symptom; 
but when it does occur in *ynocha, it rises to a degree 
which, from the debilitated state of the system, we fear-
fully ever met with in typhus: the patient becomes frantic, 
and is with difficulty retained in bed. This constitutes the 
delirium of authors. (See Delirium.) When the de-
lirium is obilimate in *ynocha, we have reason to suspect an 
inflammatory affection of the brain, which there is still more 
reason to dread, if the patient be oppressed with coma. In 
truth, between this form of disease, and inflammation of the 
brain, the diagnosis is difficult, if there be any effential 
difference. The febrile powers are more completely 
fused than in most cases of typhus: the skin, mouth, 
and throat are dry, and the mucus covering the tongue be-
comes foul and vitious; the urine is high-coloured, and the 
bowels colicky. In a word, it is obvious that the inflam-
motorsympotms of the hot stage of fever.

When *ynocha proves fatal within a few days of its com-
encement, (which, if it ever happens, is a rare occurrence) 
the pulse is fast, does not become weak or intermittent 
before death; the patient seems to be carried off by the 
viola-
ence of the excitement. When the disease continues for a 
long time, however, and the symptoms are at all evident, 
the pulse during these (although the fever has not yet affum-
ced the form of typhus) becomes weak and languid, the 
patient appearing to be exhausted by the foregoing paroxysm; 
which is renewed, however, in a short time, with all its 
former violence, or even stronger marks of excitement. The 
hemorrhages, which frequently occur in inflammatory 
fear, are generally from the nose, ears, lungs, rectum, (if 
the patient be subject to the hemorrhoids,) or from the u-
terus, and are almost always favourable: the blood discharged 
has the healthy appearance, except that the coagulum is 
frequently covered with the bloody coat. Hemorrhages 
from the upper parts of the intestines, kidneys, urethra, 
skin, eyes, &c. are rarely, from the two last perhaps never, 
observed in inflammatory fever.

Such are the symptoms of well-marked *ynocha; they 
varied in different cases from those just enumerated, to the mild 
fебile symptoms attending a common catarrh or ephemer. 
After they have continued for some time, if they do not ter-
minate the patient’s life, they always, at last in this 
country, begin to be changed to those of typhus; so that the 
whole disease is *ynocha. The proportion of the respective 
forms of the disease is different in different cases; and proves 
an endless source of variety: but the symptoms which follow the 
state of increased excitement are the most dangerous as well as 
the most varied part of the fever.

The principal indication in the cure of inflammatory fever, it 
must be evident, is that which we have stated above as 
the chief indication, in the general care of fever, (see FEVER; 
Method of Cure, vide, "to diminish excitative action." The 
means of fulfilling this indication, by the antiphlogistic re-
gimen, and evacuant medicines, in other words, by remov-
ning or diminishing all sources of irritation, and by diminu-
ishing the quantity of the circulatory fluids, have been detailed 
at length, and need not here be repeated. The higher the 
degree of inflammatory diathesis, the more requisite will it be 
to employ active evacuation, at an early period of the 
fear, and there will be the less hazard of carrying it to an 
jurious degree. In this country, however, as we have 
already stated, such a degree of *ynocha is seldom seen, as 
requires, or is better fitted to general excitement or 
heart, or yellow fever of tropical climates, the inflammatory 
extinction is more rapid and more severe, and the activity of the 
antiphlogistic practice must be necessarily greater. (See Willon on Febrile Diseases.) See FEVER, yellow.

FEVER, Intercurrent, a denomination given by Syden-
ham and others to those forms of fever which constantly 
occur sporadically, that is, independent of the particular 
epidemic season, or of the reigning contagion.

FEVER, Intermittent, a fever which occurs in distinct fits 
or paroxysms, with an interval of health, or complete ab-
ence of fever, between them: from the shivering which 
commences the fit, the disease has been called *yncha, 
which see; and according as the fit recurs, every day, every 
alternate day, or once in three days, it has been termed a pro-
tidalum, a tertian, or a quartan ague. See these words 
below.

FEVER, Intermittent, a term applied to some writers to 
those varieties of continued fever in which there is much 
diarrhoea, with feverish oedema, &c. pain of the belly, in-
flammation, or other symptoms of abdominal disorder. Other au-
thors
thors have used the epithets gaeric and nefenteric with the
same intention: and the fomes infechlorides and excremen-
tuses of others are the fame. This multiplication of names
is altogether useles, since they do not imply any difference
in the effeclual nature of the fevers, and it gives rise to
great confusion in medical language.
• Fever, Lenticular, the famine with petechial. See be-

Fever, Malignant, a vague and improper term generally
applied to fevers of a contagious origin, with symptoms of
extreme prostration of strength, petechiae, hemorrhages,
fected discharges, &c.; in a word to typhus, in its word
forms; and also to scarlet fever in its most severe modificaf-
tions, the plague, and other dangerous embemics.

Fever, Military, a modification of common fever, ac-
companied with an erection of spots not larger than millet
feas. See Military erupafion.

Fever, Milk, a fever afflicting puerperal women, and
accompanied with dilation of the mammae. See Milk-
Fever.

Fever, Morbillous, Fivered modilliform, a term given by
Sydenham, perhaps with the fame impropriety as in the
case of dysenteric fever, (see above,) to a fever occurring
during the prevalence of epidemic measles, but without the erup-
tion, or with very little of it. See Mefures.

Fever, Nervous, a name given by some writers to all
the varieties of fever, accompanied with debility, in contra-
distinction to those which are chararacterized by aeral
strength, which they call inflammatory. But Dr. Huxham,
and after him many other physicians, have appropriated the
term nervus to a particular form of fever with debility,
which goes through a long and flow course, unattended by
the exclusive excitement of inflammatory fever, on the one
hand, or by the extreme prostration of typhus on the other.
At the same time, as it is accompanied by great loss
of muscular powers and mental inactivity, without the marks
of infecion in the fluids discharged, it was supposed to
be a disease of the "animal spirits," or nervous fluid, and
not of the blood; whence the term nervous was adopted.
Dr. Huxbam’s description is considered as a very matterly
example of medical history, and we shall give the outline
nearly in his own words.

The patient at first grows somewhat bileaf, and feels slight
chills and shudders, with uncertain sudden flushes of heat,
and a kind of weariness all over, like what is felt after great
fatigue. This is always attended with a sort of heaviness
and depression of spirit, and more or less of a load, pain, or
giddiness of the head; a numb- an and difficult of every thing
soon follows, without any considerable thirst, but frequently
with urging to vomit, though a little but injurious phlegm
is brought up. Though a kind of hiced interval of several
hours sometimes intervenes, yet the symptoms return with
aggravation, especially towards night. The head grows
more heavy or giddy, the heats greater, the pulse quicker
but weak, with an oppressive kind of breathing. A great
torpor, or obtuse pain and coldness, affects the hinder part
of the head frequently, and oftentimes a heavy pain is felt
on the top, along the coronary future; this, and that of the
back part of the head, generally attend nervous fevers, and
are commonly succeeded by some degree of delirium.

In this condition the patient often continues for five or six
days, with a heavy, pale, funk countenance, seemmg not
very sick, and yet far from being well; restless, anxious,
and commonly quite void of sleep, though sometimes very
drowsy and heavy; but although he appears to those about
him actually to sleep, he is utterly inapparent of it, and de-
neys that he doth fo. The pulse, during all this time, is
quick, weak, and unequal, sometimes fluttering, and some-
times for a few minutes slow, nay, intermittmg; and then,
with a sudden flush in the face, immediately very quick,
and perhaps from after surprizingly calm and equal; and
thus alternated. The heats and chills are as uncertain and
unequal, sometimes a sudden colour and glow appear in the
checks, while the tip of the nose, and ears is cold, and
the forehead at the same time in a cold dewy sweet. Nay, it is
very common, that a high colour and heat appear in the
face, when the extremities are quite cold. The urine is
commonly pale, and often limp, frequently of a whey
colour, or like vivid small beer, in which there is either no
manner of sediment, or a kind of sooty matter, like bran,
irregularly flattered up and down in it. The tongue at the
beginning is feldom or never dry or discoloured, but some-
times covered with a thin whitish mucous: at length indeed
it often appears dry, red, and chapped, or of the colour of
pomegranate rind; but this mostly at the close of the
feared; yet, however dry the tongue and lips seem, the
patient scarcely ever complains of thirst, though oftentimes
of a heat in the tongue.

About the seventh or eighth day, the giddiness, pain, or
headaches of the head become much greater, with a coniunct
noize in it, or ti'neflus aurium, which is very disturbing to
the fick, and frequently brings on a delirium. The loon
the precordia, anxiety, and faintness grow much more
urgent, and the patient often falls into a violent delirium
or fainting; especially if he attempts to fit up; cold
fevets suddenly come on the forehead, and on the backs
of the hands, (though at the same time there is too much
heat in the cheeks and the palms) and as suddenly go off.
If the urine now grows more pale and limpid, a delirium
is certainly to be expected, with universal tremors and fufi-
tus tendinm. The delirium is seldom violent, but as it
were a confusion of thought and action, the fick muttering
continually to themselves, and fumbling in their speech;
sometimes they awake only in a hurry and confusion, and
preently recollact them felves, but forthwith fall into a
muttering dozy state again.

The tongue grows often very dry at the height of the
fever, especially in its middle part, with a yellowish hat on
each side, and it trembles gently when the fick attempt to
put it out. When the tongue at this time grows more
mud, and a copious fitting comes on, it is always a very
good sign; but where a difficulty of swallowing, continual
gulpmg, or choking in the throat supervenes, it is a very
dangerous symptom, especially if attended with any degree
of hiccup. Frequently profits; sweets pour forth all at
once about the mouth, tenth, or twelfth day; a commonly cold-
fish or clumsy on the extremities; oftentimes very thin Hools
are discharged, both the one and the other are generally
colliquative and very weakening. However, a warm
moisture of the skin is generally salutary, and a gentle diar-
hras frequently carries off the delirium and comatose dif-
position.

Now nature finds space, the extremities grow cold, the
nails pale or livid, the pulse may be said to tremble and
flutter, rather than to beat, the vibrations being so exceed-
ing weak and quick, that they can scarcely be distinguished;
though sometimes they creep on surprizingly slow, and very
frequently intermit. The fick become quite irritable and
stupid, scarcely affected by the loudest noise or the strongest
light; though at the beginning strangely susceptible of the
impressions of either. The delirium now ends in a pro-
found coma, and that foom in eternal fleep. The fleets,
urine, and tears run off involuntary, and denote a
speedy diffufion, as the vall tremblings and twitching of
Y y the

VOL. XIV.
Fever.

The nerves and tendons are precluded to a general convulsion, which at once stops off the thread of life. In one or other of these ways are the sick carried off, after having languished for fourteen, eighteen, or twenty days, nay sometimes much longer.

All persons grow deaf and stupid towards the end of the disease, some extremely deaf, though too quick and apprehensive in the beginning, insomuch that the least noise or light greatly offended them. Many, from their immoderate fears, seem to hurry themselves out of life, where little danger was apparent at the beginning; nay, several will not suffer themselves to sleep, from a vain fear of dozing quite away; and others from the wretched anxiety, and confusion which they are sensible of in it, or at waking. Where the deafness ends in an impairment of the ear, it is generally a good symptom; and if it is when a person is alternately perspiring, or a large pustular angry eruption breaks out about the lips and nose.

The feverous fever attacks persons of delicate constitution, who have suffered great evacuations, a long delirium, and immoderate watching, studies, or fatigue, as well as others who have used much crude unwholesome food and drink, or have been long confined in damp foul air, or exposed to other caustics of debility.

It is obvious that, in this species of fever, there is no opportunity of using strong measures, especially great evacuations, either by bleeding, or active purging, nor is the affection amenable, where the heats are moderate, partial, and transient. A very mild emetic or gentle laxative may be advisable in the early stage of the fever; as a little rhubarb, Epipol, rhubarb, &c. But Dr. Huxham advises, "if you give any thing draught, be assured your patient will rise for it, and you will repent it." Moderate diaphoretic medicines, with a well regulated diet, but nutritious regimen, are the remedies principally applicable to this form of fever. This regimen itself, judiciously managed, Dr. H. remarks, "will go a great way in the cure, assisted by well timed and well applied blisters, and a due care to keep the patient as quiet as possible both in body and mind." He rejects strong opium, as commonly pernicious; but where the lowness and delirium are very considerable, allows of a little more stimulating plan; as the use of camphor, caffor, and sal friction, with thin wine whey, or gruel with a little wine; and as the disease advances, a little chicken broth, fago and wine, &c; the wine being especially serviceable where profuse colicky fweats occur. As no violent measures can be adopted in this fever, with a view to hale it termination, the principal treatment necessarily consists in supporting the strength, without adding much to the excitement; for which purpose a gentle cordial diaphoretic regimen is requisite, especially towards the decline of the disease. There is seldom any very marked crisis; and time only seems, in general, to wear off the fever. A gentle diarrhea is sometimes of manifest service, indeed, towards the end of the complaint, and the patient is always mott cold, when in a gentle perspiration; but when these discharges are great, they are never advantageous, but on the contrary skulk the strength of the patient extremely. There is no evacuation of a more favourable portent, than a pretty free salivation without aphtha; where this happens, Dr. Huxham observes, "with a kindly moisture of the skin, I never despair of my patient, however weak and stupid he may seem; indeed, the dearness many times makes the sick at the close of the displeasure appear much less sensible than they really are; not but that many, under these circumstances, escaping the grave, degenerate into mere idiots." (See Huxham on Fevers, chap vii. Manningham on the Febricula.) The disease, above described, is the typhus minor of Dr. Cullen's classification.

Fever, Pesticial, a fever which spreads rapidly and extensively, and is destructive to numbers, whether typhus, the plague, scarlet fever, &c. See Epidemic, and Plague.

Fever, Pesticial, called also pectoral, puncticular, and phlegmonous, is a term applied to typhus, or other fevers, in which the purple spots, resembling flea-bites, and denominated petechic, punctular, &c. appear upon the skin. These spots are considered as marks of malignity and putrefaction, as above mentioned, in the description of the symptoms of the advanced stage of continued fever. See Pustule, and Petechia.

Fever, Puerperal, or child-bed fever, a fever which occurs within a few days after parturition, and is connected with an inflammation of the peritoneum, or membrane lining the cavity of the abdomen; hence its nomenclature of Peritonitis purpuratus, which is also Puerperal fever.

Fever, Purpura, the same with petechial, (see above) so denominated from the ordinary colour of the petechiae, which, in the language of the nurses, are called the purpura. See Puerperal, and Petechia.

Fever, Purulent, a term applied to all the forms of fever, whether typhus, intermittent fever, scarlet fever, plague, yellow fever, &c. in which there is extreme prostration of strength, with black and offensive discharges, hemorrhages, and purpura spots; with what propriety will be discussed under the head Purulente fever, which see.

Fever, Quotidian, and quotidian, appellations of intermittent fever, when the fit occurs every third day, or every day in succession. The word quotidians, signifying daily, might appear to be erroneously applied; but physicists reckon the day on which a crisis commences the first, and consequently the third day after this is the fourth of the disease; in continuing the calculation, therefore, the day of every successive paroxysm is again reckoned, viz. as the fourth of the preceding period, or cycle, and the first of the succeeding cycle. In like manner, the intermittent, which occurs on the alternate days, is denominated a tertian. The common people, however, denominate the quartan a third day age, and the tertian a second day age, not being acquainted with the more complicated medical calculation. See Ague.

Fever, Remittent, a fever consisting of periodical increases and abatements, but without an interval of freedom from the symptoms, as in the intermittent. See Remittent.

Fever, Rheumatic, a term applied to rheumatism, when accompanied by a general febrile condition, and which is then more commonly and correctly termed acute Rheumatism, which see.

Fever, Semi-tertian, that form of remittent fever in which there is daily exacerbation and remission, (see Ferrii amphiemorina) but on alternate days the exacerbation commences with rigor, or great chilliness and shivering; as if a tertian were joined with an ampheric fever. This is the hemitritis of the Greek writers; and the Amphiemorina hemitritus of Sauvages. (Nofol. Method, cl. ii. genus 6. species 7.)

Fever, Ship, is the typhus occurring in crowded vessels. See Typhus.

Fever, Scarlet, a fever of the exanthematic or eruptive class, which, like the small-pox, measles, &c. is propagated by a specific contagion, and occurs but once during the life of the individual. It is characterized by a close efflorescence, of a scarlet colour, appearing on the surface of the body,
F E V E R.

The pulse, during the eruptive stage of simple scarletina, is usually very quick and feeble. The tongue exhibits on its upper surface a whitish fur, through which the elongated papillae extend their scarlet points; the sides of the tongue are of a darker red colour. The urine is clear, and of a bright straw colour. The face is considerably tumefied. There is usually great restlessness, with a desire of itching or tingling in the skin, and often slight delirium. These symptoms continue with more or less violence from three to seven days. A few patients escape without fever, pain, or any particular uneasiness.

This disease, although now known to arise from a different species of contagion, has been considered by many authors as a variety of the measles, and, as the two diseases resemble each other, so as to be occasionally mistaken, we shall recapitulate the diagnostic characters, as pointed out by Dr. Willan.

1. The efflorescence in scarlet fever generally appears on the second day; in the measles it is seldom visible till the fourth. 2. It is much more full and spreading in the former than in the latter disease, and consists of innumerable points and spots under the cuticle, intermixed with minute pimples, in some cases forming continuous, irregular patches, in others coalescing into an uniform flush over a considerable extent of surface. In the measles the rash is composed of circular dots, partly distinct, partly set in small clusters or patches, and much less elevated, so as to give the impression of roughness when a finger is passed over them; these patches are seldom confluent, but number of crescents, or segments of circles, with large intervening portions of cuticle, which retain their usual appearance. The colour of the rash is also different in the two diseases, being a vivid red in the scarlatina, like that of a hol. lather's shill; but in the measles a dark red, with a tinge of a raspberry. 3. During the first stage, the measles are distinguished by an irritant parsi cough, with expectation of a tough serpiginous phlegm, by an inflammation of the eyes and eye-lids, with great tenderness to light, by an increased circulation from the chylial gland of the face, &c. The scarlet fever is also frequently attended with a cough, and with red cheeks of the face; an extension of the rash to the tuncia albuginea, circumstances which render the distinction between this complaint and the measles particularly difficult, if other symptoms be not clear and decisive. On minute examination, however, it will be generally found, that the cough in scarlatina is thinner and irritating without expectoration; that the redness of the eye is not attended with intolerance of light, that the ciliary glands are not affected; and that, although the eyes appear shining and watery, they never intermit. 4. When the rash appears on the third or fourth day, being scattered, and of a dark shade of colour, as respects its appearance in the second and third form of scarlatina, the disease may be distinguished from measles by the appearance in the throat, by the rigidity of the muscles of the neck, and other peculiar symptoms hereafter to be described.

For the care of scarlatina simplex, it is only requisite to keep patients in a moderately cool and equable temperature, in clean open apartments; to prescribe light diet, without animal food; and to give cooling liquors to drink. When there is no morbid appearance or inflation in the throat, our chief care should be to prevent needless applications; hence, according to Sydenham's observation, "more die of this disorder except from too great efficacies in the practitioner." It is but nominally a disease, he says, unless the patient is imprisoned in bed, and medicines are poured in "nimas docti et ferendum est."; then "mor-

**Fever.**

bus inuis intedis, et ager non raro nulla alia de causa, quam nimia medici diligentia, ad plures migrat.** *(Sec. vi. cap. 2.)* We wish that this were popularly understood; for, alas! we have a great many patients, when concluding their life, with FEVER in general, that friends and nurses will not be content without more decisive proofs of the learning and art of the doctor, whose most difficult task is, therefore, to prevent their active interference in such cases, by seeming to be active himself.

II. Scarletina anginae, or scarlet fever with sore throat, is more severe than the preceding. In this species of the disease there is superadded to the fever and efflorescence a considerable swelling of the tonsils, velum palatum palati, and uvula, accompanied with a florid redness of their whole surface, often terminating in numerous fluid ulcerations. The primary febrile symptoms are in this species the same as in the former, but more violent. The affection of the throat sometimes begins with the fever, at other times is not perceptible till the scarlet efflorescence has arrived at its height; most frequently it is felt when the rash appears, and increases and declines with it. A sudden leision of difficulties in the malleable of the neck, and lower jaw, takes place at the beginning of the disease. On the second day of fever the throat is rough and thickened, the voice becomes hoarse, and deglutition is performed with pain and difficulty. These symptoms are attended on the second, third, and fourth day, with nausea, vomiting of bile, headache, delirium, colic, and great heat, with a febrile flattening pulse, a quick respiration, and extreme languor or faintness. On examining the throat there appears a considerable enlargement of the tonsils, and a florid redness of their surface, which extends over the palate and the posterior part of the throat. The tongue also assumes a high red colour, and the papilla over its whole surface are greatly elongated. In some cases no further change is observable in the fauces, neither do the appearances above-mentioned continue beyond the fifth or sixth day: no deep or considerable ulcer forms in the tonsils. Slight imperfect ulcerations are very frequent, and more especially at the latter end of the year. They occur at an early period of the disease, as on the second or third day, sometimes later. The formation of them is preceded by a very quick respiration and the various difficulties of the throat. Small white patches are then visible over the pendulous part of the palate and the tonsils; at the same time, the red colour in those parts becomes darker in some places than in others, so that the whole surface has a peculiar speckled appearance. Soon afterwards, fissures or excoriations take place at the centre of the white patches, which are almost immediately covered with whitish leucous. When these are numerous, the throat is constantly clogged with a large quantity of tough vivid phlegm; hence the difficulty of swallowing is increased, and much pain is felt upon pressure externally applied. The leucous are in some cases removed about the fifth or sixth day, at the decline of the efflorescence; in other instances they continue to the eighth day, or even later; and when they separate, partial excoriations remain, which may, however, be readily healed.

The efflorescence, in this form of scarlet fever, differs in a few particulars from that bestowed under the head of scarlatina simplex, 18. It does not appear so early in the disease, but is often delayed to the third day. 2dly. It does not so constantly extend over the surface of the body, but comes out in scattered patches on the back, sides, neck, and breast, or about the joints. 3dly. It sometimes wholly vanishes the day after its appearance, and re-appears partially at uncertain times. Hence, 4thly, the whole duration of it is longer than in scarlatina simplex. These variations are most frequent during the autumnal and winter months, when the disease is in general less virulent.

During the state of extreme debility, which usually succeeds the scarlatina anginae, some patients are affected with anaphalous swellings of the face and hands, but more especially of the lower extremities. The swelling becomes conspicuous about the eighth or tenth day from the disappearance of the rash, and continues for two or three weeks. In cases exhibiting a very full and vivid efflorescence, the anaphaeas take place more frequently, and to a greater degree. When the throat is much ulcerated, and the rash not extensive, and when no desquamation of the cuticle succeeds, droopish swellings regularly appear. Occasionally, though very rarely, effusions of serum into the abdomen, or thorax, or the ventricles of the brain, take place. An enlargement of the parotid glands happens frequently in adults, and continues a long time without desquamation. Children, at every period of the disease, are liable to tumours both of the parotid and sub-maxillary glands, sometimes ending in tedious and painful abscesses. With these they have, during the latter phase of the disease, ulcerations at the corner of the mouth, pimyous phlegm in the ear, swelling of the upper lip, and purulent discharges from the ears, sometimes accompanied with deafness: they are also subject to pustules or small ulcerations of the tongue, which prove troublesome for some days, but without any serious consequences.

During every epidemic scarlet fever many cases occur in which the efflorescence is confined to the throat and mouth, there being no appearance of a rash on the skin: but the febrile symptoms, vomiting and delirium, continue violent for several days. A crimson colour of the throat is perceptible often before the fever commences; in the course of which numerous small specks of ulceration are formed on the tonsils, &c. and become, in many places, confluent, when the increased secretion of phlegm, the tumour, pain, and difficulty of swallowing, occasion great distress. This complaint seems peculiar to adults, and is evidently a species of scarlatina, because it affects some individuals of large families, while the rest are labouring under other forms of the disease, and because it is capable of comminuting, by its own power, into a number of individuals. It is generally gone through the scarlatina angina experience, while con- valescent with the sick, very much les. The disease remains, however, free from fever, although the swelling and inflammation of the tonsils be considerable.

The cure of scarlatina anginae requires a more active administration of remedies. Although blood-letting has been recommended by Mortor, De Iac., and others, the experience of our later writers on this subject coincides in deeming it injurious. Dr. Willan says, wherever it had been employed, great depression and faintness were the immediate consequences, the pulse becoming more weak and frequent, and often irregular. And Dr. Withering disconunents even local bleeding. Sometimes, where the fiery redness of the eyes, and the state of delirium seemed to demand the application of leeches to the temples, he observes, "I have found them applied, but never with any good effect."

Emetics are recommended by all the best writers on this disease, among whom, indeed, there is very little difference of opinion on the subject. "In the very first attack," says Dr. Withering, "the vomit fails to remove the disease at once; if the poison has begun to exert its effects upon the nervous system, emetics stop its further progress, and the patients quickly recover. If it has proceeded still farther, and occasioned that amazing action in the capillaries which
Fever.

which exits when the scarlet colour of the skin takes place, vomiting never fails to procure a reprieve to the anxiety, the faintness, and delirium." "In the throat, when the throat was more affected, when the tumescence of the face was such that the patients could not swallow, but with the utmost difficulty: when the peripneumonic symptoms threatened suffocation, and bleating was ineffectual, an emetic opened the gullet, and unloaded the lungs, so that deglutition became easy and respiration free. But it is necessary to add, that a vomit only sufficiently strong to evacuate the contents of the stomach is by no means adequate to these effects. The vomit must be powerful, and, in ordinary cases, repeated once in forty-eight hours; in those with more urgent symptoms daily; and in the worst cases twice in twenty-four hours. The patients never fail to express the relief they find after the operation, and the physician soon discovers it in the countenance and pulse. As to the form of the emetic, the practitioner may vary it as he pleases; but I generally combine tartar emetic in solution with ipecacuanha powder, that I may be more certain of their full effect on the stomach, and avoid the danger of their acting as a purgative. I also give them much larger doses than usual, in order to secure a certain violence of action upon the system." (Withering on Scarlet Fever, page 75-8.)

Dr. Rush recommends this repetition of vomiting, but he also "gave calomel in moderate doses in every stage of the disorder." Dr. Wilkins agrees with these physicians, in the propriety of administering emetics, but has never found it necessary to repeat them so often as Dr. Withering has advised.

With respect to purgatives, Dr. Withering, it is obvious from the above quotation, considered them as dangerous; and Dr. Willan affirms, that they "have nearly the same debilitating effect as blood-letting. They are indeed very seldom necessary," he adds, "for though a few patients may, on the first day, be afflicted with bilious vomiting and diarrhoea, the state of the bowels is more uniform than in other febrile complaints." Nevertheless, he thinks the occasional stimulus of a small dose, as two or three grains, of calomel, very useful. Dr. Bills expresses an acknowledgment to a brother practitioner, "for his removal of a prejudice against laxatives in the early stage of the disease, imbied from various authors, and confirmed by the dreadeful consequences I had seen when a diarrhoea came on in this fever. By his persuasion small doses of calomel and other laxatives were occasionally given; and so far from producing injury, I believe, that by evacuating the acid matter, which is often swallowed, they had a tendency to prevent exacerbations of the intestinal canal, and the consequent diarrhoea which I dreaded." (See Willan on Cutaneous Diffuses, part ii. p. 357.)

Dr. Hamilton of Edinburgh has, however, shown us that such prejudices were completely unfounded, and that moderate purgatives of calomel and rhubarb, or jalap, in the early stages of scarlatina, are as beneficial as in simple fever; and he even considers them as supereding the exhibition of emetics. We believe that both the remedies are advantageously administered; and that a laxative of the bowels, produced by medicine in the early stage, tends to prevent the diarrhoea of the succeeding periods, as Dr. Billis remarks, and as is also probable in common fever.

In cases of scarlatina angina, where the throat is inflamed and swelled, fo as to occasion very painful deglutition, Billi. ss applied to the external fauces, or between the shoulders, afford considerable relief.

It is proper to enjoin the same adherence to the antiphlogistic regimen as in the simple form of scarlatina, or as mentioned under the head Fever, particularly with regard to cool air, cool drinks, and light coverings; the cutaneous heat arises to a higher degree in this than in any other febrile disease in this country. If the thermometer be applied to the surface of the body," Dr. Currie observes, when speaking of this fever, "after the sensation of heat has become steady, the mercury will be found to rise to 105 and 106° even in mild cases, and in the more violent cases to 108, 109°, and 110°. I have known it rise as high as 112°, the greatest heat I ever observed in the human body." (See his Reports on the Effects of cold Water &c. vol. ii. p. 428.) Accordingly the experience of this excellent physician, as well as that of professor Gregory of Edinburgh, and of several intelligent correspondents, has ascertained that the external application of cold water to the skin is the most certain and effectual method of removing this disease. (See Cold, effects of, as a remedy.)

In this case, as in that of idiopathic fever, already described, the cold of the skin actually terminates the disease, when applied before the appearance of the efflorescence, and the cold washing, at subsequent periods of the disease, while the skin remains hot and dry, invariably diminishes all the febrile symptoms, and gives great relief to the feelings of the patient, as we have witnessed in numerous cases. Dr. Stanger, when speaking of the same general washing of the body, among the children of the Foundling Hospital, 7t of whom went through the scarlet fever, remarks, that "its effects in cooling the skin, diminishing the frequency of the pulse, abating thirst, and dispelling to sleep, were very remarkable. Finding this application so highly beneficial," he adds, "I employed it at every period of the fever, provided the skin were hot and dry." (See Dr. Willan's treatise, above quoted, p. 360.) With what success the cold affusion was employed by Drs. Currie and Gregory, in completely annihilating scarlet fever in its commencement, in their own children, will be remarked with pleasure by the readers of Dr. Currie's second volume, p. 457, and 455. While this remedy is used, Dr. C. observes, cold water and lemonade should be used as drinks, and the bowels opened, if necessary, by calomel. "It is left to myself I use no other means." We can add, that we have seen several cases, in which the patients rapidly recovered from a smart attack of the disease, in which the cold washing, by means of a figure, repeated from time to time as the heat was great, and a dose of calomel, were the only remedies employed.

We have before stated, that the effects of cold, applied to the skin, when there is excessive heat, and action of the cutaneous capillaries, is the most efficient mode of inducing sweating, the Cold, which, whether as a cause or a consequence and sign of the reduction of fever, has been generally an object of the practice of physicians. Many of them endeavour, in the first six days of scarlatina fever, to excite perspiration by antimonials, camph. arom. distillate, and vinegar, and vinegar with vinegar, and vinegar with vinegar. But Dr. Willan judiciously remarks, that before the decline of the efflorescence, such remedies and opposite coverings, for the most part, fail to produce their usual effects, and often increase the heat, anxiety, and restilence, which they were intended to relieve; and that before the decline he never succeeded in the endeavour to excite perspiration, yet perspiration is the almost certain result of the external use of cold water, properly employed.

The mineral acids have been found serviceable in scarlatina angina, and acidulated gargarines are generally useful, where the throat is much affected, and seem to carry off the virus with which the saliva is tainted, and thus to pre-
FEVER.

vent the irritation of the bowels, which it occasions when swallowed. The use of bark in the first days of scarlatina anginosa is now given up by the majority of practitioners as detrimental; but it is generally admitted that, at the decline of the efflorescence, if the fever also declines, and is not succeeded by a cough, the bark, mineral acids, wine, and nutritious diet, obviates the debility and oppressive languor, which remain after the disease, and contribute to prevent the accession of dropy. (See Willan, loc. cit.)

III. The symptoms of the scarlatina maligna on the first day; according to the author just quoted, are nearly the same as in the scarlatina anginosa; but some of the following peculiarities are afterwards observable: 1. A small, indistinct, and irregular pulse, a brown or black infiltration of the tongue, teeth, and lips; 2. A dial reddish of the eyes, a dark red flushing of the cheeks, delicacy, delirium, or coma alternating with fretfulness and violence: 3. Breath extremely fetid; a rattling and laborious respiration, partly occasioned by a thick rough phlegm clogging the naso; a contraction of the jaws, and painful deglutition; a fulness and livid colour of the neck, with retraction of the head: 4. Ulcerations on the tonsils and adjoining parts, covered with dark bluffs, and surrounded by a livid line: 5. An acid discharge from the nostrils, causing foreheads, or chops, and even blisters, about the nose and lips, the fluid being at first thick, but afterwards thick and yellowish: 6. The rash is usually faint, excepting in a few irregular patches; and all of it presently changes to a dark or livid red colour; it appears late, is very uncertain in its duration, and often intermixed with purple spots, or petechiae. In some instances the rash suddenly disappears a few hours after it is formed, and comes out again at the expiration of a week, containing two or three days.

Patients with the violent of the first attack of malignant scarlatina have never declined to struggle through a fever of most fatal and formidable circumstances, continued far beyond the usual febrile period. The ulcerations gradually spread from the throat to the gullet, larynx, and wind-pipe. Violent pains of the bowels, and excitations about the knees succeeded; also hectic paroxysms, with suppurations of the glands, a tooting cough, great difficulty of breathing, pains in the side, and a remarkable alteration in the sound of the voice. A few recover after having been harassed, almost incessantly, for six or eight weeks. In the year 1768, when the scarlatina maligna was epidemic in London, more than two thirds of those affected with it died between the seventh and nineteenth day of the fever. The symptoms pertaining danger are, continued coma, drenches of the eyes, labours breathing, diarrhoea, petechiae, vices, and hemorrages. The degree of danger in the complaint does not depend on the greater or less extent of the rash on the skin; the fullest redness affords to decided security, nor is the total absence of it incompatible with a mild disease. Many patients sink under this disease, unexpectedly, at a very early period, as on the second, third, or fourth day, no symptoms having preceded, which could excite an apprehension of immediate danger. It has been thought that to huddle a mortality is owing to a gangrenous state of the throat, gullet, stomach, intestines, or lungs; and this opinion seems to be confirmed by dissections.

In the treatment of scarlatina maligna, a bold and persevering course of emetics, as recommended by Dr. Withering, is considered by Dr. Willan and others as the most effectual mode of obviating the singular malignity of this distemper. When administered in due time, lays the last-mentioned author, they very generally prevent the transition from the milder to the more virulent forms of scarlatina, and remove the febrile symptoms at the earliest possible period. In dubious cases, if powerful doses of ipecacuanha, either alone, or combined with tartarized antimony, entirely fail to produce their usual effects, it may be concluded that the most unfavourable state of the disease has begun, and that the patient's situation is extremely dangerous. Blister are seldom useful in this form of scarlat fever, and sometimes prove injurious. Bleeding and purging are always hurtful, according to Dr. Fothergill, Dr. Willan, and others; a strong cathartic, or even the application of a few leeches to the throat, frys the latter, has been known to produce an immediate sinking, and sometimes death within a few hours, in cases which were formerly excepted not favourable. But from the condition of Dr. Bines, above noticed, we learn that unreasonable prejudices have existed against purging, in other forms of this fever; and we cannot easily reconcile the enemions on strong and reiterated vomiting, with the extreme fears of moderate purging, at least in the commencement of the disease.

Fumigation of the throat with nitrous acid is recommended by Dr. Willan as useful in keeping the throat clean, and often superseding the necessity of gargles; but he admits that gargles remove the vile and offensive matter from the throat, and thus preserve the fauces and bowels from its disagreeable action. Those prepared with contravera, according to the directions of Dr. Fothergill, (Treatise on the Ulcerous Sore-throat, p. 63.) are the most grateful and advantageous; and gargles of a more stimulating quality have been used with benefit. In the Wcst Indies the favourite gargle is made with camphor or Cayenne pepper, which, though productive of much pain, is said to be very efficacious. Occasional immersions in warm water are recommended in this form of scarlatina by some practitioners. Dr. Currie remarks that the application of cold water is fearfully applicable to the scarlat a purpura, and that the tepid affusion makes little impression upon it. Dr. Willan has observed considerable advantage from the application of warm vinegar and brandy to the limbs, and to the greater part of the body.

When emetics have not been exhibited at a proper period, it becomes necessary, as the diæte advances, to direct cordials, wine, opium, Peruvian bark, mineral acids, &c. according to the circumstances of the case. In this point, almost all authorities, foreign and British, coincide. The diæte is then to be treated with other fevers of extreme debility, or malignancy, as it has been termed, which the gangrenous tendency of the ulcerations, as well as the other symptoms, manifestly indicate.

IV. In the ulcerated sore throat, which affects adults without any eflfluence on the skin, emetics, given early, according to Dr. Willan, prove of great advantage, and the treatment recommended in the febrile stage, will be found effectual. Gargles, whether acid or dextrin, if very sharp, or if injected forcibly enough to remove the bluffs, occasion much pain, and often protract the disease. Dr. Wall, Dr. Johnstone, Dr. Rush, and others, recommend the inhalation of the vapour of myrrh and vinegar. Dr. Willan is of opinion, that Dr. J. Carmichael Smyth's mode of fumigation, by pouring heated oil of vitriol on powdered nitre in a proper vessel, is entitled to a preference. The refreshing antifeptic vapour, he says, detached by this process, and circulated through the room, perfectly clears the patient's throat, and at the same time removes the factor both of the breath and perpiration. (Loc. cit. p. 568.)

It is truly singular, that the slightest of all eruptive fevers, and the most violent, the molt fatal diæte known in this country, should rank together and spring from the same origins.
FEVER.

origin. Experience, however, has decided, that the scarlet fever, the scarlatina anginosa, the scarlatina (or angina) maligna, and the scarlet ulcerating fore-throat without the efflorescence on the skin, are merely varieties of one disease.

That all of them proceed from the same source of contagion is evident; because under the same roof, in large families, some individuals have the disease in one form, some in another, about the same period. According to the state of the air, the foil, climate, or season of the year, one form predominates over all the rest, and gives the general character to every epidemic scarlatina. Hence aside the various accounts and opinions respecting it, which are to be found in medical writers. Dr. Currie, however, remarks, "that the varieties of scarlatina are, in fact, not greater than the varieties of the small-pox, to which they bear a very strict analogy." (Reports, vol. ii. p. 427.) It is now understood, that the scarlet fever is liable to attack the same individual but once in his life; an occasional exception only occurring in this, as in the small-pox, measles, and other eruptive fevers. (See Dr. Binns' account, in Dr. Willan's Treatise, p. 283.)

Dr. Withering says, "I have never yet seen an instance of the scarlatina having the scarlet fever twice, and I believe it to be as an improbability as a repetition of the small-pox." (p. 53.)

The scarlet fever spreads rapidly by contagion, especially among children. (Adults are not very susceptible of its influence,) and the symptoms often commence on the third or fourth day, and the eruption appears on the fifth or sixth, after exposure to the contagion. Not only does the contagion extend itself rapidly, but when it once finds its way into large families, schools, &c. it is with great difficulty arrested in its progress, even by keeping the infected separate from the rest, by strict attention to ventilation, and to cleanliness throughout the house. (See Contagion.) This was strongly exemplified in the year 1803, in the small-pox, the quakers at Ackworth, in which, notwithstanding the active adoption of these measures, under the judicious management of Dr. Binns, 171 persons were affected with scarlatina, and the disease continued there upwards of four months. (See the whole account in Dr. Willan's Treatise before quoted, p. 53) (et seq.) Nevertheless, these measures of prevention are advisable in all similar instances, and in smaller academies than that of Ackworth they have been found effectual, when carefully pursued. Dr. Haygarth relates an instance, in which thirty-seven boarders in the family of a clergyman were infected by the infection, brought to the school by one boy, by immediate separation of the latter. "My patient's chamber was situated in the middle of the house," Dr. Haygarth observes, "at the landing of the first pair of stairs. All the scholars went close past this door several times a day. The rules of prevention were placed on the door, and rigid attention to their faithful observance was required. The event fully justified my hopes. Though all the thirty-seven scholars remained in the same house and family during the whole disease, yet not one of them was infected." At this time Winchester, and several other large schools in England, sent home and dispensed their scholars, on account of this disease, which had alarmingly spread among them. (See Dr. Haygarth's letter to Dr. Percival, p. 81.) See also Dr. Withering on Scarlet Fever, p. 67, and Dr. Black- bourne on the same, p. 21.) All these writers give a caution against the usual practice, on the appearance of the disease, of hastily dispelling the scholars, who may, after returning home, diffuse contagion in their respective families and neighbourhoods. As we deem this subject of high public importance, we shall make no apology for transcribing the active measures which were adopted, under the superintendence of Dr. Blackburne, with success in a large academy.

"In a numerous school, near town, where the scarlet fever had infected several young gentlemen, in consequence of one of them being suffered to associate with his schoolfellows, in a few days after his recovery from the complaint, which he had brought with him from home, it was effectually extinguished, and was attended with no unpleasant consequences, by adopting the following means. When it became evident that the convalescent had infected the school, he was withdrawn, and apartments allotted to him, completely separated both from the healthy and the sick: to which apartments, it will be seen, the sick were removed after a certain period of convalescence. The infected were then conveyed to an adjoining house, and the doors, which communicate between it and the bed rooms of the school, were closed up, to preclude the possibility of any intercourse. The sick were there attended by nurses, the regard of the family being kept entirely from them; and to prevent effusively the progress of any farther mischief, not only their linen, but even their knives and forks, and plates, &c. were appropriated solely to their use; and nothing belonging to them was suffered to enter the house, where the healthy still remained. One of the family, who was necessarily called to superintend the management of the sick, went at no time during the illness near the school, from an apprehension of conveying the infection, but confined herself to the care of the invalids. The school-room, dining-hall, and all the bed-rooms, supposed to be infected, were immediately cleared out, and nothing but the bare walls left; they were then white washed and disinfected; the young gentlemen in the mean time occupying apartments, which were known not to be infected, and which were afterwards also disinfected with the same form. All the blankets, counterpanes, &c. throughout the house were furred: the rooms and staircases were sprinkled with vinegar; the bedheads were taken down, well scrubbed, and fumigated with vinegar; and for some time the feather-beds were exposed to the open air, and also sprinkled with vinegar. During this period, however, and for several days, some who had originally taken the infection, but not shown the symptoms so early as the others, were successively taken ill. They were of course removed from the school, and their bedding, clothes, &c. sent with them to the sick house. Thus, it being generally imagined, that no infection could be conveyed in the first stage of the complaint, it was concluded, that such young gentlemen as had escaped in the first infallibility were, by the afore-mentioned precautions, now secured from all possible danger; and the event satisfactorily proved, that none of those who fell ill in the school had, at the time, infectious influence. The young gentleman, who was last taken ill, showed the symptoms on the eleventh day in the midst of the school, and with him it stopped. (See Facts and Observations concerning the Prevention and Cure of Scarlet Fever, &c. by W. Blackburne, M. D. 1803, p. 21.)

The origin of the disease in this school, namely, from a convalescent boy, leads us to an important question respecting the period after the cessation of the infection, when the patient ceases to carry infection about his person: as well as the consideration of the means of diminishing its infectious power. Dr. Willan remarks, that in making the separation here recommended, we must be guided on the supposition, that persons under the influence of contagion do not communicate it till they are actually affected with the fever and efflorescence." He adds, "it is to be remarked, that convalescents from scarlatina, notwithstanding
ing a minute attention to cleanliness and change of apparel, remain, for two or three weeks, capable of infecting persons susceptible, especially children, with whom they have intercourc. These periods I have been able to ascertain in several instances." (Loc. cit. page 387—8.) He therefore recommends the precautions adopted by Dr.斌 in, for purifying convalescents previous to their intercourse with the healthy, as not more than sufficient for the purpose. "When the blisters and blots in the throat were wholly removed," says Dr.斌, "the patients layed a few days in the convalescent rooms, and had an opportunity of walking in the garden, at the front of the house, to clear themselves from infection by repeated exposure to the open air. After this they went across the garden to a walk-house, about equally distant from the fever-house and the school, where they were entirely stripped, and washed with soft-soap, particular attention being paid to cleaning their hair. They then put on fresh clothing, and went up to the rooms in the school; being, however, kept apart for some time longer. Their bed and bedding lines was frequently changed on their return, as it before had been in the sick-rooms. When they had continued thus about a week, and appeared to have recovered their strength, the general ablation was repeated; and after rambling in the fields for some hours, they were permitted to mix with the other children." (See Dr. Willan's Treatise, p. 384.)

From these details, the principles upon which the prevention of the spreading of the infectious contagion of scarlet fever may be accomplished will be obvious; and in order to be effectual, they must be pursued in the strictest and most rigid manner: for, as we have already pointed out, the extent to which infection is communicated through the air is extremely limited; (see Contagion,) and therefore a perfect separation and interdiction of intercourse by persons, clothes, utenils, or other things, will infallibly prevent its communication. And as all the forms of the disease may be produced in the same family, from any one source of the contagion: the precautions above specified should be observed on the appearance of the simple scarlatina, as well as when our attention is called to the more dangerous forms of the disemper.

With respect to the history of scarlet fever, our limits will not allow us to enlarge greatly on this curious and interesting part of the subject: we must content ourselves with a brief sketch, and refer the reader, who may be de- livered of a more comprehensive view of the progress of the disease, to Dr. Willan's elaborate account of the facts, in his treatise on Cutaneous Diseases, to which we are indebted for much of the information contained in this article.

The scarlet fever does not seem to have been known in this country more than 150 years; for Sydenham and Morton are the first English writers who mention it. Sir Robert Sibbald, physician to king Charles II., for Scotland, says, in the year 1680, this disease had appeared for the first time at Edinburgh, and was so little understood, that he could not venture to give any observations respecting it. Sydenham only mentioned the simple form; but Morton has described the symptoms of scarlatina anginosa, and some cases of the malignant form, which he considered as a variety of measles. (See his treatise De Morbillis et Fecr Scarratinis, cap. iv.—v.) During the 18th century the disease was frequently epidemic in Britain, and has been amply described by Hoopman in 1734; Fothergill in 1758; Cotton at the same time; and subsequently by several other authors. On the continent of Europe, however, from a much earlier period, it has frequently raged, and ravaged towns and districts, with all the virulence and fatality of a true plague. It has been described again and again, by successive observers in different situations, as a new and unknown disease, and under a great variety of denominations.

The first account of scarlatina on record is that of Ingraaffia, a Neapolitan physician, about the year 1503; it was then known by the name of Roffullus at Naples. (See his Treatise de Morbo, puerperien naturæ, trad. in cap. t.) We next find the disease epidemic in Holland in 1517, in its malignant form, as described by Furfuris; and through Lower Germany in 1565 and 6, as described by Wierus, as a pestilential fore-throat. A few years afterwards the same disease was epidemic in Paris, and called by Balbini rubido, which he carefully distinguishes from the meadles, morbilli; the mortality of the diftemper in the autumn of 1555 was dreadful, especially among children. The scarlet fever and fore-throat is to be traced again in the garrettella of the Spaniards, which occurred after the influenza of 1580, and remained among them forty years, spreading to all the ports of Italy, Sicily, and Malta, and reaching Naples in 1618, where, as in Spain, it was described as a new disease, under a variety of new appellations, and is said to have destroyed 500,000 persons within two years: it was particularly fatal to children. This statement, however, is doubtless exaggerated. During this period, we find, from the writings of Semelius, Dorminio, and others, that the middle form of scarlet fever prevailed in different parts of Germany; and were described under the titles of morbilli igni, roffilæ, erytipalæ, and universal erytælæ. It was again described as a new disease under the title of "fæbris miliares rubra," which is said to have appeared at Leipzig in the middle of the seventeenth century. It was also called "fæbris cocciæ," and "fæbris purpureæ," by other writers at Leipzig. The scarlatina spread through Poland in the year 1665, and has been well described by Schultius under the denomination of "purpurea epidemia maligna." (See Act. Acad. Natur. cur. dec. i. ann. 6. 7. p. 206.) It was extremely fatal among infants and children. A few years after this it was noticed by various authors in Denmark, Holland, Switzerland, Lombardy, Bavaria, Austria, England, and Scotland. It raged at Berlin, under the form of scarlatina anginosa, from 1694 to 1751, and has been well described by its proper title, in the Acta Med. Berolin. dec. i. vol. 2, and dec. ii. vol. 5. § 3. Its subsequent appearances in different parts of Germany and Italy, until the middle of the last century, are noticed by several writers on the febris miliares, purpura miliares, purpura rubra, purpura febris, morbilli maligni, &c. And Dr. Willan has, in another part of his work, stated reasons for believing the "putrid measles," described by Sir William Watson, as in fact a malignant febrilis. (See Dr. Willan's Treatise on Cutaneous Diseases, pp. 328—350. p. iii.)

Fever. Spotted, the same with petechial, and purple fever. See above.

Fever, Tertiary, an intermittent fever, the paroxysms of which occur on alternate days, as explained above. See Fever, Quotidian.

Fever, Typhoid, or typhus, or subcutaneous Typhus, febris typhoides, πίερνος τέκες, of the Greeks, the opposite of inflammatory fever, or fever with debility, including the nervous, contagious, malignant, and putrid fever of authors; as well as the varieties denominated, from the local circumstances of its origin, gallo, hospital, and ship-fever; or, from the predominance of particular symptoms, brain-fever, internial, galls, and melenitic fever, purple, spotted, petechial fever, &c. It is the ordinary fever of temperate climates,
climates, and its symptoms, causes, nature, and treatment, may be considered as having been diffused above, under the general head of Fever. See Typhus.

Fever, Vascular, a term applied to a febrile disease, of the exanthematous class, which is principally characterized by an eruption of large watery vesicles; it is more commonly denominated Pemphigus, which see.

Fever, Worm, an appellation given by some writers to the febrile disorders of children, connected, or supposed to be connected, with the irritation of worms in the intestines. See Infants, Diagnoses of, and Worms.

Fever, Typhus, a name given to the endemic fever of hot climates, from the yellowness of the skin, which commonly occurs in the latter stage of the disease.

This fever, which has rendered the West-Indian islands, at different periods the grave of Europeans, and has ravaged the cities of America, has been the subject of great difference of opinion among those writers who have had an opportunity of witnessing its phenomena: it was therefore not easy to decide, at a distance, upon the points which they have left in dispute. We shall endeavour to give a succinct view of those facts which appear to be most satisfactorily ascertained; beginning with the symptoms of the fever.

The approach of the yellow fever is often announced by a feeling of latitude, heaviness, oppression, loss of appetite, and flight headache, which in a few hours, or on the following day, is succeeded by the violent symptoms of the disease. Sometimes, however, the attack is sudden and violent from the first; the patient is seized with a faintness and giddiness of the head, with a flight degree of chilliness and horror, but never with a complete rigor or shivering; these feelings are immediately followed by a high degree of fever, an arid and searing heat of the skin, accompanied by acute darting pains in the head and back, and often down the thighs and legs, and a strong beating of the arteries, particularly of the carotid and temporal arteries; the face and neck are flushed and turrid, the eyes red and protruding, with a sense of burning heat in the eyeballs, and the countenance is grim; great anxiety and oppression are felt at the precordia, with an intense burning pain at the loins, and almost continual shickens, which increase as the disease advances, with violent rendingings, in which bilious matter is brought up, afterwards a dark coloured, and sometimes a bloody fluid. There is extreme repletion, and a heavy respiration, with much fighing; the pulse is quick, generally full and strong, but oft; in some cases quick, low, and vacillating. The urine is deep coloured, and in small quantity. These symptoms continually increase; the respiration and vomiting become almost incessant, the anxiety excessive, the sighing frequent, and the shickens such that there is a continual toiling, and no ease in any posture, little or no sleep, and that disturbed, uneasy, and without refreshment to the sick. These symptoms generally continue to the third day, but sometimes not longer than the first, or second day, or even a few hours, and in others to the end of the fourth day, and may be considered as constituting the first stage of the disease.

The second stage begins with an abatement of many of the preceding symptoms, often with a deceitful apperance of a general remission of the fever. The vomiting, headaches, and burning heat, greatly abate or nearly disappear, the pulse loses its strength, and falls to nearly the usual frequency of health in many instances, but is always low and feeble. "Sometimes," says Dr. Mofley, "in this period of the disease, the symptoms are so mild, and the patient so tranquil, that the disease is supposed at an end, and all means neglected, or thought unnecessary, until the form appears that succeeds this fatal calm, arrayed in those dreadful forms, which are characteristic of the concluding stage, and completes the catastrophe." (Treatise on Tropical Diseases, page 411.) This interval, however, is often extremely short, so that the disease passes at once from the inflammatory stage to the black vomiting. At all events, either a repetition of similar violent symptoms soon takes place, accompanied with marks of greatly diminished energy, or the patient sinks at once into a comatose state, only interrupted by vomiting of a dark coloured, purulent fluid. The lochmous rejects every thing; the thirst, which in some is excessive, in others is moderate; and the skin is moistened with partial clammy sweats. The eyes were before red and inflamed, now become tinged with yellow; and this yellowness begins to appear round the mouth, eyes, temples, and neck, and soon after diffuses itself over the whole skin, varying in intensity from a yellow hue to a deeper orange tint; in many cases, however, it is altogether absent. The yellowness seems to usher in the concluding and most fatal symptoms of the disease; and growing deeper coloured, as the other symptoms become aggravated, is the immediate forerunner of death. The last symptoms are a deep coma, with a heavy respiration or convulsive kind of sighing, a low, creeping, and intermitting pulse, delirium, and constant repletion and fghing, fainting speech, trembling, starting, of the tongue, muttering of a black, bloody, and foamy fluid, and foams of a similar nature, haunorrhagies or oozing of blood from the mouth and nostrils, sometimes from the corners of the eyes and ears, black urine, livid spots or blotches about the skin, great coldness of the extreme parts, muttering, and death, either in a convulsive struggle, a state of torpid apathy, or sometimes in a calm and collected resignation of life. (See Hillery on the Diseases of Barbadoes, 2d edit. p. 152. Mofley, loc. cit. Lining, in the Edinburgh Phys. and Literary Essays, vol. ii. art. 29.)

The preceding description corresponds, with the general order and manner of the disease, when the patient dies from the third or fourth to the seventh day. But many patients do not experience all the symptoms above mentioned. Some have no chilliness at first, nor faintness, nor flushing in the face, and the pulse is sometimes deeply depriwed, and not quick; and there are gross habits of fey, which have been attached to the previous illness, in which the inflammatory period has been only of a few hours duration, and the transition so rapid, that the black vomiting, and the gorgonous condition have unexpectedly appeared, and terminated the life of the patient in twenty-four, or thirty-six hours. And, on the contrary, there are some instances where the disease has been protracted to the eighth, ninth, or tenth day; and others where it has never passed from the inflammatory stage; but being checked, though not extinguished, it has been lengthened out, and at last converted into a remittent of great duration, of most difficult cure, and of doubtful issue. (Mofley.) In other cases, it does not pass through those stages, nor put on the most characteristic symptoms of the disease. Speaking of the yellow fever in December, Dr. Pickard says, "Many of the sick now fall into a state of coma, and without exhibiting any other striking mark of illness, without uttering a complaint or a groan, lie down, very soon slip into the arms of death. The countenance becomes pale; the hair becomes a clay or lead-coloured hue; a deep sense of smothered grief; the patient lies in a state of tranquil insensibility; and without yellowness, or the other common marks of the fever, and in the course of a few days he slips to a cold death!"
Sometimes only a few hours complete the course of the disease." (Notes on the West Indies, vol. iii. p. 198.)

These various anomalies in the fever arise from the different fections in which it occurs, the difference of constitution, and habits of life of the patients, as well as of the predisposing and occasional causes, the early treatment, &c.

The greatest diversity would appear, during all the periods of the yellow fever, arises from the state of the proconsul, the burning heat, the anxiety and oppression, the constant vomiting, the extreme foreheads and uneasiness, composed of from the post partum at the pit of the stomach, all point to that region, which, in the words of Warren, "seems from the beginning to be the chief seat and throne of the furious conqueror." (In a treatise on this fever addressed to Dr. Mead.)

Hilley ascribed this particular and uniform suffering to the pericardium to the vicinity of the liver and gall-bladder; but it seems to be attributed with more correctness to the state of the stomach by others. For as Dr. Mofley observes, "this virusse seems to bear the chief burden of the disease, while life remains, and the principal internal vertiges of its effects after death." He observes, in another place, "on inspecting many dead bodies, I have always found some part or other of the stomach, and frequently the superior part of the duodenum in a gangrenous slate, and never without evident marks of injury from inflammation, let the disease have been of ever so short duration. These appearances are universally produced by a mortal yellow fever; but from the appearance of the liver, and gall-bladder, though both must be materially affected in this disease, there is no inference to be drawn that can be depended on." (Loc. cit. p. 414.)

Dr. Pinckard's observations accord with the preceding statement; he says "the appearances were not precisely such, as from converging with other practitioners, and reading a variety of authors, we had been led to expect. The stomach was found to be the organ which exhibited the strongest marks of derangement. The inner coat was furnished with blood, appearing very red, and at one front near the upper orifice it was of a livid hue, and its texture so weakened, that the finger was passed through it by only a slight pressure." (Loc. cit. vol. ii. p. 226.)

This author states in other parts of his book, that similar appearances were observed in other cases, which were examined by dissection. (Ibid. p. 322, &c.) Dr. Ruth, however, affirms, and from what we know of other fevers, we believe truly, that the morbid appearances of the internal parts of the body, as they appear by dissection after death, from the yellow fever, are different in different countries, and in the same countries in different years; as the same disease during different epidemic fevers affums very different aspects. From the observations of several physicians, quoted by Dr. Ruth, it appears that the liver and gall-bladder have been often disentangled in the yellow fever, marks of inflammation and gangrene, and a morbid colour and constancy of the bile, having been detected. The dissections of Dr. Mitchell, Dr. Mackiltrick, Dr. Phylyck, and others, coincide in the discovery of inflammatory disease in the stomach. "The stomach was inflamed both on its outside and inside;" says the first of these physicians, "its villous coat, like that of the duodenum, was covered with fuzzy and slimy matter." The second, after stating that the liver was differently affected in different cases, says "the stomach, the duodenum, and ileum were remarkably inflamed in all cases." The two last mentioned gentlemen remark, "that the stomach, and beginning of the duodenum, are the parts that appear most diseased," and inflammation of the villous membrane at the pyloric end of the stomach extending into

the duodenum, was the disease in some; extravasations of blood in others; the former in those who died early in disease, the latter in those who died at a more protracted period. In those cases in which the brain was examined by Dr. Mitchell, "it was not affected," and the two last-mentioned physicians affirm, "that the brain in all parts has been found in a natural condition." (See Dr. Ruth's Account of the Bilious Remitting Yellow Fever of Philadelphia, in 1793, 2d ed. pp. 114—122.) We may remark, by the way, that these facts are somewhat adverse to the doctrine of fever, lately promulgated by Dr. Clutterbuck, on which we have misadverted above, when treating of the doctrines respecting the nature of fever in general.

The yellow fever has been affected by some writers to be a new disease, the product of modern times, and even unknown till within a very recent period. We believe, however, with Dr. Mofley, Dr. Miller of New York, and others, that what is a modification of that disease which is familiar to Hippocrates, Aretzus, Galen, and other physicians of antiquity, the characteristic symptoms of which have been described by them, and the prognostic indications well pointed out. It is, in fact, the vesica cauful, and flavus ardens of the ancients, aggravated by the exceeding heat of climate. Hippocrates observes, in the ninth section of his book of Crises, "in burning fevers (the caufus), a yellowing of the skin appearing on the fifth day, and accompanied by hiccup, is a fatal symptom." The terrible symptom of black vomiting is also frequently mentioned by Hippocrates, and represented as being of fatal import. In the twelfth section of his prognostics, he afferts, that if the matter vomited be of a livid or black colour, it betokens ill. In the first section of his book of Crises, he enumerates black vomiting in a catalogue of the most fatal symptoms. And also in the fourth section of the same book, he considers porraceous, livid, or black vomitings, as indications of great malignancy. These maxims imply the similarity of their great author with those symptoms which are not known except as belonging to the yellow fever. (See a Paper by Dr. Miller of New York, in the Edinburgh Med. and Surg. Journal, for July, 1825.)

This destructive fever has never been known to appear, except either in tropical climates, or in those feasons, in the more temperate climates, in which the atmospheric heat has for some length of time been equal to the tropical heat, that is, at or above 80 of Fahrenheit's thermometer. This fact, Dr. Blane afferts, is incontrovertibly establised by observation; for there is no instance, either in North America or Europe, of the yellow fever appearing, except at those degrees of heat, nor of its surviving after the atmosphere had fallen to a lower degree of temperature. This is less to be wondered at in North America, where the winters are extremely severe, but it holds equally true at Cadiz, Malaga, Gibraltar, and other parts of Spain, where the winters are warm, and where this disease spontaneously disappeared, in degrees of heat equal to the usual summer heats in the north of Europe. (See Dr. Blane's Letter to Baron Jacob, respecting the Prevention of the Yellow Fever, in the Edinburgh Journal, for October, 1827.)

It seems to be well ascertained, then, that the yellow fever is an endemic of hot climates, or an epidemic of hot feasons in other climates; and this fact will enable us to explain the history of the disease, as well as to dispel our fears, that it may ever be brought to this country. By Dr. Mofley it is called the "endemiac caufus" of the West Indies.
It is a well known fact, that when Europeans first take up their residence in tropical climates, it is usual for them, sooner or later after their arrival, to undergo an attack of the endemic fever of the country. This fever of the visitors of the West Indies, in times of tranquillity, when the "new comers" are few, is termed a "feverising fever," but Dr. Pinckard observes, "in times of war, when, from great multitudes arriving at the same time, its destructive effects are more striking, it is baptized with the terrific name of yellow fever." This circumstance serves to explain the origin of the opinion that this fatal fever is the product of modern times; when the effulgum of colonial war has only multiplied the victims whom it might facilitate. (See Notes on the West Indies, vol. iii. p. 416 and 445.) The ordinary yellow fever seems to be justly considered by the most accurate observers as an aggravated form of the "bilious remitting fever," common to hot climates, especially where a particular condition of the soil, or some other source of effluvia, co-operates with the heat. The natives, or old residents in those situations, become habituated to the influence of these causes, and are less liable to be affected by this fever; and when they do suffer it, it is in a less severe degree. Creoles and negroes, Dr. Pinckard remarks, are not often affected with the disease, and are not subject to it in its continued or most malignant form, but when it does invade them, it more commonly assumes an intermittent or remittent type. Europeans, who have resided during a period of several years in the West Indies, have become in a great measure habituated to the climate, and have acquired a taste of constitution approaching to that of the natives; they are seldom attacked by the fever in its continued form; it commonly affects them in a remittent type. It is also exclusive in strangers, and in those from a northern climate, that the disease assumes the malignant and continued form. In North America, the inhabitants, who constantly reside in the most southern states, are seldom attacked with the fever in its more violent or continued form; while those of the north-east states are destroyed by it in great numbers. In a word, it appears that persons suffer the fever of hot climates in the different degrees of violence and severity of form, according as they are more or less feaoned or habituated to the temperature under which it occurs. Hence it has been properly fuggelled, that, in order to prepare our troops sent on service to the West Indies, they should be prepared for the climate gradually; for example, by first letting them serve for a time at Gibraltar, and afterwards employing them for a year or two in the more windward islands, as Barbados and Antigua, before they were sent to the other colonies.

Among the Europeans attacked with the ardent fever of the West Indies, the disease varies according to the state of the constitution. Thus the strong and plethoric, those of rigid fibre and rich blood, are the most liable to be attacked, and suffer the disease most violently and fatally. Hence, those who persevere in their accablled strong and stimulating diet suffer in like manner more severely than those whose vigour of habit is somewhat reduced by extreme temperature. It is observed that persons are most frequently attacked during or after exposure to great heat or fatigue, and to the night air, when it becomes cool and moist. Hence, on the one hand, those employed as cooks and blacksmiths are particularly liable to be feized, and lentilims, men occupied in fishing, and boat parties, on the other. We have before mentioned, when speaking of the caufes of fever, a fact related by Dr. Lind, that a boat's crew was three times destroyed and replaced, after going on shore for provisions in the night, the whole being as often seized with remitting fever, on the coast of Africa.

This endemic canus, like the remittents of northern climates, is more particularly prevalent in seasons when moist and marshy exhalations co operate with great heats, or cold and damp nights alternate with hot days. Hence, in more northern climates they have occurred only in the autumnal feasons, as at Cadiz in 1802, and at Malaga in 1803, and commonly at similar periods in New York and Philadelphia. After investigating the caufe of an exceflive prevalence of yellow fever in Demarara, in the month of July, Dr. Pinckard concluded that it was "probably the mere effect of the season, resulting from the increased heat of the days, the damp climate of the evenings, and the offensive malodours exhaled from half-spoiled mud."—"The quantity of rain that now falls is not sufficient to cover the feculent sediment of the numerous ditches, nor to prevent their unwholesome vapours from rising into the atmosphere; and the partial showers, which occur during the evening and night, by softening the dry-dried surface, favour the exhalation, while they produce a chilling dampness, which perhaps contributes to render the body more than ufally susceptibility of impression. The evenings are now so much colder to our feelings than we have found them during the preceding months, that we have lately been able to sit with the door shut, and have even thought that a blanket, during the night, might have been put on necessar." (Notes, vol. iii. p. 52.) Writing again from Demarara, in the ensuing month, (Augst), Dr. Pinckard says, "the present moment may be said to be the high feason of the yellow fever. It now rages in its utmost violence, and with every fever mark that great numbers perish from its malignity. Until the partial rains of the present period have ceased; and the dry feason will be well fitted, it is said that we are to expect a continuance of sicknefs, &c." (Ibid. p. 82.) In this respect the disease is altogether analogous to the autumnal remittents of our temperate climates, or of the warmer extratropical countries, when moisture succeeds or alternates with warmth, as we have already mentioned, when treating of the canus of fever. We have there seen that moist weather, after heat, generally produces a remittent fever, in countries where the soil is favourable to the formation of miasmas, and this is milder in its symptoms in the more northern and more violent in the southern degrees of latitude; thus it is an ague, or a remittent of moderate severity in England and Holland, but a fever and fatal ardent fever on the banks of the Nile and the Euphrates, after inundations have left the ground moist and sliny. On the shores of the Mediterranean, where Hippocrates practised, and frequently saw the yellow skin and black vomit of the ardent fever, Dr. Cleghorn found that the common tertian fever, when it attacked Englishmen, put on the usual symptoms of the yellow fever. (On the Difeases of Minorea. p. 176.) Dr. Rush, and other physicians of Philadelphia, and also those of New York, Dr. Miller, &c. are satisfied that the yellow fever, which has appeared in those cities in the autumnal seasons of hot years, originated in those cities, and was but an aggravation of the ordinary remittent fever. In Philadelphia the origin of the fever has been traced to the streets adjoining the docks and wharfs; in 1793, it was more particularly attributed to the putrification of a large quantity of damaged coffee, which was exposed in July on a wharf in the dock, in the vicinity of which the fever commenced. In New York, in 1825, Dr. Miller says, "on the whole, the low grounds on the margin of the waterfronts certainly produce a chief part of the calms." The different degrees,
FEVER.

degrees, then, of fever originating from malaria, according to the heat of the climate or season in which they occur, appear to be in the following scale: 1. Common mild intermittent fever. 2. Common remitting, or bilious remitting fever, and; 3. The yellow fever. These seem to bear the same relation to each other, as, 1. The simple continued fever.

The contagious typhus, or gaol-fever; and, 3. The plague. (See Dr. Rush on the Fever of 1793, in Philadelphia, 3d edit. p. 178. Dr. Pinckard, loc. cit. vol. iii. p. 417. Dr. Miller, Report to the Governor of the State of New York, in the Edin. Med. and Surg. Journal, before quoted.) Dr. Miller puts the identity of the ordinary remitting fever and the yellow fever in a strong light; "as the materials of putrefaction, and the degrees of heat in a large city," he observes, "greatly exceed what is found in the adjacent country; so the disease acting under such circumstances must be proportionably more malignant. The pestilential fevers of our city differ only in grade from the bilious and remittent fevers of the country. They prevail in the same climates; they come on at the same season of the year; they are chiefly disposed to attack persons of the same constitution; they commit their ravages on the same organs of the body, and produce symptoms differing only in degree, and they decline and disappear at the same season, and under the same circumstances. In the city we often see in the same family, and under equal circumstances of exposure, the malignant forms of pestilence, and the mildest forms of remittent fever; and in the country, while the great miasms of cafus are usually mild, we occasionally meet with some, which exhibit the violent attack, the intense malignity, and the rapid dissolution, which more frequently mark the pestilential fevers of the city." The identity of the yellow and bilious remitting fevers is maintained, in equally strong terms, by Dr. Rush, and twelve other physicians, who presented a memorial to the governor of Pennsylvania on the subject. Their reasons for this opinion are the following: 1. The same fevers of their origin; both being the offspring of putrefaction. 2. The yellow fever makes its appearance in those months chiefly in which the bilious fever prevails, and is uniformly checked by the same causes, viz. heavy rains and frosts. 3. The symptoms of the bilious and yellow fever are the same in their nature. 4. The common bilious and yellow fever often run into each other; and the improper use of remedies will mutually convert them. 5. The common bilious and yellow fevers are alike contagious, under certain circumstances of the weather, &c. 6. They mutually propagate each other. 7. And, lastly, the yellow fever affects the typhus more than once, in common with the bilious fever. (Rush, loc. cit. vol. v. p. 45; &c.) These reasons are satisfactorily illustrated in some length.

Is the yellow fever contagious? It might appear rather extraordinary to the general reader, that the eye witnesses of so fatal a phenomenon should be at variance with respect to the existence or non-existence of contagion connected with it; yet it is not recollected, that a similar disagreement and diffusion have occurred with regard to the contagious nature of the plague itself, and more particularly among the physicians of the 16th and 17th centuries, who had the most frequent opportunities of witnessing its devellations. Some of the writers who contend for the identity of the yellow and remittent fevers deny the existence of contagion in both, while others maintain that these two fevers are essentially distinct, the latter being void of contagion, and the yellow fever being propagated by contagion only. Most of the West Indian physicians deny the contagion of yellow fever; while Dr. Chisholm, and several of the Americans, consider the disease as generally imported and extremely contagious. We commonly find truth between the extremes. It has been well understood at least since the time of Dr. Lind, that the effluvia of human bodies, even in health, when accumulated in close and crowded situations, become capable of exciting fever, or, in other words, become infectious; and that those which arise from the bodies of persons labouring under febrile diseases still more readily become infectious, and propagate the original disease, whether idiopathic fever, dysentery, erysipelas, &c. (See Contagion.) Upon these grounds, it would seem, Dr. Rufin and his colleagues maintain the occasional contagious influence of both the yellow and bilious remittent fever. "In a West India climate," he says, "where the accumulation of the effluvia from sick people is prevented by open doors and windows, it is easy to conceive this (yellow) fever cannot be often propagated by contagion. Even in our own country, (Pennsylvania) it has rarely been observed to be contagious in the months of July and August. But after cool weather renders it necessary to exclude the fresh air from sick rooms, it is easy to conceive the same effluvia may be so accumulated and concentrated, as to produce the disease in other people. In this way it was propagated in some instances during the year 1797, but by no means so often as in 1793, under equal circumstances." (Med. Inq. and Obs. vol. v. p. 37.)

The testimony of many other writers might be adduced, in corroboration of the fact, that yellow fever has been often propagated by contagion, especially under the circumstances just alluded to; we shall content ourselves with stating the following facts and observations. "Some late authors," says the veteran Dr. Wright, "who have written on West India diseases, have roundly asserted, that in tropical countries fevers are not contagious; but whoever has had the care of crowded hospitals, of gaols, of ships of war, or of transports full of troops, must have seen numerous and fatal instances of contagion in the West Indies; more especially where cleanliness and free ventilation have been neglected. From cauæs of this fort a most fatal and destructive disorder broke out in the West Indies in 1793, and soon after in Philadelphia, viz. the yellow fever. From Dr. Rush's book, and from the numerous letters of my correspondents, there remains not a doubt in my mind of the yellow fever being typhus, excited to a great degree of virulence from climate, situation, and other adventitious circumstances." (See Practical Observations on the Treatment of Acute Diseases, particularly those of the West Indies, by Wm. Wright, M.D., &c. in the Med. Facts and Obs. vol. viii. p. 6.) Dr. Chisholm has advanced some strong evidence to prove, that the malignant yellow fever, which Dr. Wright alludes to, was generated on board a ship on the coast of Africa (at Bulaama or Boulan), and the contagion imported to Grenada; whence it was afterwards carried to the other leeward islands, and to Philadelphia. We cannot here follow out the whole detail of circumstances as given by Dr. Chisholm; the following are some of the leading facts. The ship Hankey failed from England, laden with stores, and upwards of 200 adventurers, for the projected colony at Bulaam. The project failed, and they all lived on board during nine months on this coast. In the crowded vessel a malignant fever broke out, and destroyed three-fourths of the crew, leaving only the mate and two seamen to navigate the ship when she failed. Four men were put on board from ships of war at St. Jago to aid in navigating her to the West Indies. On the third day after leaving
leaving St. Jago, the men they procured from the ships of war were feized with the fever, and two of the four died; the remaining two were put on shore at Grenada and St. Vincent in a wretched state. No method was taken to purify or ventilate the ship, or the clothes, bedding, &c. From this period at which the Hangley arrived at Grenville, the 16th of February, to the commencement of the defructive yellow fever, the progress of which he describes in the following manner. A captain Remington was the first person who visited the Hangley after her arrival in St. George's Bay. He went on board the evening after she anchored, and remained three days, at the end of which time he left St. George's, and proceeded in a coasting vessel to Grenville bay, where his own ship lay. He was seized with the malignant fever on the passage; and the violence of the symptoms increased so rapidly, as on the third day to put an end to his existence. The crew of the Defence were the next who suffered by visiting this ship; the mate, boatswain, and four sailors went on board the day after her arrival; the mate remained either on deck or in the cabin, but the rest went below, and layed all night there. All of them were immediately seized with the fever, and died in three days. The mate was also taken ill, but, probably from his having been less exposed to the virulence of the infection, he recovered. The crew of the ship Bailleys, from the same imprudent civility or curiosity, were the next who suffered. These communicated the infection to the ships nearest them; and it gradually spread from those nearest the mouth of the Carenage, where the Hangley had for some time layed, to those at the bottom of it; not one escaping in succession, whatever means the captains took to prevent it. Had the disease arisen from the exhalations from the Lagoon, of the mangroves around that piece of water, it must have originated of course among the ships in the inner part of the harbour, Dr. Chilghom remarks, and its progress would have been onward towards the mouth of the Carenage, and not inward towards the bottom of the harbour. In the short space of time from the beginning of March to the end of May, 1790 of about 750 seamen, who manned the ships of the regular trade, died of this fever. About the middle of April the disease began to appear on shore. The first house in which it shewed itself was situated close to the wharf, and the infection was evidently introduced, Dr. C. says, by a negro wench, who took in sailors' clothes to wash; it extended to every individual of the family, a few negroes excepted. Among the troops, it first appeared in that part of the garrison quartered nearest to where the Hangley lay. One of the officers visited the ship, and with two or three soldiers who rowed his boat, remained on board some time. The consequence of this imprudence was fatal to himself almost immediately after; and in a little time to many of the men; the officers and men were successively feized, but it proved fatal only to recruits who had lately joined. (See an Essay on the Malignant Peltidial Fever, introduced into the West Indies by Boullon, on the coast of Guinea, as it appeared in 1793, 4, 5, and 6, inter- fered with observations and facts, tending to prove that the epidemic existing at Philadelphia, New York, &c. was the same fever introduced by infection from the West Indies islands, &c. by C. Chilghom, M.D., &c. vol. i.) How far the latter part of the statement in the title page is proved, we cannot pretend to decide.

Dr. Blane has stated a circumstance, very clearly shewing the propagation of yellow fever by contagion. "The prevalence of yellow fever being limited by a determinate range of atmospheric heat," he says, "and also by a certain degree of purity of air, many people of the belt under-
F E V E R.

See also Dr. Pinckard’s notes, &c. vol. ii. p. 238. Dr. Rush, loc. cit. p. 238. As those who have been daily occupied in the midst of the devastation of the yellow fever have disagreed as to the mode of its propagation, it is impossible to decide, at a distance, in what instances it was combined with contagion, or when it was the result of the seamen and maimates only. It would seem, however, that while the probability of infection arising in the close and crowded parts of a large city, when a fever is by any means introduced, is very great; the actual progress of the fever of Philadelphia, for instance, appears to favour the notion of an exciting contagion. (See Account of the Fever of Philadelphia, in 1793, by Matthew Carey.)

The violence and rapidity of the symptoms of yellow fever render the prostration extremely difficult and uncertain; no particular symptom affords any accurate prognostic; and it is only from attention to the general state of the patient, or the result of a combination of all the signs, that any idea of what the event may be is to be obtained. The state of the eyes, the change of voice, the general aspect of the countenance, and the degree of torpor or insensibility of the system, afford the most important information. Dr. Chircholm remarked, “that the longer the symptoms of the inflammatory ditheses continued, provided their violence was not progressive, the event became more favourable; and, on the contrary, that when the sudden disappearance of the fever was immediately succeeded by a seeming state of apyrexia, the worst symptoms, such as coma, delirium, chilly cold sweats, vibices, and death, might be soon expected. In the first case, the patient was gradually thrown into an agreeably warm and universal diaphoresis; irritability of stomach sealed; the eyes became more lively; and, in a little while after, the signs of returning health were evident.” (Chircholm, loc. cit. chap. v.)

Dr. Rush presents us with the following combinations of symptoms, as indicating a more or less favourable issue of the disease:

Signs of moderate danger.—1. A chilly fit accompanying the attack of the fever. The longer this chill continues, the more favourable. 2. The recurrence of chills every day or twice a day, or every other day, with the return of the exacerbations of the fever. A coldness of the whole at the above periods without chills, a coldness with a profuse sweat, cold perspiration, and hands with febrile heat in other parts of the body, and a profuse sweat without chills, or coldness, are all less favourable symptoms than a regular chilly fit, but they indicate less danger than their total absence during the course of their fever. 3. A purging of green or yellow bile on the first day of the disease is favourable. A discharge of black bile, if it occurs on the first day of the fever, is not unfavourable. 4. A discharge of green and yellow foids. It is more favourable if the foids are of a dark or black colour, and of a sted and acrid nature, on the first or second day of the fever. 5. A profuse and moist urine on the skin, in the beginning of the fever. 6. A feaue of pain in the head, or a sudden transfiguration of pain from internal to external parts of the body, particularly to the back. An increase of pain after bleeding. 7. A feverish. 8. A white or a yellow tongue. 9. An early disposition to spit freely, whether excited by nature, or the use of mercury. 10. Blood becoming fizes, as having exhibited the usual marks of great morbid action in the blood vessels. 11. Great and exquisitely sensitive in the fenfe of feeling coming on near the close of the fever.

Signs of great danger.—1. An attack of the fever, suddenly succeeding great terror, anger, or the intemperate use of venery. 2. The first paroxysm coming on without any premonitory symptoms, or a chilly fit. 3. A coldness over the whole body, without chills for two or three days. 4. A sleepiness on the first and second days of the fever. 5. Uncommon paleness of the face, not induced by bleeding. 6. Contiunt or violent vomiting without any discharge of bile. 7. Obdurate colicines, or a discharge of natural or white fluids. 8. A diarrhoea towards the close of the fever. 9. A suppuration of urine. It is most alarming when without pain. 10. A discharge of dark-coloured and bloody urine. 11. A cold, cool, dry, smooth, or shining skin. 12. The appearance of a yellow colour in the face on the first or second day of the fever. 13. The absence of pain, or a sudden cessation of it, with the common symptoms of great danger. 14. A disposition to faint upon a little motion, and fainting after losing but a few ounces of blood. 15. A watery, glairy, or brilliant eye. A red eye on the fourth or fifth day of the disease: it is more alarming if it become so after having been previously yellow. 16. Imperfect vision, and blindness in the eyes of the diffuse. 17. Deafness. 18. A preternatural appetite, more especially in the last stages of the fever. 19. A slow, intermittent, and shattered pulse. 20. Great rellingness, delirium, and long continued coma. 21. A discharge of coffee-colored or black bile from the stomach after the fourth day of the fever. (Ruth. Med. Ing. &c. vol. i. p. 129—133.)

The methods of cure adopted in the yellow fever have been very dilimiliar, and not very successful, on the whole. That the practice pursued in different countries, and in the same country at different times, must be dilimiliar, if judiciously chosen, cannot be doubted; for the same disease, when epidemic at different periods, and under different circumstances of climate, constitution of the people, feasons, &c. is wont to assume very different characters, and to demand a corresponding difference of treatment. It has been too much the practice with medical men to prescribe for the name of a disease, neglecting the varieties of type and character which it puts on; but it is sufficient to mention the modifications of small-pox and scarlet fever, to prove the error of such sweeping rules of treatment. Between the mild distinct small-pox, and the virulent confluent small-pox, there is hardly any analogy (in a practical view): and between the simple scarlet fever, which is scarcely a disease, if the busy hand of art does not interfere with it, and the pestilential scarlet fever with the malignant ulcerated sore throat, the practical difference is as wide as possible: yet they are the same disease, originating from the same poisons. In like manner, the yellow fever, when it occurs as a remittent among the natives or long inhabitants of hot climates; as a more severe remittent or continued fever, among the emigrants from northern latitudes, or the people of countries where a tropical degree of heat is only casual; or as combined with a typhoid contagion: in all these cases it assumes a form varied in point of severity and fatality; not to mention the varieties of the same form, according to the different epidemic constitution, as the phrase is, the cause of which we cannot explain. Thus, in one epidemic fever the inflammatory symptoms, or morbid excitement may run high; in another the succeeding failure of the vital powers may be more prevalent, &c. Perhaps a consideration of these circumstances, and of the different hypothetical notions which individuals adopt, may enable us to explain both the diffimilarity, and the general want of success, in the treatment of yellow fever, unless the cathartick and mercurial treatment may be excepted.

Two opposite modes of practice have been pursued in this fever: the one dictated by an opinion that the disease was luguely putrid, and the other that it was of a highly inflammatory nature. Other practitioners again have, to a certain
Fever.

A certain degree, combined these plans, instituting moderate evacuations in the first stage, as on the first or second day of the fever, and afterwars supporting the vital powers by bark, wine, laudanum, and aromatic tonics; not to mention the exhibition of mercury, so as to excite salivation, which others have employed. The practice suggested by the notion that yellow fever is of a highly putrid nature, viz. the use of bark, wine, and other cordials, from the moment the disease was seen, shall be brief, briefly noticed, and dismissed as a benevolent mode of treatment, which has been happily exploded by practitioners in general.

Dr. Chiholm remarks, that, "from the history of the disease it will not appear extraordinary that practitioners should have recourse to bark very early in it; and before they become sufficiently acquainted with its true nature and peculiarities. The suddenness of the changes, and the apparent sinking of the vital powers, a few hours after the accession of the fever, naturally incline us to consider it as a disease wherein tonics and antifeptics, with the whole tribe of cordials, could alone be useful. But no indication can be more fallacious than this; and innumerable instances occurred of the fatal consequences of adopting it. The use of the bark in the violent cases of the malignant pestilential fever, immediately after the operation of the evacuating medicines, was hurtful in the extreme, &c." (Loc. cit. vol. i. p. 365.)

Dr. Rush affirms, that, "had the whole materia medica been ransacked, there could not have been found any of these medicines more opposite to the disordered than bark, wine, and laudanum. In every case in which I preferred bark it was offensive to the stomach. Wine was nearly as disagreeable as the bark to the stomach, and equally hurtful. I tried it in every form, and of every quality, but without success: it was either rejected by the stomach, or produced in it a burning sensation. Laudanum has been called by Dr. Mofley "a fatal medicine" in the yellow fever.

In one of my patients, who took only fifteen drops of it, without my advice, to ease a pain in his bowels, it produced a delirium, and death in a few hours." (Med. Inq. and Obs. vol. iii. p. 298.)

At the commencement of the destructive epidemic of 1793 in Philadelphia, Dr. Rush used this plan fully, until his want of success compelled him to turn his attention to other measures. I had recourse to a gentle vomit of ipecacuanha on the first day of the fever, and to the usual remedies for exciting the action of the expectoration system: I gave bark in all its usual forms, of infusion, powder, and tincture. I joined wine, brandy, and aromatics with it. Finding them all ineffectual, I attempted to route the system by wrapping the whole body, agreeably to Dr. Hume's practice, in blankets dipped in warm vinegar. None of these remedies appeared to be of any service; for although three out of thirteen recovered of those to whom they were applied, yet I have reason to believe that they would have recovered much sooner, had the cure been trusted to nature." (Ibid. p. 193.)

Dr. Rush, having requested the advice of a West Indian physician, accidentally at Philadelphia, was recommended to add the cold affusion to the large administration of bark; but the bark was offensive to the stomach, or rejected by it in every instance. The affusion of buckets full of cold water frequently upon the sick was grateful, and produced relief in all cases, by inducing a moister on the skin. But three out of four of the patients thus treated died: some physicians lost all their patients, and whole families were swept off, where these medicines were used.

In a word, this early use of stimulant medicines is in this, as we believe in all other fevers, decidedly prejudicial. And, although season and climate vary all diseases, we are disposed to apply still more generally Dr. Rush's observation, when he says, "without fear of being refuted, I will notwithstanding assert, that the proper remedies for this fever, at all times, and in all places, in its first stage, must be evacuations." (Ibid. p. 335.)

The succues which Dr. Rush, and many others upon his suggestion, experienced by commencing the cure by evacuations, especially purging, was remarkable; and we cannot but enter into the heartfelt gratification of this distinguished physician, when, in the forlorn state of ignorance as to the means of allaying the distresses of his fellow citizens, in the commencement of a raging pestilence of unparalleled fatality in that city, he was accidentally directed to an useful remedy; and in his note-book of the 15th of September wrote the following: "Thank God! out of one hundred patients whom I have visited, or preferred for this day, I have lost none." This remedy consisted of a combination of calomel and jalap, employed as a speedy purgative, in the dose of ten grains of the former with fifteen of the latter: "even this dose was low and uncertain in its operation. I then increased three doses, each consisting of fifteen grains of jalap and ten of calomel; one to be given every five hours until they procured a certain evacuation. The effects of this powder not only answered, but far exceeded my expectations. It perfectly cured four out of the first five patients to whom I gave it, notwithstanding some of them were advanced several days in the disorder." (Ibid. p. 241.)

The succues of this remedy was communicated to the College of Physicians, and the plan was immediately adopted by several physicians with a great and decided superiority over all other means hitherto employed. Large families were altogether recovered by it. From this moment Dr. Rush gained a great accession of patients, and the demand for the purging powders became greater than could be easily supplied. Together with this evacuation, Dr. Rush employed other means of abating the excords of fluxus from the sytem: these were blood-letting, cool air, cool drinks, low diet, and applications of cold water to the body. By these measures Dr. Rush publicly ascertained that a greater proportion than ninety-nine out of a hundred of all who applied to him on the first day of the disorder, before the 17th day of September, were cured. And others were in a similar manner successful. "Dr. Pennington assured me," he says, "on his death bed, that he had not lost one out of forty-eight patients whom he had treated agreeably to the principles and practice I had recommended." Dr. Griffiths triumphed over the disease in every part of the city, by the use of what were called the new remedies. My former pupils spread, by their success, the reputation of purging and bleeding wherever they were called. Not only is the general success of this plan of treatment thus shown; but it is farther evinced by the great confidence which was excited in it. "Twenty men," says Dr. Rush, "employed constantly in putting up this medicine, would not have been sufficient to have complied with all the demands which were made on me for it. Hundreds who were in health called or sent for it, as well as the sick, in order to have it in readiness, in case they should be surprised by the disorder in the night, or at a distance from a physician."
FEVER.

With respect to the propriety of clearing the bowels at the commencement of typhus fever, by cathartics, the most experienced and intelligent practitioners agree, although they differ as to the extent to which this evacuation should be carried. Dr. Hillary is satisfied with the use of a syrup, or very gentle laxative; and Dr. Chisholm is of opinion, that it is never necessary to excite a larger discharge by physic than is barely sufficient to remove the acrid and offensive humours from the bowels; and from the wonderful aptitude of the persifls of the sick, in the malignant pestilential fever, to sink into an irrecoverable state of debility, under alvine evacuation carried beyond this, I have considered it unjustifiable, in every respect, to adopt such practice. It is probable, indeed, that the nature of the epidemic in the West Indies was such as to bear severe evacuation, even in its commencement, with less safety than the epidemic of Philadelphia. Some practitioners in the West Indies I find, says Dr. Chisholm, have adopted the plan of Dr. Rush, but by no means with the wonderful success he has attributed to it. The hope is, however, that too many proofs of its disastrous consequences in a hot climate. In the year 1796, at Port Royal, where the malignant pestilential fever was epidemic, many of the practitioners gave calomel and jalap in the manner recommended by Dr. Rush, and consequently excited a most profuse discharge. The event was, however, very different from the statement of Dr. Rush; for the mortality among the inhabitants was very great; some ships were entirely flipp'd of their crews, and many lost more than half. I am well assured, that five out of six perished on this occasion of the whole seafaring with this dreadful malady. A hyperaesthesia was induced, under which the sick immediately funk." (Vol. i. p. 169.) Although the plan, which was successful in North America, might be too violent within the tropics, when carried to the same extent, it would seem, however, that the principal was usefully applied, and that Dr. Chisholm himself, notwithstanding his favourite object of exciting mercurial action in the fyltem, adopted the principle in a great measure. His first practice was confined to clearing the bowels by purgatives and antimony; on the re-appearance of the disease, in 1794, he gave calomel alone, repeating it till the intestinal canal was cleared of its contents; and he afterwards increased its activity by the addition of jalap, or any other purgative medicine of quick operative effect. "The great rule, in short," he affirms, "is to empty the intestinal canal as speedily and as completely as possible, so as to prepare it for the reception and absorption of mercury." Whatever be the mode of reposing on the subject, it is obvious that, in point of fact, this practice is essentially the same, except in degree and extent, with that of Dr. Rush; and we may therefore conclude, that purging, in the attack of yellow fever, has been found the most efficient remedy that has hitherto been employed.

Dr. Chisholm, however, administers the calomel with a view to its influence on the constitution as a mercurial, not merely as an evacuant; but it is obvious that, in the quantity in which he employs it, it must produce considerable evacuation in general. "My mode of using the calomel," he says, "after the re-appearance of the malignant pestilential fever in 1794, was to give ten grains, either alone, or with an equal or a double quantity of jalap, to an adult patient as soon as possible after I saw him. This generally acts as an evacuant in the degree required, about an hour or two after it is given. At the end of three hours I repeated the dose of calomel. At the end of three hours more, the same quantity is given, adding opium or not, as the preceding doses have acted. In this manner ten grains of calomel were given every three hours, till the bowels became made, which generally happened in less than twenty-four hours from the commencement of the treatment, if it was faithfully conducted. The effect of the medicine, given in this manner, may be perceived after the third dose in general; the patient becoming calmer, less restless, less anxious; his skin being softer, and protected of an agreeable heat; the bowels being perfectly retentive, however irritable it might have been before; and the eyes recovering their former lucidity and sensibility. When at length salivation takes place, the patient is left free from distress, with a moderate warm moisture on his skin; and very soon after signs of returning health are indicated by calls for food, &c. The recovery of strength is proportionally rapid to that from distress; nor is it at all necessary to have recourse to bark, or any other medicine whatever; a circumstance truly gratifying both to the patient and the physicians, in a disease wherein nature revolts at the very idea of it. There are circumstances, however," Dr. Chisholm candidly adds, "in which the utmost difficulty is experienced in obtaining this effect from calomel; and others in which the candid practitioner must acknowledge its insufficiency." (Loc. cit. vol. i. p. 252.)

Dr. Chisholm declares, that the success attending this practice exceeded his most sanguine expectation: "To great, indeed, was it, that I did not lose a single patient in whose case it was pushed to the full extent:" (ibid. p. 352.)

In the frequent occurrences of the epidemic in Philadelphia, Dr. Rush employed the mercurial remedies, to as to produce salivation, with great advantage. He endeavoured to excite it early in all those cases which did not yield immediately to bleeding and purging. "I was delighted," he says, "in the success in many cases which I used it. These effects were as follows: 1. It immediately attracted and concentrated in the mouth all the scattered pains of every part of the body. 2. It checked a nausea and vomiting. 3. It gradually, when it was copious, reduced the pulse, and thereby prevented the necessity of further bleeding or purging. I wish it were possible to render the use of this remedy universal in the treatment of malignant fevers. It is a rare occurrence for a patient, that has been sufficiently bled and purged, to die after a salivation takes place." "I lost but two patients in our late epidemic in whom the mercury excited a salivation. One of them died from the want of nursing; the other by the late application of the remedy." (See Rush's Medical Inquiries and Observations, vol. iv. p. 93, and vol. v. p. 117.)

The good effects of purging and of salivation, speedily excited in the yellow fever, appear, then, to rest upon strong evidence; for besides their personal experience, both Dr. Rush and Dr. Chisholm have adduced the testimony of several other practitioners, in whose hands the administration of these remedies was attended with a similar success.

The evidence, with respect to the advantages of blood-letting, is somewhat more contradictory: Dr. Rush, and several other physicians of Philadelphia, conjointly bleeding with the purging plan, and their successes are said to have been generally great. Dr. Rush affirms that "blood-letting, when used early on the first day, frequently deftroyed the disease in its birth, and generally rendered it more light, and the convalescence more speedy and perfect." But he admits that where it "had been omitted for three days, in acute cases, it was seldom useful," nay, he even says, "I am not sure that it ever shortened the duration of the
the fever, where it was not used within a few hours from the time of its attack." (Med. Inq. and Obf. vol. iii. p. 266 & 7.) Yet he mentions numerous instances in which the benefit was most decided, and has described at length the obvious advantages which generally resulted from it. He does not however recommend it indiscriminately; the repetition of the operation, and the quantity of the blood to be drawn, must be regulated by the observation of the physician. Dr. Chitholm considered the evacuation as invariably pernicious in the yellow fever of the West Indies in his first publication. In his second, he says, "with a trifling modification, it is the opinion I now hold, after again facing the disease, and after becoming acquainted with the sentiments on it of the most judicious West India practitioners, I am satisfied, that when it is possible to see the sick in this disease at the period of its accession; that when there are young robust men, immediately from England, or any other country pos- sessing a similar climate; that when the temperature of the weather is such as seems most to favour the propagation of the disease; and that, when the predisposing causes have been such as have a tendency to accelerate the motion of the fluids and to give rise to other unequivocal signs of an inflammatory disposition; then one plentiful bleeding may, undoubtedly, be of infinite service. But when most of these circumstances are absent; and when, consequently, no just indication for the employment of this remedy can be formed, I consider the use of it as a wanton abuse of confidence, and as inevitable destruction to the patient. This observation may be extended to the yellow remittent fever without limitation; for in it the means of unqualified depletion are fully as pernicious as those of repletion, or those which serve to maintain or augment the vigour and tone of the body." He attributes the freedom of Dr. Rush's practice to the difference of climate, the greater ten- dency to local inflammations, and the other circumstances above mentioned. The testimony of Dr. Jackson, Dr. Mofley, Dr. Pinckard, and others, tends to prove the salutary effects of early bleeding, even in the yellow fever of the West Indies. (See Dr. Robert Jackson on the Fevers of Jamaica, Drs. Mofley and Pinckard, as before quoted.) It cannot be questioned, however, that, generally speaking, this remedy is principally beneficial at the very oniet of the disease; and that when its vigour is abating the practice must be disadvantageous, and accelerate the malig- nant symptoms. Dr. Rush admits, that even an active pur- gative, given after the fifth day, has been hurtful.

On the whole, it seems to be demonstrable, that the treatment of the yellow fever has been most successfuly conducted upon the principles which we have laid down for the cure of fever in general; namely, by a steady sflem of withdrawing all stimuli, internal and external, at the com- menecement, i.e. by the antiphlogistic plan, purged with a vigour proportionate to the violence and fatality of the disease; and that stimulants and cachetics are pernicious, if given early, and nearly unnecessary at the later periods, where the proper evacuations have been adopted in the beginning.

For the same reason which suggests the propriety of diminishing internal stimuli by evacuations, the diet must be light and liquid, and the drink cold and diluent. All solid animal food is to be forbidden for many days after the entire cure of the fever; as the indulgence of the appetite too suddenly in that way is the cause of numerous relapses. A weak vegetable diet, with fruits, should be strictly adhered to. The drink should be thin and diluent; such as cold water, toat and water, lemonade, tamarind or raw apple- water, or weak balm and camomile tea, where the Romach is affected with sickness. The subacid drinks were prefer- red in most cases. Dr. Rush says, as being not only most agreeable to the taste, but because they tended to correct, by mixture, the acid qualities of the bile. All these drinks may be taken in the early stage of the disorder. In the convulsive stage of the fever, and in such of its remissions, or intermissions, as are accompanied by great languor in the pulse, wine whey, porter and water, and brandy and water, may be taken with advantage.

Upon the same principle of withdrawing stimuli and irritation, cool fresh air, and cleanliness, are very beneficial. Cool air is equally proper. Dr. Rush observes, whether the arterial system is depressed, or whether it showed in the pulse a high degree of morbid excitement; and is only in- proper where a chills attends the disease. Cold bathing, or affusion of cold water upon the skin in the hot stage of the yellow fever, has been found extremely beneficial; Dr. Rush found its employment advantageous under the same circumstances as Dr. Currie recommended it. (See Cold, and Fever above.) Dr. Chitholm and Dr. Jackson affirm that the cold affusion is most effectually used in a manner somewhat similar to the practice of the American Indians, and of the Russians, viz. by a succession of alternate warm and cold bathing. The patient being first immersed in a warm bath, and then removed, while the sen- sation of the heat is still upon him, a bucket of cold water is thrown over his naked body. Dr. Jackson recommends this practice after evacuation by blood-letting has been em- ployed, and Dr. Chitholm affirms that evacuating medicines are advantageously used at the same time. The local ap- plications of cold have been often very successful in remov- ing local symptoms, such as head-ache, delirium, irritability of stomatch, &c. Cold water, or a solution of salts, such as the muriate of ammonia, or of soda, applied by means of cloths repeatedly soaked in them to the head, and pit of the stomatch, have often quelled excessive action in those parts, and thus afforded material relief. Cold water injected into the bowels by way of clyster has produced similar results; and bathing the feet in cold water has frequently had the agreeable effect of relieving the head, the oppression at the precordia, and the general heat. Dr. Rush affirms that cold water thus applied to the feet very certainly diminishes the frequency of the pulse, and mentions an experiment, in which the pulse, in the course of a few minutes, was reduced 24 strokes, and became too weak as hardly to be perceptible.

With regard to the employment of blisters in the yellow fever there is the same contradiction of sentiment, as to their use, among the physicians of our climate in fevers in general. Dr. Chitholm, both upon his own observation and the testi- mony of others, affirms that blisters were never of any use, at any period of the disease, or to whatever part of the body they were applied, not even in relieving head-ache, or other local symptoms; while Dr. Rush, like Dr. Lind, considers them of great service, when applied to any part of the body, but particularly to the crown of the head. In his subsequent publications, however, he expresses himself rather less favourably of their utility, and limits their good effects to a particular juncture, which he calls the blissing point, and which, in bilious fevers, he says, is generally con- summated within eight and forty hours; for "when ap- plied in a state of great arterial action, they do harm; when applied after that action has nearly ceased, they do little or no service." (See Med. Inq. and Obf. vol. iii. p. 291. iv. 9.; and v. 122.) We are very sceptical as to the operation of blisters in fever, except in relieving local congestion.

After the reduction of the morbid action of the blood- volan.
FEVER.

vessels, by means of the remedies which have been mentioned, no other tonic is necessary than a nourishing and gently stimulating diet, and change of air. The best authors coincide in stating that, contrary to what occurs in most febrile diseases, bark and wine were not only useless or absolutely hurtful, but were generally loathed and rejected by the convalescents. The diet which is generally most agreeable to the palate, as well as the lightest and most nourishing, consists of fag, pandu, and arrow root, prepared with Madeira wine, and spice, with ellers, eggs, and malt liquors, which the patients relish greatly. The convalescence from the yellow fever is generally rapid, but in some cases it is very slow. As long as the patient remained in the infected room or house, Dr. Chisholm remarks, although the symptoms of the disease had disappeared, the progress of his recovery was relatively slow, and more especially when bark had been employed in the treatment, without the previous use of debitters, and the appropriate antiphlogistic. A change of air and situation became advisable from the moment that signs of convalescence appeared; and the purer the atmosphere, and the more elevated the situation to which the patient was removed, the more rapid was his acquisition of strength.

Prevention of Yellow Fever.—As those persons, who were in the highest strength and vigour of health, and who were not relaxed and enfeebled by long residence in hot climates, or by a low diet, were the most frequently attacked by the yellow fever, when it was epidemic, both in the West Indies and in America; so a system of diet and regimen, which was conducive to a diminution of plethoric, was the most effectual means of preventing individuals from being attacked by the disease. Dr. Rush recommended his fellow citizens to reduce their diet during the prevalence of the epidemic. He lived sparingly himself upon tea, coffee, milk, and common vegetables; but his favourite drink was a mixture of milk and rum, with a small quantity of linseed meal and camphor. His drinks were milk and water, weak claret and water, and weak porter and water. "I sheltered myself," he says, "as much as possible from the rays of the sun, and from the action of the evening air, and accommodated my dress to the changes in the temperature of the atmosphere. By similar means, I have reason to believe many hundreds escaped the disease who were constantly exposed to it. There appears to be no connection of climate and maladies that can reftit the good effects of abstinence or depickting medicines, in preventing or moderating an attack of this fever," (Med. Inq. and Ofe. vol. v. p. 39.) He recommended also to the people, besides a diet of milk and vegetables, cooling purges to be taken once or twice a week, and moderate blood-letting to all such as were of a plethoric habit; and he advised them to avoid heat, cold, labour, and every thing else that could excite the contagion (which he knew to be present in all their habitations) into action. (Ibid, vol. iii. p. 295—297.) The advice of Colfin, during the prevalence of pestilence, is very comprehensive: "Vite fatigationem, eructationes, feces, diuretes, calorem, lumbalem, multoque magis esse contigit." But it is a mortifying consideration, Dr. Chisholm remarks, that few of our countrymen can be prevailed upon to submit to the deprivation of any gratification, which, if within their ability to purchase, is very generally and very pertinaciously refused to. The comparative security from, and less mortality of, the yellow fever in the French and Spanish than in the English islands in the West Indies, have been justly attributed to the more temperate habit of the people. When the pestilential fever raged at Grenada, Dr. Chisholm observes that the French inhabitants remained almost totally exempt from it. Among them, animal food and strong liquors were very moderately used; their diet being chiefly composed of vegetables, and small acid red wine. The same author, indeed, remarks, "during the prevalence of pestilence, I am inclined to think, from a variety of facts, that abstinence from every species of strong liquor, wine itself not excepted, is more conducive to the maintenance of health, than any other dietetic regulation whatever. It is an established fact that water-drinkers either escape the malignant pestilential fever altogether, or had the disease in a remarkably mild degree. On the other hand, many instances occurred of free drinkers receiving the infection in the morning, and having the attack of the fever after a plentiful repast of animal food and wine in the following night." (Ibid. vol. ii. p. 491.) In short, the fact, that extreme temperance, and even evacuations in those that are plethorics, when in hot climates, is the most certain to escape the disease peculiar to those countries, and especially the yellow fever, is now ascertained beyond all question. Dr. Moxley says, "the English drink more wine and spirits than the French; the French more than the Spaniards; and we calculate the mortality of it by this rule. The Spaniards live to great ages in the plains of St. Jacques, &c. in St. Domingo, partly from the slowness of the air, but chiefly from their sobrietie." (On Tropical Difeases, p. 53.) And he affirms, that, while the inflammatory diathesis of the body remains, (as it will with some people, who migrate to hot climates, for many years,) "those who use water for their common drink, will never be subject to troublesome or dangerous diseases." (Ibid. p. 57.)

The question relative to the contagious or non-contagious nature of the yellow fever, above noticed, is not a matter of mere curiosity and speculation, but of the greatest practical importance, with a view both to domestic and to public life. The means to be adopted for the prevention of the spreading of the epidemic must necessarily be very different, if it arise from imported contagion, and if it be of domestic origin. Those means which afford security in either case must be useless, and therefore virtually detrimental in the other. Should the fever be the result of imported contagion in its origin, the usual methods of quarantine, and fumigation, &c. of goods, ships, and persons, must be resorted to. (See Contagion, Plague, and Quarantine.) But the best writers attribute the yellow fever to the misjudgment and puritil exhalations from various domestic sources; and we have understood that by diminishing those sources of the pestilence, Philadelphia has been much less subject to its occurrence in the usual feason. In the memoir of the thirteen physicians above alluded to, the governor of Pennsylvania is informed, and the information is supported by accompanying documents, that the epidemic fever was derived from the following circumstances, which are stated more in detail by Dr. Caldwell. There are, 1. Puritil exhalations from the docks and wharfs, the streets, fewers, gutters, cellars, privies, dirty yards and alleys, ponds, and collections of filth in the neighbourhood of the city; and also 2. The foul and noxious air emitted from the holds of ships. Of the origin of these fevers from the puritil exhalations, arising within and around Philadelphia, Dr. Caldwell and others have stated much evidence; (See Med. & Phil. Memoirs, containing, among other subjects, a particular inquiry into the Origin and Nature of the late Pestilential Epidemics of the United States. By C. Caldwell, M. D. Philadelphia, 1801.) and the correctness of attributing the origin of these fevers to such causes, is further strengthened by our knowledge of the connection of remittent and pestilential fevers in London,
con, and the other large cities of Europe, in similar feasons, with a sffthy condition of the streets and houses, and a bad arrangement of the sewers, gutters, &c. See Epidemic. (See also Dr. Heberden, jun. on the Incresse and Decrease of Dit. Lond. 1801, and the Annual Med. Regifter, vol. i. for 1828.) With respect to the second source of fevers, viz. the foul air of ships, Dr. Ruth has adduced some strong evidence of its occurrence in ships, containing especially vegetable matters in a state of putrefaction. In 1797 the yellow fever first appeared on board a veifil at one of the wharfs, and in the neighbourhood, affecting a great number of persons at the fame time: this ship had in her hold a quantity of prunes, almonds, olives, capers, &c., in a putrid state, and emitted a most offensive smell, after which vessel had discharged her cargo, which was perceived by persons several hundred yards from the wharf where she was moored. At Tortuga, Dr. Ruth states, a fever was produced, in June 1787, from noxious air generated from a few barrels of potatoes, which destroyed the captain, mate, and most of the crew in a few days. Some rattled bags of pepper on board a French Indian man produced the yellow fever, in June 1793, at Bridgetown: "all the white men, and most of the negroes, employed in removing this pepper, perished with the yellow fever, and the foul atmosphere affected the town," where it proved fatal to many of the inhabitants. Several other facts, of a similar nature, are mentioned, and Dr. Ruth adds, that this flush of yellow fever in warm climates is far too well known, and it is generally admitted, that Dr. Shannon, a late writer, in enumerating its various caufes, expressly mentions it as the putrid effuVia of a ship's hold." These facts not only lead to the certain means of preventing one of the sources of the yellow fever, but serve to explain the reasons why sailors are so often its first victims, and why, from this circumstance, the origin of the disease has been so habitually ascribed solely to importation.

Under these impressions as to the origin of the yellow fever, Dr. Ruth, Dr. Caldwell, and the others who addressed the governor of Pennsylvania, recommended the following means of prevention. 1. A continence of the laws for preventing the importation of the diseafe of the West Indies, and other parts of the world where it usually prevails. 2. A removal of all noxious matters from the streets, gutters, cellars, gardeus, yards, foles, vaults, pouds, &c. which, by putrefaction in warm weather, afford the most frequent remote cause of the disease in America. 3. "We most earnestly recommend the frequent washing of all impure parts of the city in warm and dry weather; a measure which we conceive promises to our citizens the most durable exemption from similar fevers of all kinds, of domestic origin. 4. To guard against the frequent source of yellow fever from the noxious air of the holds of ships, we recommend the unloading all ships, with cargoes liable to putrefaction, at a distance from the city, during the months of June, July, August, September, and October. To prevent the generation of noxious air in the ships, we conceive every vessel should be obliged by law to carry and use a ventilator, &c." They add, "It has been by adopting measures, similar to those we have delivered for preventing pestifential diseases, that most of the cities in Europe, which are situated in warm latitudes, have become healthy in warm feasons, and amidst the closest commercial intercourse with nations and islands, constantly afflicted with those diseases. The extraordinary cleanliness of the Hollanders was originally imposed upon them, by the frequency of pestifential fevers in their cities. This habit of cleanliness has continued to characterize those people, after the cauies which produced it have probably ceased to be known." (Ruth, Med. Inq. & Obf. vol. v. p. 54, &c. 1807. Caldwell, loc. cit. Chifholm, vol. ii. chap. 1.)

Besides the denominations of fever above explained, several others are to be found, especially among the older medical writers, which, however, require no notice here, as they are improperly applied, and are not used at present. Such are arthritic, ophthalmic, typhus, bilious, febrifus, fever, &c. See Arthritis, Asthma, Hysteria, &c.

Fever wards, Fever-houfes, or Fever-dispens, wards or houses fit apart for the reception of typhus, or contagious fever, are likewise established.

The country is indebted to Dr. Haygarth, formerly of Chitter, now of Bath, (1809,) for the foundation of these admirable institutions. It had been observed by Dr. Lind of the Hallar hospital, that the infectious distance of common contagious fever was small; or, in other words, that the effluvia from the bodies of persons labouring under typhus were incapable of infecting those in health, at a greater distance than a few feet, and that in a pure atmosphere, or well ventilated room, the effluvia were so much diluted and weakened, as to be no longer capable of communicating the disease. Hence the inference, which Dr. Haygarth proved by the test of experiment, that by separating those persons, labouring and contagious fever, from others in the same hospital, or by appropriating wards to this disease, the contagion might be prevented from spreading in the crowded receptacles of the sick; and fecondly, that by having each wards, or separate hospitals, for the reception of fever, constantly open for the admittance of patients, especially in crowded towns, or in epidemic feasons, whole families might be at once recovered from the contagion by the removal of the first person infected into them; and that thus the contagion of typhus might be exterminated. Upon this principle, such fever-wards were erected in the hospital at Chitter, and in that of Liverpool, and as frequently separate hospitals have been established in many of the large towns in England and Ireland; first at Manchester, then at Cork, Waterford, Dublin, Leeds, London, &c. These were happily named, we believe by Dr. Ferrar of Manchester, "Houfes of Recovery;" a denomination conveying the fignification of the word, and that by which they are now generally designated. These Institutions are not only calculated to preserve the crowded population of large towns from the fatal effects of epidemic fever, but to diffuse the maxims of cleanliness and ventilation, which are inculcated in the habits of the poor, whence patients are removed; and also to dispel those false and pernicious notions, respecting the general diffusion of contagion in the air, which are too widely prevalent even among the unlearned part, i.e. the majority of the profession, who, by the aid of the principal upon which these institutions have been founded, as well as the successful result of their practice, and the regulations under which they are conducted. (See also Contagion.) Haygarth on the small-pox, and his Letter to Dr. Pecial respeaking the suppression of contagion. — An excellent Collection of Papers on the subject of a similar establishment at Newcastle. Also Dr. Ferrar's Med. Histories and Reflections. The Reports of the Houfe of Recovery at Dublin, Cork, London, &c.

Fever, in the Veterinary Science, is a disorder to which horses are very subject from a variety of causes. The symptoms which denote the horse to be afflicted with a fever are very red eyes, by reason of which he ranges from one
end of the rack to another, beating of the flanks, redness and inflammation of the eyes; a parched and dry tongue; his breath is hot, and of a burning freck; heoles his appetite, and nibles his hay without chewing it, and frequently flinches to the ground; he dung often, but little at a time; and his dung is usually hard, and in small pieces; he sometimes flares with difficulty, and his urine is highly coloured; he is always craving for water, and drinks often, but little at a time; and his pulle beats full and hard, fifty strokes and more in a minute. The first part of the case is bleeding; and the quantity, if the horse is strong and in good condition, should be two or three quarts; then give him four times a day a pint of the following infusion: take, baum, fage, and camomile flowers, each a handful; an ounce of liquorice root, sliced; and, three ounces of nitre; and pour on these ingredients two quarts of boiling water; when cold, strain it off, and squeeze into it the juice of two or three lemons, and sweeten it with honey; or an ounce of nitre mixed into a ball with honey may be given thrice a day instead of the drink, and washed down with any small liquor. The horse’s diet should be scalded bran in small quantities, or dry bran sprinkled with water, or a handful of picked hay may be put into his muck. His water should be a little warmed, and given to him often and in small quantities; his covering should be moderate. If the horse refuses to feed, in a day or two more blood should be taken away, and the drinks continued, to which may be added two or three drams of affiron. If his dung continues hard and knotty, a cypher may be given, prepared by boiling two handfuls of marshmallows, one of camomile flowers, and an ounce of fennel feed, in three quarts of water; fill it to reduce to two, and adding to the strained liquor four ounces of treacle and a pint of linseed oil or any common oil. This cypher should be repeated every other day; and on the intermediate day the following drink may be given: take of cream of tartar and of Glaner’s salts, of each four ounces; dilute them in barley-water, and add an ounce or two of lenitive, diet, or a dram or two of powder of japh. By pursuing this treatment the horse will begin to recover; and nothing more will be found necessary than to give him gentle exercise in the air, and plenty of clean and fresh air. All fever to which horses are subject, more dangerous than the former: this is a low fever attended with great depression; the horse is sometimes inwardly hot and outwardly cold, and at other times hot all over: his eyes appear moist and languid; his mouth is continually moist, so that he has no inclination to drink, and he is satisfied with very little. He eats little, moves his jaws in a feeble loofe manner, and grates his teeth; his body is commonly open, his dung loof and moist; his flaking irregular, sometimes little, and at other times profuse, and his urine pale, with little or no sediment. These fevers are attended with a running at the nose, and the matter discharged is of a reddish or greenish dusky colour, and of a conhuent like glue. About three pints of blood should be first taken away, and bleeding repeated according to the strength and fulness of the horse, the degree of his cough, or any tendency to inflammation. After this the nitre drink already prescribed may be given, with the addition of an ounce of snakeroot, and three drams of affiron and camphor dissolved in a little spirit of wine. The horse’s diet should be fedded or sprinkled bran, and the best hay, with which he should be fed by hand, as he sometimes cannot lift up his head to the rack. Drinking plentifully will greatly contribute to dilute the blood; but if the fever should increase, balls of contrayerva root, myrrh, and snake-root, powdered, of each two drams; affiron, one dram; mithridate or Venice treacle, half an ounce, mixed with honey, should be immediately given twice or thrice a day, with two or three hours of infusion of snake root sweetened with honey; to a pint and a half of which may be added half a pint of treacle water or vinegar; if these fail produce no sensible effect, let a dram of camphor or calomel be added to each of them; or the following drink may be substituted in their stead for some days: take a dram of camphor dissolved in one ounce of rectified spirit of wine; then gradually pour on a pint of diluted vinegar warmed, and give it at two doses. If the horse should be coltive, recourse must be had to emulsions or the opening drink; and if he purge to a considerable degree, diazordium may be added to his drinks instead of the mithridate. The operation of medicines in this disease is much promoted by plentiful drinking; the horse’s faeces should be restrained when it is considerable and weakening, by proper astringents, or by mixing hine-water with his drinks; and when he is remits in this respect, and faeces do little as to occasion a feeling of his body and legs, two or three of the following balls may be given at intervals, with a decoction of marshmallows sweetened with honey: take of sal prunella or nitre, one ounce; juniper-berries and Venice turpentine, of each half an ounce; and make these ingredients into a ball with oil of amber. If with this treatment the horse’s skin feels kindly, his ears and feet are moderately warm, his eyes brisk and lively, his nose becomes clean and dry, his appetite increaseth, he lies down well, and faeces and dungs regularly, there is a fair prospect of a speedy recovery; but he should be fed sparingly, and his diet should be light, and increased by degrees as he gains strength. If the fever should interrupt, give an ounce of Jesuit’s bark in the interval of the fits, and repeat it every six hours till the horse has taken four or fix ounces. (Bartlet’s Farrier’s Dictionary.)

Mr. White, in his “Compendium of the Veterinary Art,” distinguishes only two kinds of fever, the one, an idiopathic or original disease, and termed simple; the other dependent upon external inflammation, and usually denominated fever, or inflammatory fever. The former does not occur so frequently as the latter, nor is it by any means so formidable in its appearance. The symptoms are obvious, succeeded by loss of appetite, dispeased appearance, quick pulse, hot mouth, and some degree of debility; the horse is generally coticile, and voids his urine with difficulty. The disease is also often accompanied with quickness of breathing, and in a few cases with pain in the bowels, or symptoms of colic. As soon as a horse is attacked with this disease, Mr. White advices, that he should be tied freely; and in case of colicines, to give a pint of castor oil, or the oil of olives, and to inject a cypher of water grauel. The following drink he has found to be a very useful laxative; take of Barbadoes aloes powdered, 3 drams, prepared kali 1/2 dram, castor oil 3 oz to 6 oz. simple mint-water and pure water, of each, 4 oz; these ingredients should be mixed and will serve for one dose. After the operation of the laxative, the fever powder is to be given once in twelve hours, and continued until it has produced considerable diuretic effect. Mr. White has given several formules for preparing this powder, e.g. 1. Powdered nitre, 1 oz. and camphor, and tartarized antimony, of each, 2 drams; or 2. Powdered nitre, 1 oz. and unwhisked cals of antimony, 2 drams; or 3. Antimonial powder, 3 drams, and camphor, 1 dram; either of these to be mixed for one dose. Warm water and mallow are to be administered frequently in small quantities,
FEVER.

warm clothing, frequent hand-rubbing, and a liberal allowance of water are also necessary. And when the fever runs high, it is advisable to infest rowsels about the chest and belly, in order to prevent the recurrence of internal inflammation. When the difeafe appears to be going off, the horfe-looking more lively and active, let him be led out for a short time in some warm situation, and give now and then a malt mash for recovering his strength.

The symptomatic fever is generally occasioned by high feeding, clove flables, and want of proper exercise; in some cases it is caused by a sudden transition from a cold to a hot temperature. This kind of fever is not preceded by shivering, like the simple fever; nor is it to sudden in its attacks, except when it is occasioned by great and long continued exertion. In this case the complaint affin a very dangerous appearance in its earliest stage. The symptoms which this fever has in common with the simple fever, are loss of appetite, quick pulse, dejected appearance, hot mouth, and debility; and if to these be joined difficulty of breathing, and quick working of the flanks, with colicnes of the legs and ears, the caufe of it may be concluded to be an inflammation of the lungs. If the horfe hang down his head in the manger, or lean back upon his collar with the appearance of drowsiness, the eyes appearing watery and inflamed, it is probable that the fever depends upon an accumulation of blood in the vessels of the brain, and that the flaggers are approaching; in this case, however, the pulse is not always quickened, but sometimes has been found unusually slow. When the symptoms of fever are joined with a yellowness of the eyes and mouth, an inflammation of the liver is indicated. If an inflammation of the bowels be the cause, the horfe is violently gripped. An inflammation of the kidneys will also produce fever, and is distinguished by a profusion of urine, and an inability to bear pressure upon the loins. When the fever arises from inflammation of the bladder, the horfe is frequently flaking, voiding only very small quantities of urine, with considerable pain. Extensive wounds, and particularly those of joints, will also produce symptomatic fever. In all cases of this kind, the effential remedies are copious and early bleeding, with rowels and blisters. (See INFLAMMATION.) In cases of symptomatic fever it will generally be necessary to take away four or five quarts of blood at the first bleeding; and even six quarts have been taken away with manifest advantage.

Some modern writers on farriery have described another kind of fever, termed putrid or typhus, in which bleeding is extremely injurious. On this subject Mr. White makes the following observations. The grand characteristic of fever he conceives to be an unusually quick pulse, i.e. from seventy to one hundred in a minute; a peculiar kind of sensation which it gives to the finger, as if it were frizzed sharply by the vibration of a cord; and at the same time a feebleness, or smallness, quite different from the gradual swell of the healthy pulse. When a horfe labours under considerable debility, either from hard work, want of sufficient food, or other causes, except fever, the pulse is more or less languid or weak, sometimes flower, and sometimes a little quicker than usual; nevertheless, it swells gradually, and does not give that sensation which physicists term "hardness," and which has been already described. Simple debility, or weakness, is distinguished from fever by other circumstances: the mouth and tongue are in their natural state; the horfe readily sweats; and when the weakness is considerable, the ears and hind legs will feel rather cold, and its flanks generally move quicker than usual. If blood be drawn, it will be found very different from that of a horfe labouring under fever or inflammation. Though bleeding in such cases is extremely injurious, a mild laxative is useful, unless the dung be fetter, and is more copious than natural; and if there be a deficiency of urine, or any difficulty in voiding it, a diuretic, composed of camphor and nitre, should be given. After the laxative, tonics, with a nutritious diet, and good grooming or nursing, generally restore the animal in a short time to health. This disease is sometimes mistaken for fever, and treated improperly. Several cases have occurred where debility succeeded the inflammatory commencement, and rendered bleeding, and sometimes purging also, highly improper; and perhaps, says Mr. White, such cases have been mistaken by some writers for the typhus, or low putrid fever; or others may have copied their description of it from that given by authors on human diseases. In cases of simple debility, the following medicines have been found very beneficial, giving the laxative in the first place, if the horfe be colicive, or even if the bowels be in a natural state; during its operation, however, it is advisable to give strong gruel instead of bran mashes. The laxative is prepared by mixing, for one draught, Barbades sloes, 3 dr.; powdered canella, 1 3/4 dr.; prepared kali, 1 dr.; and mint-water, 8 oz. The tonic is composed of yellow Peruvian bark, 6 dr.; cafevalla, 1 dr.; powdered opium, 5/4 dr.; prepared kali, 1 fer.; with syrup enough to form a ball for a dose. It is often found necessary to increase the proportion of bark, and sometimes of the other ingredients; but when the horfe becomes colicive, the opium must be omitted, the most proper food on these occasions is good sweet oats, and the beet hay, given frequently in small quantities. The horfe should be allowed to drink frequently, and his exercise should be very moderate. If he become colicive, a Clyder, or even a mild laxative, may be given.

Fever, Epidemic, or Diaphemor of Horfes, generally appears in the form of a violent catarrh, or cold; the first symptoms are cough, heaviness of the head, the eyes often watery, or a little inflamed; sometimes there is a quickness of breathing; and the inflammation of the membrane which lines the nose, throat, and windpipe, is often so considerable as to cause a difficulty in swallowing; and the pulse is generally quicker than usual. Without resorting to the proper remedies, weakness ensues, and considerable fever takes place; the appetite goes off; the cough and quickness of breathing increase, and debility is so great, that the animal flaggers in his walk. The lofe discharges offensive matter; and after lingering for some time, the horfe dies from a consumption.

When an epidemic happens, horfes should be carefully watched; and on the first appearance of any symptoms of the disease, the animal should be bled moderately, unless he is in low condition, or previously exercised by hard work, old age, or unwholesome food. After bleeding, give the following laxative, viz. Barbades sloes, 2 dr.; tartarized antimony, 1 dr.; milk mixed with quantities of warm water, and then add 4 oz. of sallo oil; the whole to be given as a dose; let the horfe's diet consist of bran mashes, sweet hay, and a very small quantity of oats. A relapse should be prevented by good nursing, and giving every day a dose of some antimonial preparation, of which, that which resembles Dr. James's fever powder is the best. But when the inflammatory symptoms are at first violent, when there is a quickness of breathing, f oreness of the throat, and disflecting cough, a blister to the throat is necessary; and unless weakness forbids, bleeding even to three quarts is proper. A laxative is always beneficial at first, if the bowels be not too open; after which, the antimonial with nitre is to be given daily. Warm clothing, and freq
quent hand-rubbing to the legs, are useful; but a close
stable is injurious. "The hort should be turned loose into a
large flail; and if a discharge from the nose appear, let it
be encouraged by causing the vapour of warm water to pass
through the nostrils, and caressing the head and ears.
When the disease, from being neglected, or improperly
borne and treated at first, becomes alarming, and the weakness is con-
iderable, nothing but tonic medicines and a nutritious diet
can do any good.

Fever, in Myology, one of the Roman divinities, who
had a temple on Mount Palatine, mentioned by Cicero.
Valerian Maximus says that the bad doctors, into which they carried
the remedies used in diseases. On one monument
she is called the "Holy Fever."

Fever-Root, in Botany. See Trigostemum.
Fever-Weed. See Eryngium.
Feverfew. See Matricaria.
Feverfew, Bogard. See Parthenium.
Feverfew, in the Materia Medica, the parthenium of
Dioccorides, has been very generally employed since his
time for medical purposes. In natural affinity it ranks
with camomile and tansy, and its febrile qualities shew it to be
nearly allied to them in its medicinal character. According
in Berrias its virtues are tonic, homoeopathic, and emmenagogue. It has been given successfully as a vermi-
fuge, and for the cure of intermittent; but its use is most
celebrated in female disorders, especially in hysteria; whence it is
supposed to have derived the name "Matricaria."
Its small, tall, and analysis prove it to be a medicine of
considerable activity: so that we may lay with Murray,
"Rarius hodie preferibitrum quam debetur."

The leaves and flowers communicate by inflaion their
strong smell and bitter taste to water and rectified spirit.
The watery infusions, infilipent, leave an extract of con-
siderable bitterness, and which also discovers the saline matter
both to the talse and by throwing up to the surface small
crystalline efflorescences in keeping: the peculiar flavour of
the matricaria exudes in the evaporation, and impregnates
the diffusid water, on which also a quantity of effluent oil is
found floating. The quantity of spirituous extract, accor-
ding to Cuthener's experiment, is only about 4th the weight of
the dry leaves, whereas the watery extract amounts to
near one-half. Lewis Woodsill.

Feversham, in Geography. See Faversham.
Feugerolles, a town of France, in the depart-
ment of the Rhône and Loire; 5 miles S. of St. Etienne.
Feulliens, in Ecclesiastical History, an order of
religious clothed in white, and going bare-foot, who live
under the strict observance of the rules of St. Bernard.

The name was occasioned by a reform of the order of
Bernardus, first made in the abbey of Feulliens, a village
in France, five leagues distant from Thoulouze, by the four
Barrières, who established it about the year 1530.
It was approved of by pope Sixtus V. and the popes
Clement VIII. and Paul V. granted it its particular
fipers. King Henry II. founded a convent of Feulliens in
the Taubersack St. Honoré at Paris in 1587.

There are also convents of nuns who follow the same re-
form, called Feullienses: the first of which was established
near Thoulouze in 1590.

Feuille de Siv, in Heraldry, expresses that an
ordinary, as a fesse, pale, or the like, is indicated only on
one side; because it then looks like the leaf of a tree, as
the French phrase imports.

Feuillage, literally named by Linnaeus in honour
Schreb. 690. Julii 397. (Nandiroba; Plum. Gen. t. 27.)

Class and order, Diocese Pentandria. Nat. Ord. Cer-
trifolium? Jaff.

Gen. Ch. Male, Cal. Perianth of one leaf, bell-shaped,
rounded at the base, spreading in the upper part, cut half way
down into five segments. Cor. of one petal, wheel-shaped;
limb cut half way down into five convex, rounded seg-
ments; the centre closed with a double flar, whole rays
are alternately longer and shorter, regarding the course of the
fun. Stami. Filaments five, awl-shaped; anthers two-
loiced, roundish. There are five compreessed incurved fil-
ments, ranged alternately with the stamens.

Female, Cal. Perianth in the male, but with the ger-
men at its base. Cor. as in the male; the central flar fur-
nished with five heart-shaped plates. Pet. Germin inferior;
styles five, thread-shaped; stigmas heart-shaped. Peric. Berry
very large, ovate, obtuse, three-celled, with a woody
coat, encompassed by the calyx. Seeds several, orbicular,
compreessed, oblique.

Stamens five, with five alternate barren filaments.
Female, Cal. and Cor. as in the male. Styles three.
Berry hard, three-celled. Seeds orbicular.

Obl. The above characters, copied from Linnaeus, ap-
pear to have been taken by him entirely from Plumier's
figure; except that the division of the fruit was partly
broadened from Maregrave. We have seen the seeds, sent
from Jamaica by the name of Antidote Cocoon, which app-
ellation is mentioned in Browne's Jamaica, p. 374; and as
they agree with Plumier's figure above quoted, we are so
far right as to the genus.

With regard to the species, whether one or two, they are
to be known from Plumier and Maregrave only.

200. "Leaves heart-shaped, angular." (Nandiroba
faendana, foliis hederaceis angulis; Plum. Gen. 20.)
Native of the West Indies, or South America. Stem
climbing, ferrowed. Leaves alternate, stalked, heart-
shaped, acute, with three or five flat angles, entire,
smooth on both sides, reticulated with numerous veins,
dark green above, rather paler beneath. Stipulas none.
Tendrils spiral, foliary, simple; short as long as the
leaves. Flower-forks axillary, either with respect to
the leaves or the tendrils, compound, alternately branched,
nearly serrated. One described was, from Plumier's
figure, multifid by a leaf gathered by himself.

210. "Leaves with three (or five) lobes." (Gandh-
iroba, vel Nandiroba Brasiliensis; Maregr. Brasil. 46, cum
Sloane Jam. v. 200.) Native of Brazil and Jamaica, in
woods and hedges. This appears to differ from the
former chiefly in the form of its leaves, which are deeply
three-lobed, the lateral lobes being moreover generally
elngated at the base into two other shorter more obtuse
lobes. In colour, texture, and habit, they appear, by an
original specimn, to agree precisely with the former. The
infloruscence is so different in Plumier's, t. 210, that we
apprehend some mistake. It there consists of a few foliary
flowers, from the bosoms of small leaves on a lateral branch.
Yet this is not altogether dissimilar to Maregrave's figure.

Linnaeus seems to have been led by Browne to unite the
two in Sp. Pl. ed. 2., by the name of F. indicans; but he
together separated them in his Syll. Veg. He very errone-
only confounded with the latter his own Triosteum parvifolium, Sp. Pl. 1332, as well as the Triosteum of
Browne's Jamaica, 354, two plants unlike each other as
they are to either of the Feuillées. As great a mistake exists
in his son's herbarium, where, under the name of F. triloba,
FEV

is found the Medsska of Rheed Hort. Malab. v. 8. 35. t. 20. This belongs to a genus hitherto not defined by flemmatic botanists, though mentioned by Julieu, for future consideration, under Peffifora. Linnaeus in his second Monitoria, 336, strangely confounds it with Convolvulus paniculatus. We have a species or variety of Modsska from Sierra Leone, gathered and ascertained by Dr. Afzelius, which flowered in September 1793, in the flower of the Lady Amelia Hunt, where we gathered and fully described it. This very plant, which was a male, bore some simple heart-shaped leaves, like those of Oreismodsska, Hort. Malab. t. 23, with others that were variously lobed, mostly three-lobed, like t. 20. See also t. 21. Such a variation, in a plant so much allied in natural affinity to Feuillea, may justify the union of its two supposed species into one. S.

FEUILLÈE, Louis, in Biography, a Franciscan friar, of the order of minims, celebrated as a botanist and natural philosopher, was born at Marseilles, in 1762. He travelled to the western coast of South America, investigating the natural productions of New Spain and the neighbouring islands, from the year 1793 to 1797. He had previously visited Carthagena, and the island of Martinique, in 1793 and 1794. There, with several other voyages, the number and course of which are not exactly recorded, he accomplished under the patronage of Louis XIV. by whom he was patronized and greatly encouraged. The king caused an observatory to be built for him at Marseilles, in which town Feuille, wore out his labours, died in 1732, aged 72. He is said to have been of that modest simple character, which belied an ecclesiastical and a true philosopher. Nevertheless, he was excited to a considerable degree of resentment against Montfieur Prezier, a rival philosoper and naturalist, sent out likewise by Louis XIV., whom he denounces at some length, in a rather contemptuous style, in the preface to the Journal of one of his voyages.

Feuille published "Journal des Observations physiques, mathematiques, & botaniques, faicts par l'ordre du Roi, sur les côtes orientales (occidentales) de l'Amerique meridionale, & dans les Indes occidentales, depuis l'année 1707 jusques en 1712," Paris 1714, in two vols. 4to. with numerous plates. This is a circumstantial and exact work, written with no elegance of style, but valuable for solid information upon all the subjects announced in its title, with various incidental matter besides. What relates to Peru makes a principal part of these volumes. The descriptions of plants occupy 62 pages at the end of the second, accompanied by 50 very tolerable plates, in which Linnaeus confided for his definitions of several species, without seeing specimens, a measure he rarely adopted. But it does not appear that Feuille was one of those writers who, having been found to have misled him, cauised him, in the preface to his Species Plantarum, to declare against that practice in future, "non vidas plantas hinc obtine, tutas chibas ab autenteribus." The reputed medical virtues of the plants met with laudable attention from Feuille, and are always added to his botanical descriptions. Haller remarks that he first published the genus Foppititis in this work, and he certainly describes some species still unknown to us, not only of that genus, but several others. (See Epipactis.) The magnificent Flori-pendio (Datura arbores) was here first made known to botanists.

He published another quarto volume, with a similar title, in 1735, in the preface to which he dedicates Prezier, as above-mentioned. The appendix, of 71 pages, with 50 plates, describes many extremely interesting plants of Chili, among which are the first described Cactœstis, the Sweet Potato, Convolvulus Batatas, whose flower is scarcely known but from this figure, the Buddlea globosa, now so common, as well as the equally common, but transcendentally elegant, Pelachia coccinea.

These 100 botanical plates were, according to Haller, published at Nuremberg in 1756 and 1757, in two vols. 4to., with a German translation of their descriptions.

The original drawings of Feuille, many of which were never published, remain in the Bibliothèque Nationale at Paris. They are very rudely coloured, and without any pretensions to the skill of a painter. Whatever merit of that kind, flight as it is, can be discerned in his plate, is entirely owing to the engraver. S.

FEUILLE, in Geography, a town of France, in the department of the Lower Saône: eight miles W. of Grenay.

FEUILLON, a town of Germany, in the principality of Culmbach: 16 miles S.E. of Culmbach.

FEUQUIERES, Anthony de Pas, Margueris, in Biography, was descended from a family distinguished in arms and born in 1648. He, following the steps of his ancestors, became noted for acts of heroism and military prowess. His conduct in the campaign in Germany, in 1668, obtained for him the rank of marshal-de-camp. For the part which he took in several actions in Piedmont, he rose, in 1693, to the rank of lieutenant-general. This was the highest promotion he obtained; and he felt most fervently the flight put on him, as he thought, impeding him whenever others were appointed marshals of France. He became the enemy of all contemporary commanders, whose conduct was rigidly scrutinized by Feuquiers. He discovered, and enumerated, twelve capital blunders which the French generals had committed at Blenheim. He published the results of his enquiries and criticisms on the generals employed by Lewis XIV., in a work entitled "Memoirs." This volume has a good reputation for cleverness of style; for the freedom of its representations, and for the depth and facility of its remarks. He died in 1711, having a few hours before his death written a letter to the king, in which, with great feeling, he recommended to his majesty's favour his only son, as innocent of what had made him unfortunate, and born of a race which had always faithfully served their king. Gen. Biog.

FEUQUIERES, in Geography, a town of France, in the department of the Oise; eight miles W. of Granvilliers.

FEUERDON, Justin, in Biography, who flourished in the 17th century, was brought up to the profession of the law, which he soon relinquished for the study of theology and the belles lettres. He obtained several respectable situations, till at length, on the death of Pelivin, in 1617, he was made professor of divinity at Guise, of which town he was already the pastor of the church. In 1629 he was nominated preacher to the court by the Landgraviess George; and in the following year he received still higher preferment at Guise. After this, his high reputation secured for him invitations from other places, but he preferred staying the remainder of his days at Guise, where he died in the year 1655. He was author of many theological works which are enumerated by Moret and others.

FEVRE, Guy de, was born in 1541, at the family seat of La Boderie, in Lower Normandy, whence he obtained the title of "Seigneur de la Boderie." It has been reported, from the bent of his studies, that he was intended for the ecclesiastical profession. He was a diligent student in the oriental languages, and had, in after life, a large share in the compendium
FEV

FEV

fition of the Polyglott of Antwerp, of which Arias Montanus was the chief director. He complains that neither himself, nor his brother Nicholas, who had likewise a share in the same work, was properly remunerated for their labour. On his return to France he was made secretary and leguill to the duke of Alençon, who was likewise deficient in the principle of gratitude. He died on his estate at La Boderie in 1598, leaving behind him various works relative to the Syriac, Chaldæan, and other oriental languages. He translated a treatise on baptism, written by Severus, patriarch of Alexandria; and wrote some poetical pieces, by which he acquired considerable reputation among his contemporaries. His brother Anthony, born about 1555, was sometime Charge des affaires for Henry IV. at the court of Rome, and afterwards ambassador extraordinary in England, and when he left that country he received singular marks of friendship from King James and several of the nobility. An account of his negotiations, in letters written by him to the ministers, and their replies, were published 15 vols. 12mo. under the title of "Ambassadeurs de M. de la Boderie en Angleterre sous le Règne de Henry IV. et la minorité de Louis XIII."

FEVRE, of Fevre, James de, who flourished in the 16th and 17th centuries, was born at Etupes. He was of low extraction, but polished vigorous mental powers, which he improved by a diligent application to the different branches of useful and ornamental learning. He pursued his studies in the university of Paris, where he afterwards took the degree of doctor, and delivered lectures to numerous pupils in the belles lettres and philosophy. The system which he taught, or rather his opposition to old and long established theories, exposed him to the jealousy of ignorant sciolists, by whom he was accused of being friendly to Lutheranism. He was obliged to leave Paris, and, on the invitation of William Brigg and Bishop of Mener, he took refuge in the family of that worthy ecclesiastic, who was obliged, in a short time, for the sake of his own peace, and that of his family, to withdraw the protection of which Fevre so much cried in need. He was now abandoned to the wide world, and fled to Blois, thence to Guiscraine, about which time he was degraded from the doctor's degree, by the faculty of the Sorbonne. Not content with this, his enemies induced the parliament of Paris to order a process to be carried on against him; from the effects of which he was timely delivered by an order from the sovereign Francis I., who forbade them to come to any resolution against Le Fevre without his intervention. Margaret, sister to the king, and herself queen of Navarre, took the persecuted man under her protection, and honoured him with her confidence and esteem during the remainder of his life. By her authority he went to Strauburg to confer with Bucer and Capito, respecting a reformation in the church; it does not, however, appear that he was prepared to go far into the business of reformation. He continued, by profession at least, attached to the church of Rome till his death in 1557. But towards the close of life he felt unaccustomed at not having been more bold in the cause of truth. While at dinner with his patroness, the queen of Navarre, and in a company of learned men, he was observed, in the midst of the entertainment, to burst into tears, and, in explanation, he declared that his confidence accused him of being highly criminal, in having known the truth, and taught it to others, who had sealed it with their blood, and yet shrank from his duty in avowing it, and timidly taken refuge in a place of security, far from the scenes where the crowns of martyrdom were distributed. The queen endeavoured to console him, but probably without much effect; he felt that he had not done all that he might and ought to have done, and was come to that point of time in which self-deception could no longer avail. This declaration seemed to give ease to his labouring mind; he made some arrangements with regard to his property, and almost immediately expired. Le Fevre published various works that display much solid erudition, and great critical skill; and if the opinion of Simon be of weight, he is to be ranked with the best commentators of his age. His translation of the New Testament into French is highly esteemed, and is now very scarce. Le Fevre once involved himself in a contesl with Erasmus, by treating his notes on the New Testament with undue severity, and even charging the author with intentionally corrupting the scriptures, and advancing impurities. Erasmus vindicated his conduct in the most satisfactory manner, and freely forgave his antagonist, affuring him that he should, notwithstanding what had happened, continue to respect him. Such liberal conduct on the part of Erasmus produced the happiest effect on Le Fevre, who sincerely repented of his having attacked Erasmus; and "they continued," says the learned and candid Jortin, "to speak of each other with great respect and esteem;" hence, he infers, that "it would be happy if wrangling geniuses would copy from their example, and consider a little how all men of fene and manners applied such moderation, and how they abhor and despise those, who having begun on quarrel, perhaps upon mere babbles, never end their contentes and animosities, till death comes and puts them to silence." Bayle. Moreri. Jortin.

FEVRE, TANNEQUIX LE, was born at Caen in the year 165. He received a private education, and then finished his studies at the college of La Fleche, where he distinguished himself. At Paris he obtained the patronage of cardinal Richelieu, who procured him a pension of 2000 livres, as inspector of the works printed at the Louvre. At the death of Richelieu he went to Langres, where he avowed himself a Protestant, and was invited to Saumur to the professorship of classical literature. His mode of instruction was so excellent that he had pupils from all parts. Voltaire, in speaking of him, affirms, that he deplored those of his feet, and lived among them more as a philosopher than a huguenot. He died in 1672, as he was preparing to quit Saumur for Heidelberg, whither he had been invited by the prince palatine. His works were translations of, and comments on, Greek and Latin authors; he published two volumes of "Letters," and Greek and Latin poems. He wrote Latin elegantly, though not without some Gallicisms. He was a man of strict probity and integrity, of which he gave proof by dedicating a work to Pelisson while a state prisoner. Moreri.

FEVRE, CLAUDE LE, a painter, a native of France, born in 163. He principally painted portraits, but he likewise attempted flowers, and even historical subjects, but not with so great success. He came to London, where he met with much encouragement for several years, and there he died in 1675.

FEURS, FORUM SECUSIANORUM, in Geography, a town of France, in the department of the Loire, and chief place of a canton in the district of Montbrison; 25 miles W. of Lyons. The place contains 1,756, and the canton 14,016 inhabitants, on a territory of 250 kilometres, in 18 communes. About a league from this town, at the foot of a rock, called Dinzy, is a mineral spring, of a fulphureous quality.

FEUTSKING, JOHN HENRY, in Biography, was born in the duchy of Holstein in the year 1672. Having acquired a good stock of elementary knowledge, he went to Röstock
Rollock to Rady philosophy and theology, and from thence he removed to Wittenberg, where he was created doctor in philosophy, in the year 1692. Here he acquired much reputation, and was appointed professor and perpetual-ant of the diocese of Jaffa in the year 1697. In the following year he was admitted to the degree of doctor in divinity. He obtained several offices, and at length became pastor of the church of St. Bartholomew at Zerbil, preached to the court, and ecclesiastical councillor, and perpetual-ant of the diocese of Zerbil, in Amhdt, by the prince of that name. In the year 1709 he undertook the offices of professor of divinity, and afeedor of the ecclesiastical consistory of that city. At the same time he preached once a week before the electors of Saxony, and was honoured with the post of ecclesiastical councillor to the duke of Saxo-Gotha. His last appointment was that of con-
feedor to the electors of Saxony, in 1712, an office that he enjoyed but a few months, as he died in 1713, when only 41 years of age. His works, which are very numerous, are chiefly on theological subjects. They are enumerated by Mereni, who may be referred to by the curious.

FEY, in Geography, a barony of the county of Armagh, Ireland, with a village of the same name. The south and west parts of this barony are full of mountains. The soil of these mountains is much inclined to gralls, which is less coarse than that usually met with on mountain ground, so that the cattle have always full pasture, except in time of continued snow. The grass-farms are large and extensive; and there is also much tillage in this district. The Fevs abound with whins or gorse (ulex Europæus), ferns, and those plants which flourish in a warm foil. There is no limestone in the district, but either a brittle and decayed freestone with a ferruginous tinge, or a hard stone found in large blocks, which is called whinstone, but which differs from other stones called by that name. Coote's Armagh.

FEY, in Rural Economy, is a term which signifies the winnowing or cleaning of grain by means of the natural wind. It likewise signifies the bed or stratum of earthy materials by which chalk, marl, and other similar substances are covered, and which must be removed before the workmen can come at them. This sort of labour is consequently termed feyng, and is usually paid for by measure, according to the difference in depth. In both chalk and marl pits they are considered the more valuable the less the fey.

Fey is also in some districts applied to the cleaning and digging out of ponds and wells.

FEYDANY, in Geography, a town of Samogitia; 16 miles S.S.W. of Miedaki.

FEYDEAU, Matthew, in Biography, was born at Paris in the year 1616. He pursued his studies in the college of the Sorbonne, and so conducted himself in that place as to obtain the esteem of persons of all ranks. In the year 1645, he was engaged by M. de Bellegarde, archbishop of Seins, to deliver a course of instructions to the candidates for holy orders in his diocese. He obtained some preeminent in the church, and composed several useful books, among which was one entitled A Catechism on Grace, which was afterwards reprinted with the title of Illustrations of certain Difficulties respecting Grace. This work was con-
demned by a decree of the inquisition at Rome, which M. Fouquet, attorney-general of the parliament at Paris, would not permit to be promulgated in that city. In 1656, M. Fey-
dau was one of the seventy-two doctors who were expelled by the faculty of the Sorbonne, for refusing to subscribe to the condemnation of M. Arnauld, and on this account he was obliged to relinquish his church preferment. After this, for several years, he lived chiefly in retirement, and produced his Reflections on the History and Harmony of the Gospels, in 2 vols. 12mo; a work which has gone through several editions. In 1665, he was preferred by the bishop of Aheth with a prebend in his diocese; this he resigned in 1668, in order to undertake the cure of Vitré le Frangis, in Champagne. Here he officiated seven years, and was then obliged to give up his congregation in consequence of the persecutions with which his party was harassed, being bannied by a lettre de cachet to Bourges in 1677: and by another process he was sent to Annonay in the Vivarès, where he died in July 1694, in the 75th year of his age. He published many works, and left behind him many others that have not yet appeared. A long Latin epitaph was engraved on his tomb, which is preferred by Mereri.

FEY-HIANG, in Geography, a town of China, of the third rank, in Po-chesi; 12 miles S.E. of Quang-ping.

FEYJOO, Benedict Jeron, in Biography, a learned physician of the order of St. Benedict, born in Spain, who died in the year 1765. By his writings many have thought that he contributed as much towards curing the mental diffi-
culties of his compatriots, and reforming the vicious taffes of his countrymen, by introducing liberal notions in medicine and philosophy: as the great Michel Cervantes had done those of a preceding age, by writing his immortal work, the in-
comparable history of Don Quixote. In the Teatro Critico, published in fourteen volumes, are many severe and cutting refutations against the ignorance of the monks, the licentiousness of the clergy, tedious privileges, abuse of pilgrimages, exorcisms, pretended miracles, &c. &c.; by which he made a formidable body of oracles. The confess-
or of truth, he would certainly have been also a martyr, had the numerous calls of vengeance been listened to by those in power. In a superstitious country like Spain, it was sufficient only to have praised such men as Bacon, a Def-
cartes, a Newton, &c. to incur the charge of heresy. The learned part of the nation, however, undertook his defence, and he cleared the grasp of the inquisition. And although in his writings he has demonstrated the uncertainty of the healing art, and the charlatany of many among its practitioners; yet the medical college at Seville conferred on him the degree of doctor, and honoured him with a seat at their board. Mr. Bourgoing observed, that Dr. Feyjoo, or Feijoo, was one of those writers who treated this conjectural art in the most rational manner. Tableau de l'Espagne.

FEYOE, in Geography, a small island of Denmark, a little to the north of Lolland. N. lat. 54° 57'. E. long. 11° 35'.

FEYREGG, a town of Austria; 8 miles W.S.W. of Steyr.

FEYSTRIZ, a town of Austria; 15 miles S.S.W. of Ebifinuth.

FEZ, a province of the empire of Morocco, in Africa, situated to the north of Tarifa and Shawana, and having to the west the provinces of Benzahafen and Garb, and mount Atlas to the east, and stretching to the north as far as the provinces of Shans, Rif, and Garet. This was formerly a kingdom of very great extent, and still its dependences are numerous and extensive, including several mountains, abounding in inhabitants, and well cultivated. According to Jackson, the district of Fez, exclusive of the cities or towns, contains 1,250,000 inhabitants. The kingdom of Fez has been united to Morocco, since it first became an independent sovereignty in the 15th century. Although a considerable part of this country has been, and at last to the west of Old Fez abound with marshes, which render the
FEZ

air unhospitable, and the people unhealthy; the soil is fertile, and produces, in the greatest abundance, corn, fruit, flax, fat, gum, wax, &c. and also oranges, lemons, figs, and olives. The mountains abound with game, and the forests with wild beasts. The lions of Fez are the most dangerous and savage of any in Africa; horses, camels, kine, sheep, goats, and hares, are very numerous. The principal exports from this province are hides and leather of all sorts, particularly that denominated Morocco, skins, furs, wool, dates, almonds, figs, raisins, olives, honey, wax, silk, cotton, flax, horses, olibrich-feathers, gold-dust, &c.

The imports chiefly consist in spice, cuchineal, vermilion, iron, brass, steel, iron, arms, ammunition, drugs, watches, small looking-glasses, quicksilver, tartar, opium, alum, aloes, English and other linen and woollen clothes, mohair, calicoes, fullers, gold wire, silk of all kinds, brocades, damasks, velvets, and woollen caps, toys and trinkets of all sorts, Guinea cowries, combs, paper, and a great variety of curiosities.

Fez, a city of Africa, and capital of the province of that name, was built, about the end of the eighth century, by Edris, the descendant of Mahomet, and Abi, whose father, flying from Medina to avoid the proscriptions of the caliph Abdullah, retired to the extremity of Africa, and was proclaimed sovereign of the Moors. Edris, succeeding to the crown of his father, founded the city of Fez, in 793, and built the mosque in which he is buried. From that time the city of Fez has been considered by the Moors as a sacred asylum, and an object of devotion. In the first moments of that zeal which every religious novelty inspires, a still larger mosque was built at Fez, and called "Caubum," because it was founded by the Arabs of Carthage. This is one of the finest edifices in the whole empire. Many other mosques were successively built at Fez, to which were annexed, according to the custom of the Mahometans, colleges and hospitals; and this city was held in so high a degree of veneration, that when the pilgrimage to Mecca was interrupted, in the fourth century of the Hegira, the western Mahometans, as a compunction, repaired to Fez, while the eastern journeyed to Jerusalem. When the Arabs had extended themselves in Asia, Africa, and Europe, they brought to Fez the knowledge they had acquired in the arts and sciences; and, to the religious schools, this capital added academies, for philosophy, physick, and astronomy. Fez, referred to as almost all Africa, and the object of the devout pilgrimages of the Mahometans, soon became the rendezvous of the neighbouring provinces. The increase of wealth produced the love of palaces, and every species of luxury; licentiousness quickly followed; and as its progress in hot countries is always more rapid, Fez, the school of sciences and manners, soon became the seat of every vice. The public baths, which health, cleanliness, and custom render necessary, became the receptacle of the most infamous debauchery. The Mahometans of Andalusia, Grenada, and Cordova, during the revolutions of Spain, passed over to Fez, whether they brought new manners, knowledge, and, perhaps, some degrees of civilization. They taught the Spanish method of dressing and dying red and yellow gauze and silk skins, then called Cordova-weather, now Morocco, from the city of that name, where, however, the eye is kept in perfection. At Fez, likewise, they established the manufacture of milled woollen caps, worn by the Moors and eastern nations. Cozines, felt, silk, and beautiful fashions, were reared in gold and silver, are manufactured at Fez; and the little they do possess how much might be done, if usually were encouraged. Some love of learning is still preferred at Fez, where Arabic is better spoken than in the other parts of the empire. The rich Moors send their children to the schools at Fez, where they gain more instruction than they could do elsewhere.

The city of Fez contains some tolerably convenient inns; the freights are ill-paved, and so narrow that in many places two horsemen cannot ride abreast. Fez, though in times past it attracted the attention of travellers, is in no respect preferable to the other cities of the empire, except by its situation, schools, industry, and somewhat greater urbanity; yet, though more polished than their countrymen, the Moors of Fez are vain, superstitious, and intolerant. The faults, whom they pretend to have buried in that city, furnish a pretext for prohibiting Jews and Christians to enter it; and an order from the emperor is necessary to gain admission. The local situation of Fez is somewhat singular. It is seated at the bottom of a valley, and surrounded by hills in the form of a funnel, flattened at the narrow end. The upper part of the valley is divided into gardens, planted with high trees, orange groves, and orchards. A river, called Rifen, winds along the valley, watering it in various directions, turning by its streams a number of mills, and supplying water in abundance to all the gardens and most of the houses. On the height of Old Fez is a plain capable of great cultivation. Jacob-Ben-Abdallah, of the race of Beni-Merins, built in the 15th century, New Fez, contiguous to the Old, and, by its situation, keeping the latter in awe. The high town, which is fortunately situated, contains some old palaces, in which the sons of the emperor live. The new town is inhabited by some Moorish families, but, by a greater number of Jews, who trade with Old Fez, notwithstanding the contempt with which they are treated by the inhabitants; their gains, however, reconcile them to this contempt. Fez is about 200 miles N.N.E. of Morocco. Fez is said to have about 3000 inhabitants. N. lat. 33° 50'; W. long. 5° 20'. Chénevière's Morocco, vol i.

FEZZAN, a country of Africa, situated to the south of Tripoli, and 60 journies west of Cairo. Mr. Horneeman, a late traveller, sent out at the expense of the African association, a formus, that the greatest length of this cultivated part of this country is about 350 English miles from east to west, and the greatest width 200 miles from east to west; but the mountainous region of Haratish to the south and east to the south and west are reckoned within its territory. The borders of the north are Arabs, nominally dependent on Tripoli. Fezzan, to the east, is bounded by the Haratish and line of deserts; to the south and southeast is the country of the Tribbous, to the southeasterly point of the nomadic Tuaregs; on the west are Arabs. The kingdom contains 101 towns and villages, of which Mourzouk is the capital. The principal towns next in order to the imperial residence are Sougha, Sibba, and Wadon to the north, Gatron (or Kattoua) to the south, Yerma (or Jerma) to the west, and Zoua to the east. The climate is at sea level temperate and agreeable. During the summer the heat is intense, and when the wind blows from the south it is fiercelyupportable, even by the natives. The winter might be moderate, were it not for the prevalence of a black and penetrating north wind during that season of the year, and which chilled and drove to the shelter only to the people of the place; but, even myself, the native of a northern country. It rains at Fezzan seldom, and then but little in quantity. In January 1799, there were some lightnings without thunder. Tempests of wind are frequent both from the north and south. There is no rice or even violet defering notice throughout the whole country. The soil is a deep land covering calcareous rock.
or earth, sometimes a stratum of argillaceous substance. Dates may be termed the natural and staple produce of Fezzan. In the western parts some fennas is grown, of a quality superior to that imported from the country of the Tlibboos. Pot-herbs and garden vegetables are plentiful. Wheat and barley are sowed on the sandy soils, and even there few in number; they are employed in drawing water from the wells, and slaughtered only in cases of extreme necessity. The ordinary domestic animal is the goat. Sheep are bred in the southern parts of the kingdom, but the general supply is furnished by the bordering Arabs. The wool is manufactured into Abbis, or coarse woollen cloths, the general clothing throughout the country; with the meat the skins are roasted while fresh, and eaten. The horses are few; asses are the beasts of general use, whether for burden, draught, or carriage. Camels are exclusively dear, and kept only by the chief people, or richer merchants. All these animals are fed with dates, or date kernels. The commerce of Fezzan is considerable, but confined merely to foreign merchandise. From October to February Mourzouk is the great mart and place of resort for various caravans from Cairo, Bengui, Gourama, Tawat, and Soudan; and for other smaller troops of traders, Tiliboos, Turannuck, and Arabs. The caravans from the south bring slaves of both sexes, ostrich feathers, zibette, tiger skins, and gold. Iron from Bombay copper is imported in great quantities. Cairo silk, muslins, dyed and striped blue and white calicoes, woollen cloths, glass, imitations of coral, beads for bracelets, and East-India goods. The merchants of Bengui, who often join the caravans from Cairo at Angela, import tobacco, snuff, and fandery wares fabricated in Turkey. The caravans from Tripoli chiefly deal in paper, sable corals, fire-arms, fabrics, knives, cloths called abbes, and red worsted caps. Those trading from Gadames bring nearly the same articles. The smaller caravans of Turannuck and Arabs import butter, oil, salt, and corn; and those coming from the more southern districts bring linen, ollrache feathers, and camels for the slaughter house. Fezzan is governed by a sultan, descended from the family of the Sheriffs. The tradition is, that the ancestors of the reigning prince coming from western Africa, invaded and conquered Fezzan about 500 years past. The sultan reigns over his dominions with unlimited power; but he holds them tributary to the head of Tripoli. The amount of the tribute was formerly 6000 dollars; it is now reduced to 4000, and an officer of the bhadah comes annually to Mourzouk to receive this sum, or its value, in gold, jennas, or slaves. On his journey he takes travelling merchants under his protection. The throne is hereditary in the eldest prince of the royal family, whether nephew or son. The revenues are produced from a tax on gardens and cultivated lands, fines and requisitions, with a further income from duties on foreign trade; from domains of the crown, fish ponds, water lakes, &c. The public expenditure consists in the maintenance of the sultan, his court, and palace. The cadi and department of justice, the religious, and the great officers of government, are supported from the produce of date tree woods, and gardens set apart for that purpose. The dignity of cadi or judge, who is also chief of the clergy, is hereditary in a certain family. The population of Fezzan is loosely estimated at 75,000 or 75,000, all of whom, without exception, profess the Mahometan religion. The colour or complexion of the people varies; those of the northern parts have a complexion and features similar to those of the Arabs. In the southern districts they have mixed with the natives of the great nations bordering on that quarter, and bear a resemblance to the Tiliboos and the Turannuck. The genuine and indigenous race of Fezzanians may be discerned as a people of but ordinary stature, and their limbs by no means muscular or strong; their colour a deep brown, their hair black and short, their form of face such as in Europe we should term regular, and their nose left flattened than that of the negro. Their men, women, and children, abound in a want of energy either of mind or body. The tyranic government, the general poverty of the country, and their only food consisting of dates, or a kind of farmaceous pop, with no meat, and rarely with a little rauced oil or fat, sufficiently account for the abject state of the inhabitants. Throughout Mourzouk Mr. H. could not find one artificer skilful in any trade or work: indeed there are no other tradesmen but shoemakers and smiths. The latter work every metal without distinction; and the same man who forges shoes for the sultan’s horse, makes rings for his princecesses. The women manufacture woollen cloths solely by hand, as the weaver’s shuttle is unknown. The dreds consist of a shirt or frock, made of coarse linen or cotton cloth, brought from Cairo, and the abbe. The muddling claes wear frocks made in Soudan of dyed blue cloth. The richer people, and the Mandchakes of the sultan, are clothed in the Tripolitan habit, over which they wear a Soudan shirt of variegated pattern and colours, and likewise the abbe. The ornaments are chiefly confined to the head dreds, and rings on the arms and legs. The women are fond of dancing, and are wont to dance in their manners. The men are much addicted to drink and music. Their beverage is the fresh juice of the date tree, called lugabi, or a drink called buta, prepared likewise from dates. The houses are miserably contructed with fencs or bricks of a cucurceous earth mixed with clay, and dried in the sun. They are low, and the light enters by the door only. As to diet, says Mr. Horneman, I never knew a more abomnious people than those of Fezzan. Meat indeed is a food they can at no time abandon from, when let before them; but meat is not an article of food with the people in general. To indicate a rich man at Mourzouk, the usual expression is, “that he eats bread and meat every day.”

FEZZARA, a town of Egypt, on the W. branch of the Nile; 13 miles S. S. E. of Rosetta.

FI, a syllable in French notation, with which some musicians express / or, m., b. See Solmisation.

FIACONE, in Geography, a town of Genoa, on the coast of the Milanese, between Genoa and Toronta.

FIALSIO, a town of Sweden, in the province of Angermanland; 85 miles N. N. W. of Hannotal.

FI LEO, a town of Naples, in Abruzzo Ultra; nine miles S. of Terni.—Alio, a town of Italy, on the Tiber; 15 miles N. of Rome.

FIANONA, a sea-port town of Ipiri, with a good harbour; 36 miles S. E. of Treffe. N. lat. 45° 49'. E. long. 14° 18'.

FIANTS, or FOUNTS, the dung of a badger, fox, and other vermin.

FI R, in Rural Economy, a term applied, in the northern parts of the kingdom, to certain averaged returns of the prices of different sorts of grain, &c. In Earl Lothian, according to the agricultural survey of that district, from time immemorial, it has been the practice of it and the same.
F I A R.

some others to fix, by public authority, fair or average prices of each kind of grain sold within the county for ready money. In it the average is taken only of wheat, barley, oats, and peas, as these were formerly the staple produce of the country; but though at present a large quantity of beans are grown, no fair prices of them have ever been struck. In performing the business, the sheriff of the county, who strikes the fairs, calls before him, some time in the last week in February, or first week in March, a number of respectable tenants, and other persons who deal in corn; when he requires of them an account of the quantity and price of the grain bought or sold within the county, for ready money, from the time that the preceding crop came first into the market, until the day of the proof. Having procured an account of this, he strikes a general average for each of the four species of corn; he then finds the number of bills that have brought a price above that average, of these he likewise takes an average; and he proceeds in the same manner with what has been sold below the general average. To each of these rates he adds two and a half per cent., and they then form what are called the first, second, and third fairs. The addition of two and a half per cent. to the real prices must appear a singularity to strangers, who may not easily perceive either the object or propriety of it. It is explained in the following ingenious and seemingly just manner. Upon looking into the extract from the second of the fairs it will be found, that from the year 1617 down to 1647, the fairs were struck only once in the year, and as the record is silent as to the date for the first thirteen years, it is impossible now to say at what period of the year these fairs were struck; but in the year 1648 the record shows that fairs were struck twice for that year, namely, at Candlemas and Lammas. In the following year, 1649, the fairs were struck only once, but in the year 1650, and for every year down to 1675 inclusive, with the exception of the year 1665, the fairs were struck twice, namely, at Candlemas and Lammas; but in the year 1676 they again were struck only once, namely, at Candlemas; and this practice has continued uniformly down to the present time.

It is consequently extremely probable, that the two and a half per cent. was first established by being added to the Candlemas fairs for the year 1676, and was continued to be added to them for every year from that period downwards.

Upon examining the fairs for the twenty-six years, during which they were struck at Candlemas and Lammas, and taking the average of both, which seems to be the fair medium price, it will be found that, in point of fact, the Candlemas, with the addition of two and a half per cent., is somewhat below the average medium of the double fairs. This appears to account in a satisfactory manner for the origin of the two and a half per cent.; and shews, that they who first introduced it had paid considerable attention to the subject. It is evident, indeed, that fairs taken at Candlemas cannot show the average price of grain through the year, because, in the early part of the season it lies not reached its full value. Whittintide would, perhaps, be the most proper time for finding a just average, and the addition made to the fairs taken at Candlemas may amount nearly to the same thing.

It may, however, be observed, that there is one objection to the manner of striking the fairs in this county, which is deserving of attention. The first price taken is the true average, the highest and lowest are only the averages of the highest and lowest market days, whereas they should express the average of the best and worst grain. A person who makes a payment according to the highest fairs, may in fact pay considerably more than the average price of the best grainfold throughout the season. The sales of a few high market days, in which prices rife much above the level of the season, thrown into the general mass, may cause the highest fairs to be much above the current value of the best grain. It would seem to be a fairer mode to strike the fairs from the weekly prices in the Haddington market; the averages of all the market days would give the general average, while the highest prices on each market day, thrown into one mass, would throw into one mass, would furnish the true average of the best and of the world grain. The fairs in this county are, however, paid to be taken with greater correctness than in most other parts of Scotland.

In the more northern parts of Scotland, as in Perthsire, they are annually settled, in the same manner as in other counties, by a jury of traders in grain; a method which would seem to be improper, as the persons examined in respect to the prices of the grain may all have an interest in perplexing in the same way, being themselves dealers in the article of which they fix the price; whereas, were only one-third of that jury corn merchants, another third actually farming gentlemen, and the other third farmers, who pay one hundred pounds or upwards of yearly rent, every chief of the community would be represented in those meetings, every intermed were attended to, and every objection flated and considered; so that there would be every chance, that the judgment given would rest on the broad basis of the general good of the whole county. The sheriff should continue, as at present, to be the chairman of the jury, the umpire in case of an equality of votes, and have the power of judging of any objection that may be brought forward against any of the members, as a dealer in grain, which might disqualify him for holding a seat at the meeting.

The time of settling these average prices is seemingly capable of being changed for the better, as Candlemas is too early a period; as but a small proportion of the corn is by that time brought forward to be sold, and even that small portion of the crop which is threshed out, and so brought, is in a green state, and consequently disposed of at a undervalue. A fair estimate can, perhaps, hardly be made of any crop before the end of March, or perhaps a later period. As frequent decisions in courts of law are given in respect to the prices of grain, many contracts entered into, and much corn and meal sold with a reference to the fairs, as well as the rents of land, and the stipends of the clergy in various parishes, received according to them; there can hardly be a retrospective rule or regulation of equal publicity, or of equal authority devised, or more properly calculated for directing such transactions; consequently, too much care and circumspection cannot be employed in the choice of establishing them, as the medium prices of all sorts of grain, for the respective years in which they may have a reference.

However, in order to afford a better idea of what has been the average prices of grain in the first of the districts noticed above, for several years past, according to the method of forming them just described, it may not be improper to introduce a list of fairs, from 1794 to 1804 inclusive.

These records of the returns of grain are highly useful and interesting, in showing the different prices of corn in different years, for a considerable period, in the northern parts of the kingdom, and afford perhaps the best views of the subject that can be given.
China and Cochinchina. Stem shrubby, climbing, without tendrils, long, woody, brachied, as thick as the arm, composed of large plant fibres, of a golden yellow, ranged in concentric circles, with perforations between. Leaves alternate, ovate, acute, entire, front margins unequally ribbed, veiny. Flowers white, minute, in long lateral clusters. Berry small, yellow, not edible. The flavour of the whole plant is bitter.

The roots and lower part of the stem are esteemed resolvent, deobriuriant, and diuretic. The bruised bulbs afford, by boiling, a yellow dye, which is not very vivid, but lasting, and serves as a basis for Turnerick and Safflower, which, though more beautiful, are not so durable.

Loureiro, from whom the above account is taken, supposes the Taba florii, Rumph. Anboin. book 7. chap. 23. t. 24. to be nearly allied to this plant, as well as the Abuta of Aublet. t. 250, 251. ins. 284. In the latter he seems to be right, as the natural order is concerned, and in the former at least equally so. That they are all one species, as he supposes, is manifestly not the case. Aublet gives his Abuta, which have downy leaves, as the Pareira Brava of the Portuguese.

FIDRÉ, in Anatomy and Physiology, is generally understood to denote the elementary component parts of the animal body: the most simple forms of the organized matter, to which the more complex organs of the frame can be reduced by the various methods of examination employed by the anatomist. In this sense, it is to the physiologist what the line is to the geometer, that from which all other figures are produced. Haller has devoted the first section of his great physiological work to the consideration of this subject. He observes that all the solid parts of the frame are composed of fibres, and that these are reducible into earth, water, oil, iron, and air. The simple fibre is invisible, and cannot even be brought under observation by the assistance of microscopes: since the smallest animals, which are only discernible by very great magnifying powers, are themselves composed of such elementary parts. He proceeds to explain that their primary and invisible fibres unite together to constitute visible fibres and plates of animal substance, from the amalgamation and connection of which our organs are composed. Our respect for so great an authority shall not induce us to repel any great confidence in such statements as the foregoing: they appear to us to be very ill examined, and therefore hypothetical. The fact is, that these supposed elementary fibres are invisible, and must lead us to receive with great caution accounts of their physical and vital properties. And the obvious differences in the composition and texture of our organs will naturally give rise to an inference, that the elementary constituents of these are probably different. We do not speak here of the chemical elements into which parts may be resolved; but of the primary animal fibre resulting from them. Without troubling ourselves with descriptions of an object, the very existence of which is not yet proved, we shall proceed to explain firstly the composition of the body, as far as it can be ascertained by our senses. In this investigation we shall find structures of very different appearance exhibited in the different organs of our frame; so that the imaginary fibre will not be found to afford the physiologist much, whatever benefit the line may afford to the researches of the geometrician. The following account is derived from the ingenious work of Bichat, entitled "Anatomy. General."

An animal body is an assemblage of various organs, each of which, exercising some function, coexists in its own manner in the preservation of the whole. These organs may be regarded as so many particular machines contained in the general machine of the individual. But the latter are made up of several structures or tissues of very different natures, which form the true elements of the organs. Chemistry has its simple bodies, which form combinations by the various combinations of which they are susceptible. In the same way, anatomy has its simple tissues, which, when combined in numbers of four or more, make up the animal organs. They are, 1. the cellular; 2. nervous of the animal life; 3. nerves of the organic life; 4. the arterial; 5. the venous; 6. that of the exhalants; 7. that of the absorbents and their glands; 8. the officious; 9. the medullary; 10. the cartilaginous; 11. the fibrous; 12. fibro-cartilaginous; 13. mural of the organic life; 14. mural of the organic life; 15. the mucous; 16. the serous; 17. the fynovial; 18. the glandular; 19. the serous; 20. the epidermoid; 21. the hairy. Such are the organized elements of our parts: they poffefs the same nature in all situations; as the simple bodies in chemistry are the same, whatever combinations they may enter into. The advantage of considering the structure of the body under this point of view is, that it is not imaginary, but real on the real foundation of observation. The lines of demarcation between the various tissues are drawn by nature, and not produced by metaphysical abstractions.

The forms are every where different; here flattened, there rounded. The simple tissues may be arranged in membranes, tubes, or fibrous bundles. But these differences of form are merely accidental. The nervous tissue forms a pulp in the retina, and cords or threads in the nerves. The fibrous constitutes fasciculi or bundles in the ligaments, and membranes in the aponyrodes. The organisation and properties are the sources of the essential distinctions.

None of the simple tissues are analogous in their organisation, that is, made up of common and of proper parts; and the former are very differently arranged in each case. In one instance cellular tissue, blood-vessels, and nerves, may exist in abundance; while in another one or two of these may be found very sparingly, or may be entirely deficient. Here we have an abundance of capillary vessels: there this system can hardly be demonstrated. The proper or characteristic parts are decidedly different. Their colour, thickness, hardness, density, &c. are all various. Simple observation is sufficient to detect the various characteristic attributes; but further properties are discoverable by the application of heat, air, water, acids, &c.

At the same time that nature belован on each system a different organic arrangement, she endowed it also with different properties. (See Life, and the account of the particular systems.) The consideration of these systems, as entering into the composition of organs, where they may be dissected independently of each other, is of the highest importance in physiology; and the separate affections of particular tissues in a compound organ will come more particularly under notice in chronic diseases.

The organic systems of the living economy may be divided into two grand classes. Those of one kind, distributed over the whole body, and present everywhere, concur not only in the formation of all the organs, but also in that of the other systems, and constitute a common and uniform basis to every organized part: these are the cellular, arterial, venous, exhalent, absorbent, and nervous systems. The others, placed in certain determined apparatuses, and foreign to the whole of the economy, have a less general existence, and are often almost isolated. Such are the offensive, cartilaginous, fibrous, muscular systems, &c. &c. Bichat calls the former the generating systems. All organized parts are not necessarily provided with all the six. Some have no arteries.
arteries nor veins; some no nerves, &c., but they meet together in most of the organs, and there are always some present, although others may be wanting. Thus tendons and cartilages, which have no blood, possess exhalants, absorbents, &c. The two last-mentioned sytems are the most universally found. Nutrition supposes their existence: that function, in fact, results from a double motion, of composition which brings nutritive matter to the organs, and of decomposition which removes it. The exhalants are the agents in the first of these motions; the absorbents in the second. Since every organ is nourished, and the mechanism of nutrition is uniform, it follows that these two sytems must belong to all organs. The cellular exils the most generally after these. It is sometimes found where there are no blood-vessels, and it always exists where there are found. The arteries and veins come the next in order: often there are no nerves where these penetrate, as in the apancreoses, the fibrous membranes, &c. The nervous is that of all the generating sytems, which can be traced into the fewest organs. The nerves, membranes, the fibrous, fibro-cartilaginous, and bony sytems, &c. appear to want it.

The generating sytems, besides entering into the structure of other organs, also belong reciprocally to each other. Thus, cellular fabulence is found in the nerves, arteries, and veins; the latter ramify in the cellular fabulence, &c.

It will be expected, from the preceding observations, that the generating sytems, considered as the common basis of all the organs, ought to be developed more early than the others; and we find this in the fetus. The nerves, with their centre, the brain; and the arteries and veins, with their central organ, the heart; the cellular tissue, the exhalants and absorbents all present this phenomenon. With respect to the two latter, it is sufficiently clear from the great activity of absorption and exhalation at this period.

The general sytems must perform the most important part in the office of nutrition. They constitute the nutritive parenchyma of every organ: this is the cellular, vascular, and nervous matter, into which the nutritive fabulence of the organ is deposited. The latter, different in every instance, constitutes the difference of the various organs. It is phlo-plate of fine and gelatine in the bones; gelatine only in the cartilages, tendons, &c.; fibrine in the muscles; albumen in other organs. If, therefore, the nutritive parenchyma of a bone was filled with fibrine, it would constitute a muscle in the form of a bone, and under the opposite circumstances, we should have a bone in the form of a muscle. The nutritive fabulence are histerto for the most part unknown to us: but as the parenchyma is greatly analogous in all cases, if the former were removed, the only differences would be in form, volume, a rangement of cellular laminas, and of vessels and nerves; without any essential variation in nature and composition.

The mucous mafs of the fetus, in the early periods of conception, seems to be merely an aestimulage of general sytems. The organs exist only in their nutritive parenchymas. As these grow, and become developed, the nutritive matters penetrate them; and then each organ, histerto figurar in its nature to others, begins to be distinguished, and to possess an isolated existence; each derives its appropriate fabulence from the blood.

The sytems of the second kind belong only to some particular apparatus of the animal economy: thus, the sifonous, muscular of animal life, cartilaginous and fibrous are peculiarly set apart for the locomotive organs; the feroous, mucous, muscular of organic life, &c. belong to the digestive, respiratory, and circulating apparatuses, &c. All these, therefore, are much more isolated, and perform a less extensive five part in the animal fabric. Concentrated in peculiar organs, they are foreign to others, and have an independent life; while the vitality of the primitive sytems is blended with that of the organs, into the composition of which they enter. The different parts of these sytems are not connected together; and this is exemplified in the bones, muscles, cartilages, glands, &c.; various organs of different nature, and belonging therefore to other sytems, are interposed between them. The primitive sytems, on the contrary, are every where continuous, and uninterrupted. The cellular, arterial, venous, absorbing, and nervous sytems, are fo disposed, that, if we were possible to remove all the organs, which they penetrate, and leave them only, there would still be a whole continuous fabric, but be deprived. If, on the contrary, the organs, intermediate to the bones, cartilages, fibrous, cartilages, &c. were removed, the various parts of these sytems would be immediately isolated. The particular accounts of the different sytems will be found under their respective articles in the Cyclopædia.

**Fibre.**

Fibre, Animal, fibrin, muscular fibre, in Chemistry. The muscle or fil of animals is composed of as many number of cylindrical, soft, nearly inelastic, semi-transparent fibres; these, when examined by the microscope, are seen to be filled with fibrous sublimated into bundles of parallel shreds, bound together by very fine cellular membrane. The living muscle is moreover penetrated by arteries, veins, nervous fibres, and lymphatics with their contents; and thus a considerable quantity of extraneous matter is mingled with the pure fibre of the muscle, so as to throw a certain degree of ambiguity on the chemical analysis of this latter fabulence. By means, however, of maceration with cold and hot water, and mechanical pressure, much of the foreign matter may be got rid of, after which the fibre exhibits the following properties.

Its colour is greyish white; in the state it is infusible, its texture is stringy; it hardens rather than softens by the long-continued action of hot water. When dried slowly in a warm air it becomes semi-transparent like horn, and very brittle.

Fibre, prepared as mentioned above, is entirely infusible in water, in most of the acids it dissolves readily; with the dilute nitric acid it gives out a large portion of azote gas of great purity, but it stronger nitric acid is made use of, a more complicated action takes place, by which according to Berthollet, one portion of the fibro is changed into a kind of fatty fat, which floats on the surface of the liquor, while the rest is converted into oxalic acid.

Mr. Hatchett's valuable experiments on this fabulence throw great light on the composition of muscular fibre, and point out a variety of before unnoticed points of resemblance between fibre and condensed albumen. Of these, the principal are the following; muscular fibre (previously expansil by long maceration in cold and hot water of every thing soluble in this liquor) was dipped for a fortnight in nitric acid, dissolved with various parts of water, and the end of that period the acid was become yellow, and had removed the properties of a nitric solution of fibrin. The undissolved residue, which could not of far the greater portion of the fibro, being thoroughly triturated by the acid, was dissolved in boiling water, in which it dissolved, the liquor upon afforded a gelatineous milk, which, after being clarified in water, was precipitated by the addition of nitric acid, and a mixture of tin, precipitated with the fleshy part of the fibro, and as the solutions of albumen. Thus penetrating and thoroughly, by nitric acid, is for the most part soluble in water, forming a liquor of a brownish orange colour. By digestion with potash the albumene is given out, and a tanninaceous matière produced.
If washed fibre, however, is treated with boiling nitric acid, the solution still more resembles that of albumen in the same menstruum, but with this additional circumstance, that, on superheating with ammonia, a copious white precipitate falls down, consisting of the phosphat and oxalat of lime, the former of which pre-existed in the fibre, while the acid of the latter was produced by the action of the nitric acid on some portion of the fibre, and then united with the lime which naturally exists in fibre, in the state of carbonat. Lime, therefore, is found in muscular fibre in two states; as a phosphat, which is chiefly separable by long boiling, and in some other state in which it is not soluble in water, but remains ready to combine with the oxalat acid so soon as formed; this state is probably the carbonat, and the quantity of lime thus combined is such as to afford 17 grains of dry oxalat from 200 grains of dry fibre.

The proportion, however, of earthy salts contained in fibre varies greatly, according to the age of the animal; for it appears from Mr. Hatchett's experiments, that though beef contains both phosphat and carbonat of lime, veal gives hardly any indication of the latter, and a much smaller proportion of the former.

The analysis by fire shows the following very notable difference between gelatine, fibre, and albumen, (the three great constituents of the soft parts of animals) in their proportions both of carbon and earthy refidue.

500 grains of sinews, being gelatin in its purest form, distilled with a strong heat in closed vessels, left 56 grains of refidue, of which 54.7 disappeared by subsequent calcination in the open air, and therefore were carbon, the remainder, amounting to 1.5 gr. appeared to be phosphat of soda, with a trace of phosphat of lime.

500 grains of dry albumen, treated in the same manner, gave 63.25 grs. of carbon, and 11.25 grs. of refidue, consisting of soda in a semi-carbuncle state, together with phosphat of soda, and a very small portion of phosphat of lime.

500 grains of beef, well washed and dried, gave 82.1 grs. of carbon, and 25.6 of refidue, the greatest part of which was carbonat of lime, mixed with some carbuncle fibre and a little phosphat; this is to be observed, however, that this is by no means the whole earthy contents of the muscle, as by its previous digestion in boiling water nearly the whole of the phosphat of lime would be dissolved out.

The general inference from these experiments, and from others that have been mentioned under the article Albumen is, that the principal constituent of muscular fibre is a substance which, from its habits with the principal chemical reagents, may be considered as nearly identical with infusitated albumen.

A few miscellaneous circumstances concerning muscular fibre may be added. When thoroughly washed and freed from all that can be extracted from it by cold water, it does not readily putrefy; but in its natural state it soon undergoes this change, the texture becoming flabby and loose, the colour pale, and the odour exceedingly rancid. The flesh of young animals putrefies sooner than that of old ones in similar circumstances. When imbibed in running water, emburied under ground in large masses, it changes to that singular fermentative matter already described in the article Acidulce. When slowly and thoroughly dried, and kept in a dry air, it will remain long without undergoing any change. Alcohol deprives it of colour, hardens its texture, and effectually prevents the access of putrefaction; and it may be observed that antiseptics in general are more efficacious in preserving muscular fibre than any other of the soft parts of the body.

The most important of the volatile products of the dry distillation of fibre is ammonia, which also indicates the presence of much azot in the fibre itself. An acid also is given out at the same time, which is acid, muriatic, and has the peculiar odour of roasted meat. It was first described by Berthollet as a peculiar acid, and was named by him the zoanic; the general opinion of chemists however at present concerning this substance is, that it consists of septic acid, fouded and rendered empymematic by the action of heat on the substances from which it is procured.

Fibre, Vegetable. Almost all plants contain a fibrous matter, which is distinguished from the other vegetable principles by its comparatively inoffuscibility in chemical menstrua, its indissolubility by spontaneous decomposition, and a certain toughness and elasticity occasioned by its minutely fibrous texture. In some plants these fibres are remarkably flexible and tough, as in the flax, the hemp, the alfa, and the inner bark of the lime, the birch, and other trees that furnish the materials of Rutilia matting; in the cane and bamboo these fibres, though still considerably flexible and elastic, are inferior to those produced by the preceding plants; and in the ligneous fibre or wood of the larger trees they exhibit still greater density and diminished flexibility. The chemical characteristic of vegetable fibre is, that it presents on analysis a greater proportion of carbon and earthy matter than any other vegetable substanee; as will be detailed at length under the article Wood.

FIBRILLAE, a little fibre, or capillament.

FIBRO-CARTILAGE, in Anatomy, a tisue of the animal body, partaking of the characters both of ligament and cartilage. An ingenious French anatomist distinguished it by this name; and he has included, under the expression fibro-cartilagineous syltem, all those parts of the body which exhibit this kind of structure. From the mixed nature of their properties, the fibro-cartiligious organs have been partly arranged among the ligaments, and partly among the cartilages. They may be conveniently arranged under three divisions.

1. The membranous fibro-cartilages; as those of the ear, nose, trachea, eye-lids, &c. They are very thin, disposed in an uniform plane, or convoluted in various directions.

2. Articular fibro-cartilages; of very variable forms, but in general thick; interposed between the opposite ends of bones, in some instances unconnected by their surfaces, and moveable, in others closely attached, as in the vertebrae.

3. Fibro-cartilages of tendinous sheaths; consisting of a thick layer covering the bone in some instances, where the tendon passes over it. The structure and vital properties are not exactly the same in all these organs.

The peculiar tisue of this system is composed, as some indicates, of a fibrous substanee, with the addition of a true cartilage. The former seems to be the basis of the organ. It is very distinct in the naihes which connect the bones of the vertebrae, but much less so in the membranous fibro-cartilages. The fibres are sometimes parallel, and sometimes interwoven. This fibre is exactly of the same nature as in the fibrous syltem, compact, hard and strong; and hence arises the strength of the different organs belonging to this system. The solidity of the union which connects together the bodies of the vertebrae, and the difficulty of removing the fibro-cartilages of the knee, jaw, or clavicle, sufficiently exemplify this. These organs bend in every direction, whereas the true cartilages, if powerfully bent, would break. The cartiligious substanee is interposed between the fibres, and is particularly discoloured in the articular fibro-cartilages; which owe to it their elasticity, white colour, and the
the inorganic appearance exhibited by a fiction. These are rendered yellow and transparent by boiling, and are converted into jelly, although not quite so readily as the true cartilages. The fibro-cartilages of the organs of sense, which we have already adverted to in the article Cartilage, are not resolved into gelatine by boiling: they are softened, but remain whitish. After some time their fibrous membrane is detached, and the substance itself breaks in several places. After macerating for some days they become red. Defaecation renders them hard and brittle, without imparting the yellow colour which tendons or aponeuroses receive on such treatment. The inter-vertebral substances have, when dyed, a remarkable transparency, without any yellow tint. They swell when detached, and placed in water.

The fibro-cartilages in general have no perichondrium. Those of the tendinous sheaths are in contact on one side with the bone, and by the other with the synovial membrane. The articular ones are covered by the synovial membranes of the joints, and those of the vertebrae are covered only by the anterior and posterior vertebral ligaments. A very distinct and closely adhering fibrous tissue covers those of the organs of sense; and is rendered white by maceration.

The cellular texture is difficultly seen in these organs; but maceration brings it into view. Very little blood circulates through them in the ordinary state; but they become vascular when inflamed. No nerves can be traced into them.

This system is distinguished most particularly by its elasticity. The fibro-cartilages of the organs of sense and of the trachea, when bent, immediately restore themselves; and those between the vertebrae, being compressed by the motions of the bones, resume their former state, as soon as the compressing force ceases to act. (See Cartilage.) They have the power also of bending in every direction, without any risk of being broken. They possess extensibility, and contractility.

Their vital properties are very obscurely marked. They have no animal sensibility or contractility in the natural state; but the former appears under inflammation. Organic sensibility, and insensible contractility, exist in these organs as far as they are necessary for the purposes of nutrition. This obscurity of the vital properties renders all the vital phenomena very slow. If the ear of a dog be cut, and the fides of the incision brought together, the skin quickly unites; but the cartilage is not agglutinated until long after. From the same cause we must explain the rare occurrence of dissection in these organs. No parts in the body are so seldom diseased as the fibro-cartilages of the nose, ear, trachea, &c. Gangrene produces hardly any alteration in them, and it is almost doubtful whether they ever suppurate.

This system is developed at an early period: the ends of the bones are large in the fetus, and the articular fibro-cartilages are consequently considerable. Those of the tendinous sheaths are not to be distinguished from the cartilaginous epiphyses which in the fetus form the ends of the bones. The gelatinous portion exceeds the fibrous part in the fetus; particularly in the inter-vertebral spaces; and its proportion is in all always in an inverse ratio to the age of the subject. The membranous fibro-cartilages are developed very early in the fetus.

The parts become stronger and more dense as the age advances; and in the old subject they take a hard form. Hence the stiffness and inflexibility of the vertebral column.

Vol. XIV.

The fibro-cartilages are much less prone to ossification than the cartilages. This change has never been observed in the membranous ones. Those of the vertebrae are almost the only ones in which effusive matter is sometimes deposited, and this is very rare. Bichat, Anatomie Generale, tom. iii.

FIBROLITE, in Mineralogy, a substance first noticed by the count De Bouron, and found by him among the mastix of Corundum, from India and China. It is of a whitish or dirty whitish grey colour; it occurs in masses of an indeterminate form and fibrous texture. The count De Bouron has only once seen a specimen that had a tendency to a regular form, which was that of a rhomboidal prism of about 60° and 80°. Longitudinal fracture fine fibrous, the fibres in some specimens interwoven in all directions; crescent fracture, compact, with a vitreous infusible. Translucent at the edges. Hardness about as quartz, when tried in a direction perpendicular to or across the fibres. Gives spurs with ease, and a deep reddish phosphoriferous light when rubbed against an hard body. Not electrical by friction. Specific gravity about 2, being, like all fibrous substances not found in a crystallized state, of different degrees of density. Inifiable per fer by the blow-pipe. Analysis by Mr. Chenex of fibrolite from the peninsula of India and China.

The remarkable circumstance of the fibrolite from India yielding nothing but silica and alumina, and its always occurring in amorphous masses of a fibrous texture, induced the discoverer to give it the above name. See the interesting paper on Corundum, by the Hon. Mr. Greville and the count De Bouron, printed in the Phil. Trans. for 1802.

FIBROUS SYSTEM, in Anatomy. This includes a great many organs of the body, composed of the same elementary parts, but differing widely in their forms. Varieties, together with the differences of function and position, occasion them to be distinguished by the names of tendon, aponeurosis, ligament, &c. For these are not under any general term, like that of muscle, or nerve in the muscular or nervous systems, to denote the organisation whatever the form of the organ may be. There are two leading divisions of form, under which all the fibrous organs may be arranged, i.e., the membranous, which thin and broad; and that of chords, which is thick and elongated.

I. Division. Fibrous organs of the membranous form, including fibrous membranes, fibrous epidermis, tendinous sheaths, and aponeuroses. The fibrous membranes are the pericardium, dura mater, sclerotics, subligaments, and capsules of the kidney, spleen, &c. They generally envelop the organs, and enter into their texture. The fibrous epidermis consists of cylindrical bags, surrounding cartilage, cartilages, particularly those of the humerus and femur, which connect very closely to the capsule and synovial membrane. The sheaths confine the tendons rolling over bones, and when they are reflected wherever they are reflected they are subject to displacement from the muscles; and in consequence, transmit imperfectly to the bones the motion imparted by the muscles. They may be divided into two divisions: 1. Such as are common to the tendons of flexor muscles, as at the wrist and tarso; 2. Such as belong to one tendon only, or two, as in the fingers and toes. Aponeuroses consist of large sheets of fibrous texture, being:
to the locomotive organs, and disposed in some instances so as to form coverings of parts; while in others they afford points of attachment to muscles. Hence they are distinguished into aponeuroses for enveloping, and aponeuroses for insertion. The former either surround the muscles of a limb, forming for it a general sheath, as in the thigh and forearm; or else they invest and confine some particular muscles, as that which extends between the two posterior serrati, that which is placed in front of the soleus, &c. The aponeuroses of insertion either form broader or narrower surfaces, as at the attachment of the triceps femoris, rectus crus, gastrocnemius, &c.; or they consist of separate fibres, giving distinct attachments to the muscular fibres, as at the origin of the iliacus internus, tibialis anticus, &c., or they form arches, which both give attachment to muscular fibres, and at the same time allow the passage of veins, as at the diaphragm and calf of the leg.

2d Division. *Fibrous organs in the form of chords,*—constituting tendons and ligaments. The former are placed at either of the attachments, or in the middle of muscles. They are generally simple, consisting of elongated chords; but in some cases they are more complicated, being divided into several smaller chords. Ligaments tie together the articular surfaces of bones. They may form either constant and regular fasciculi, as at the elbow, knee, &c. or irregular ones, as at the pelvis.

The following table exhibits the fibrous organs according to the preceding arrangement.

Fibrous membranes, Fibrous capsules, Fibrous sheaths, Aponeuroses, Tendons, Ligaments,

Although the numerous organs included in this table belong to parts of very different structures; although they seem disposed irregularly in the animal economy, without mutual connection, and apparently isolated; they are in fact nearly all continuous. The common centre of this system is the periosteum, with which all its parts are closely connected, excepting the albuginea, the coats of the kidney and spleen, and the perichondrium of the larynx.

Organization of the fibrous system.—This is nearly the same, under all the variety of forms which have been just particularized; and consist of a peculiar tissue, with vascular, cellular, and other textures.

All fibrous organs have for their basis hard, inelastic, and infusible fibres: incapable of contraction; sometimes parallel to each other, as in the tendons and ligaments, sometimes variously interwoven, as in the capsules, membranes, and sheaths; of a white or grey colour, and great powers of resilience.

The latter property enables all these organs to sustain great efforts; and they are employed in offices which require such a power. The ligaments firmly hold the articular surfaces in contact. The aponeuroses confine the muscles and resist their displacement. The tendons are placed between two powers;viz. the powerful energy of muscular contraction, and the greater or less resistless force, which that action is designed to move. The resistless power of the tendons is in many instances superior to that of the bones: thus, the patella, the olecranon, and the os calcis may be broken by muscular contraction. The difficulty of producing luxations in the dead subject, and the great force required in the former barbarous punishment, of fixing four horses to the four limbs of a criminal, in order to tear them asunder, sufficiently exemplify the great strength of this tisue. A tendon requires an enormous weight to bend from it to break it. Yet this resilience, however great, is sometimes overpowered in the living body; and we see the strongest tendons, as that of the calf, ruptured by muscular contraction. We cannot help being surprised, on these occasions, that the soft tissue of the muscles should not yield rather than the tendons.

Some anatomists have fancied that the fibrous and muscular systels were analogous, and have affirmed that a tendon is formed by the conduction of the muscular fibres. This notion is altogether absurd. The fibrous membranes and aponeuroses are expanded, but they resemble muscular fibres in no respect. The chemical composition, the vital properties, and the apparent texture are widely different. Their functions have not the least analogy. In fact, there is no resemblance between the muscular fibres and the tendon, in which they are inserted, than between the latter and the bone, to which it is attached.

What then is the nature of the fibrous tissue? This we cannot determine, as we cannot recognize in it any very determined character. Its properties are rather negative. It has not the contractility of the muscular, nor the facility of the nervous tisue. It is always passive, and obeys the motion impressed on it, without having any of its own.

The parts, in which this is found, are very different from the skin, the cellular texture, cartilage, &c.; and hence the referring of all these to a common class of white organs is a premature generalization, resting entirely on external appearances, and imperfect analysis, in which the texture, vital properties, and functions of the organs are disregarded.

The fibrous tissue, exposed to maceration at a moderate temperature, does not experience any change for some time. Its density gradually diminishes, and its substance softens, but it does not swell. The fibres may now be drawn asunder, so as to expose the connecting cellular tissue. After a very long period they are reduced into a soft whitish pulp, of homogeneous appearance. Tendons are the fuscet acted on; then aponeuroses of infection; afterwards those of envelopment; then the fibrous membranes, capsules, and sheaths; and lastly ligaments.

Any fibrous organ plunged into boiling water, or exposed to considerate heat, curls up, and becomes contracted, like most other animal tissues: its volume is diminished, it becomes

{Simple, | Complicated. |
| With regular fasciculi, | With irregular fasciculi. |
comes more solid, and acquires an elasticity, which it had not in the natural state, and which it loses again, when softened. The force with which the fibres contract on exposure to heat is very considerable.

It is sufficient, when bones are boiled for a long time, to produce rupture and detachment of the perioleum; and, when the bones, surrounded by their ligaments, are exposed to the action of boiling water, to lock the articular surfaces so closely together, that they cannot be moved.

The fibrous tissue softens in boiling water, becomes yellow and semi-transparent, and at last is partly dissolved. These changes take place most quickly in the tendons, then in the aponeuroses, the membranes, the capsules, and fibrous sheaths, and lastly in the ligaments. But all ligaments do not soften equally. Those which connect the spinous processes of the vertebrae, at their roots, do not undergo the same changes, but remain white and tenacious.

The evaporation consequent on exposure to the air destroys the whiteness of the fibrous system; it contracts, becomes yellow and transparent, and is easily broken. By immersion in water, in a few days after being dried, the whites and softness are recovered, and the part regains nearly its original appearance. This is particularly the case with the tendons. Nitrous and sulphuric acids soften the fibrous tissue very quickly, and reduce it into a blackish pulp in the latter, and yellowish one in the former case. It curls up and contracts when first plunged into the acid, as it does on exposure to boiling water.

It resists putrefaction for a considerable length of time, and remains unaltered, when skin, muscles, nerves, &c. are completely disorganized. But it yields in the end.

Cellular texture exists in all fibrous organs; being more or less abundant, in proportion as the fibres are more or less approximated. Maceration renders it obvious enough in all cases. As the cellular tissue itself can hardly be perceived, no fat can be distinguished in it. But an adipose exudation has been noticed, in some instances, after fibrous organs, carefully cleaned from all surrounding substance, have been dried. Tendons are found in very different states in different parts of the fibrous system. They are numerous in the dura mater and perioleum, very few in the aponeuroses, and not discernible at all in the tendons. The former organs are the most liable to inflammation and swelling. Abscesses have not been detected in the fibrous system nor nerves.

Properties of the fibrous system.—Its elasticity is very striking; but becomes considerable, when parts are removed from the body, and dried. Thus tendons, and strips of aponeuroses, which are insensible of vibration in their fresh state, produce sound when very dry.

The extensibility and contractility of these organs is not considerable; and it always takes place slowly. The fact is exemplified in hydrocephalus, swellings of the bones, tumefaction of the limbs, dilatation of the abdomen, &c. If the force be applied suddenly, and the resistance of the fibrous organ too great, various symptoms arise. Prefere of the most painful kind, and dangerous consequences, is produced on the contained parts, as in inflammatory tumefaction of the limbs, inflammation of the teliis, eyeball, &c. When the power is too great, the organ is torn, as in the rupture of the tendo Achillis, of the ligaments in luxations, &c. The contractility corresponds in its kind and degree to the extensibility; no fibrous organ can be suddenly extended, so it cannot recover suddenly after dilatation. Hence, when a tendon or aponeurosis is divided in the living state, there is scarcely any separation of the margins. The separation consequent on rupture of a tendon arises from muscular contraction, or from the position of the limb. Indeed, if the muscle be in a state of action, the end of the divided tendon attached to the muscle is drawn away from the other a little; but that portion of the tendon which is fixed to the bone undergoes no change. When a tendon is divided, while the muscle is relaxed, no separation ensues.

The vital properties of these organs have been a subject of great controversy among physiologists. Numerous experiments have been instituted, and many works published on the question. Whether or not they possess sensibility, Haller and his followers maintain the negative, and their publications contain a vail of experiments. There is little doubt that they possess feeling, or, what Bichat calls animal sensibility; although this does not flow itself by the usual phenomena. The different mechanical and chemical stimuli produce no pain, unless the organ be inflamed. This is the case with the tendons, the aponeuroses, the fibrous membranes, and the ligaments, when exposed and cut in operations, or irritated chemically in living animals. But, if these parts are suddenly exposed to violent dilatation or twirling, acute pain is produced. Bichat appeals, for the proof of this statement, to experiments on living animals. And he considers that this mode of sensibility is appropriate to the functions of the organs. They have no concern with exterior forces of excitation; but, in performing their offices, they are liable to be drawn, twisted, and stretched in the motions of the limbs. The senation, which they transmit in these cases, is a warning of the danger, by which its further progress is prevented. The great pain of lusations, and of the extension employed for their reduction, and of brains, seems to confirm the preceding statement.

These organs possess no animal contractility. They have organic sensibility, and organic insensible contractility in common with all other organs.

The vital powers are more developed in this than in the bony and cartilaginous systems. The peculiar kind of feeling, which we have just explained, is a proof of this. It is much more frequently the seat of pain and inflammation, and the pain is much more acute. This is exemplified in rheumatism, which affects the fibrous organs about the articulations. It seems that this system, hardly in any infaile, forms pus.

In the gelatious substance, of which the embryo consists, the fibrous organs can hardly be distinguished; and they cannot be recognized until several other parts are formed. The fibres are not perceptible until towards the seventh month; and, as they increase, the organs become more hard and resilient. They possess at this time a peculiar white sheen, of a very fine degree. It is only by degrees that they acquire the firmness which particularly characterizes their tissue.

The comparative softness of these organs in the first years of life will explain many circumstances both of natural phenomena and diseases. As the subject grows up, the fibrous system becomes dense and hard; and it remains stationary in the adult. It is still more compact in old persons; yielding less easily to putrefaction and maceration. Hence the flabbiness in the articulation at this period. All the parts now become yellow.

The fibrous membranes will be considered under the article Membrane. The capsules are described in the account of the articulations to which they belong. See Extremities.

The fibrous sheaths belonging to one tendon form a canal, in which the tendon runs. There is a channel in the bone, completed into a canal by the fibrous organ, and lined
FIBROUS.

internally by a closely adhering synovial membrane, which is reflected to the retained tendons at the extremities of the canal. These sheaths are connected externally to the surrounding parts by a loose cellular texture. They are extremely dense in their texture, and in proportion to the efforts which they have to sustain. The particular sheaths will be described in the account of the muscles to which they belong. The larger ones of the hand and foot, common to several muscles, are described in the article Fascia.

The aponereos of envelopment are considered under the article Fascia. Thos of infection, belonging so effectually to the muscles, will be treated, as well as the tendons, under Muscle.

The ligaments will be spoken of in the account of the structure of Joints. This article is drawn entirely from the Anatomic Generale of Bichat, vol. iii.

Fibrous Amethyst, or thick fibrous amethyst. It is generally of a dark violet blue colour, sometimes of a pale and lighter one, which borders on grey, from which it passes to bluish and yellowish-white. It occurs only massive and in rolled pieces. Internally it is glistening, sometimes shining, and is vitreous. The principal fracture is thick fibrous, and is straight and diverging fibrous; the fracture in some instances is intermediate between thin fibrous and splintery; the edge fracture is generally imperfectly conchoidal, approaching to uneven and splintery. Commonly translucent, but varies from that to transparent. Hard, rather more so than rock crystal; gives sparks with file.

Not very difficultly frangible. Specific gravity 2.750. According to Karsten it is composed of

Infusible per se in the strongest heat of a wind furnace, but melts upon charcoal when exposed to a stream of oxygen gas.

It is found in large veins, and is generally accompanied by common amethyst. When both kinds occur together the fibrous is supposed to be the oldest, as it adheres to the sides of the vein. Its geographic situations are very numerous; it is found in abundance in various places in Saxony, in the East Indies, Spain, the Uralian mountains, &c. The most beautiful specimens are brought from Catherinesburg, in Russia.

The lols of its colour by heat indicates either that the colouring matter is very volatile or very little in quantity; and it has been doubted, by some philosophers of great reputation, whether this and many other highly coloured stones owe their colours to metallic oxides, or to some unknown modification or affection of light; and it is well known that flour and other phosphorescent stones lose their power of emitting light with the loss of their colour.

Fibrous Gypsum. — See Gypsum.

Fibrous Limeflone. This subspecies is usually divided into two kinds: 1. Common fibrous limeflone. 2. Fibrous limeflone, flàlātīce, kalkfinter of Werner.

1. Common Fibrous Limeflone. — Its colours are white, greyish, or yellowish-white, and sometimes reddish-white. It occurs massive. Lustrous glistening, often shining, and is pearly and chatoyant, particularly when cut and polished. Fracture from coarsely to extremely delicately fibrous. The fibres straight, undulating, or contorted, and are generally parallel, sometimes diverging. Splits easily in the direction of the fibres. Fragment prismatic; edge fracture perpendicular to the former. Moderately translucent. Rather harder than crystallized carbonate of lime, which it feraciously. Specific gravity 2.7. The beautiful variety called flàlātīce was first discovered, in 1798, by Mr. Mawe, in small veins, lying between pyrites in a calcareo-argillaceous schist, in the county of Cumberland.

It is said, in some late treatises on mineralogy, to be found in Derbyshire; but this mistake has perhaps arisen from the circumstance of its having been wrought into a great variety of beautiful ornaments, as necklaces, lockets, rings, &c. at the manufactory of Brown and Mawe of Derby and Matlock. A variety, but of inferior quality, for the above purposes, has been very lately found at Ashover, in Derbyshire, in cutting a road to the mine works through the upper bed of toad-stone, where it was very abundant in small veins and nodules; and it is a remarkable circumstance, that all the carbonate of lime found in this toad-stone is fibrous; that of the nodules radiating from a centre. It has a considerable resemblance to fibrous gypsum, but may be distinguished from it by its great hardness, and by its being generally traversed by small veins of pyrites. It may be distinguished from zeolite by its greater specific gravity and inferior lustre, and from both the frigid fibrous gypsum, by its off-white, and with salt. Sattin spar is now very rare, the vein being long since exhausted. Analysis by Mr. Pepys:

2. Stalactite, Kalkfinter of Werner. — Its common colour is white, from which it passes into greyish, greenish, and yellowish-white; from these it passes into the various degrees of yellow, brown, green, blue, &c. deriving its colour from the mineral substances by which it is accompanied.

Dr. Kidd, in his mineralogy, says, that the greenish-white stalactite of Derbyshire owes its colour and peculiar beauty to oxidized carbonic acid. It occurs most commonly massive, also in a variety of external forms, but most often stalactitic. Its surface is generally rough and drusy, and the stalactites are frequently terminated either by a single crystal, or group of crystals, sometimes having the appearance of a crystaliod. Its internal surfaces vary from glimmering to glistening, and is generally pearly. Fracture straight, and feebly diverging fibrous. Fragments mostly indeterminately angular, sometimes splintery and wedge-shaped. It occurs most commonly in concentric lamellar concretions, which are bent in the direction of the external surface. The stalactitic and tuberose varieties are often hollow. It is considerably translucent, in some cases even semi-transparent. Its hardness, fragility, and specific gravity, nearly the same as crystallized carbonate of lime.

It is found in all countries where limedone, particularly of the older formation, abounds. Its localities are too numerous to mention, but in England the most beautiful specimens are found in Cumberland, Durham, Yorkshire, &c. particularly Derbyshire, where it is wrought into various ornaments. It is also used for purposes where very pure lime is wanted, as it is free from many impurities that contaminate common limedone.

The afbalater of the ancients is said to be flàlātīce carbonate of lime, brought from Arabia, and used for the drapery...
Fibrous roots, in Vegetable Physiology, confide entirely of fibres, without any tuberous or bulbous part, except such a common bafis, or point of connection, as is neceffary to hold them together. The fibres, or radicule, are the only effectual part of a root, being what immediately absorbs nourifhment from the foy. They are produced after every year, when vegetation firft awakes from the torpor of winter, and it is only before they firft forth that plants can be removed, or kept for some time out of the ground, in perfect safety. The radical fibres of fuch grafts as grow in loofe fand, are usufally very downy, probably to attach them more firmly to fo flippery a fupport, or to multiply the surface, or points of absorption, in fo meagre a foil.

Grafts and annual plants, in general, have fibrous roots. Such have a natural direétion downwards, and penetrate with facility through the foftest parts of the foy, their extremities chiefly being elongated, or rather formed, as they go. If they grow in water, or a perfectly homogeneous foy, where the refilience is every where equal, the fibres are quite ftraight; but this being fearely ever the cafe in ordinary ground, they assume that contorted and divaricated figure we ufually obferve in all roots.

Some parafitical plants have a peculiar kind of fibrous roots, which attach them to the branches or freams of trees, and therefore are bare on one fide. They may absorb moifure by that fide from the air, perhaps in as great abundance as they derive nourifhment on the other from the tree. See Root.

Fibrous-rooted Plants, in Agriculture, are all thefe which have fine thread-like roots which spread out laterally near the surface of the ground, without flinking very deeply into it. They are diftinguifhed into feveral different sorts from the nature of the roots and the manner in which they grow. See Fibrous Roots and Root.

Fibrous Roots, in Gardening, all fuch as confift principally of fimul filaments or fibres. There are great numbers of plants which have roots of this kind, both of the flower and other decriptions. They are likewife diftinguifhed into different fronds from the nature of the roots: when the roots penetrate downwards in a direct manner, they are determined by particular; when they creep under the furface, horizontal, and creeping; when they are thicker, folijy; when extremely thin, capillary; when they run all the way undivided, simple; when they are divided as fend of smaller roots, branched; and when covered with very fine fhort fibres on the furface, hairy. See Root.

Fibrous Shells, in Natural History, is a name given to certain fojiil shells which have acquired, on account of their breaking abruptly acrofs, and leaving a fibrous or transversely ftriated texture, which occurs their thus breaking short, and being fo brittle, that very few if any of the shells can be obtained whole. A very fingular kind of fuch fibrous shells abounds in certain beds of the chalk flatas, mostly in small fragments; and the fints which interlaven the chalk beds have often, in these cases, their fragments set or imbedded in their folid fubfiance. Often when, fome fints are found among alluvial matter, and broken, the pieces of fibrous shells are decomposed and gone, and a fingular narrow and deep cavity, like a fmall mortife-hole, is fet; a circumflance which moft obervers, in or to the well of chalk dilfrac, cannot fail to have noticed. In the great alluvial mafles of Bedfordshire, at ten or fifteen miles from the edge or ending of the chalk flatas, these fints, with fibrous shells in them, and sometimes large and nearly perfect fibrous shells, are found among the fints and other ruins or fpoils (as Woodward calls it) of the chalk flatas, which is mixed with the chalk of the flatas, superior to the chalk, as should seem from the large Ladius Helmontii and others of its products, which are found mixed in the greatest confusion, through the fubfiance of hills, many miles long, one or two wide, and eighty or one hundred feet high, which are there found, of thefe dilfuall alluvial matters, covering the regular fan and other fints of the dilfrac, and wherein fragments of grey-weathers, the produce of the uppermost and flatas above the chalk, are found, some of them weighing a ton or more.

Fibrous Spars, in Mineralogy, is a variety of calcareous fpar, (carbonate of lime,) found in Derbyshire, and elsewhere, which is often manifefled on the furface, owing probably to hollows in the furface of the fparre or crack which it once filled; the fpar or fpara of this fpar crofs it tranfverfly, and occasion its fudden and fandy fracture, like the fibrous fsh above defcribed. Fibrous fpar is very common in the fparres near the top of the fird or upper edge, as in the entrance cut to Hockley lime-quarry, near Aiton, over town, a quarter of a mile N.E. of Bontal church, in Longstone-edge mine in Longstone, Whednedge mine in Alnover, &c.

Another kind of fibrous calcareous fpar (fpar-plate of lime or gyplan,) is dug at Elvaston, Cheadle, Tutbury, and other places, in or near Derbyshire: it lies in the flatas, the fpar or fpara of which crofs it vertically, and occasion nearly a fimilar fracture in that direétion to that of the fpar and flata above defcribed.

FIBULA, in Anatomy, the fmall bone of the leg.

Fibula, in Natural History, a name given to a class of the echinodermata, which have their mouth in the middle of the fide, and the aperture of the anus on one edge. There are found principally among the fojiil kinds, and fome to have had their shells of the affiliated kind, or compofed of fmall plates joined tranfverfly to one another. Of this class there are two genera, the codinus and diploides.

Fibula, in Surgery, an instrument in use among the ancients, for the closing of gaping wounds.
Celsius speaks of the fibula, as to be used when the wound was so patent as not easily to admit of being sewed. Op. lib. vit. cap. 25. apud fin.

Authors are somewhat at a loss as to the form of the ancient fibula. Guido says there were iron circles, or semi-circles, bent backwards both ways; the hooks whereof, being fastened on both sides to the wound, answered exactly to each other; but as this might have been an insupportable pain to the patient, this description is generally left aside.

Falloppius, Sanctorius, and others, take the word fibula to have signified, in reality, no more than the sewing up of the wound with a needle and thread, as used at this day.

**Fibula, Luxation of.** See Luxation.

**Ficaria**, in Botany, Pleworf, so called by Brunfelsius and other old writers, on account of the fig-like tubercles of the root, which resembling the dises of called the piples, the plant was ingeniously supposed to be a remedy for that complaint. The next step was to affirm it to be so, as we find in such writers, "either applied outwardly, or taken internally." As it is very acid, and even caustic, we cannot recommend a trial.

Hudson established the *Ficaria* as a separate genus from *Ranunculus*, see Fl. Angl. 444, on account of the smaller number of its calyx-leaves, and greater number of its petals; but he has not been followed. *Ranunculus* is too natural a genus to admit of such a separation on artificial principles alone.

**Ficedula**, in Ornithology, a name given to several species of *Metacilla*, (which see.) See also *Turdus* triphilus, *Musciaca* atricapilla, and *Parus* americanus.

**Fichant, Figens**, a French term used in Fortification: thus, a flank fchant, or a line of defence fchant, is a place, whence the shots made do not only raze the opposite face to be defended, but also enter within it.

The word is formed of *ficher*, to lick a thing in.

**Fiche**, in Heraldry. See *Fitchee*.

**Ficiteruolo**, in Geography, a town of Italy, in the department of the Lower Po, on the Po; 13 miles W.N.W. of Ferrara.

**Fichtelberg**, a mountain of Franconia, which extends from the vicinity of Barenth to Eger in Bohemia. It is one of the highest mountains in Germany, and contains in it many deferts, rocks, bogs, and morasses. It takes its name from the great number of pines, with which it is covered; it also has many oaks, beech, elm, and other kinds of trees. The extent in length is 22 English miles, and 16 miles in breadth. The summits have various names: the Oichenhof being reckoned the highest. The lake, called "Fichtelsee," is a cavity of this mountain, called the See Loh, and is remarkable merely as the source of the White Mayn. Other parts of this mountain give rise to the Eger, which runs to the E., and the Sala and Nab flowing to the N. and S.

**Ficinus, Marsilius**, in Biography, a celebrated physician, divine, and philosopher, was born at Florence A.D. 1433. His father being physician to Cosmo de Medici, the son was noticed by that liberal prince; and on the death of his father, Marsilius obtained the same honourable distinction. He studied not only medicine and divinity, but acquired the knowledge of both vocal and instrumental music and could perform upon several instruments. He was profoundly skilled in the Latin, Greek, and other learned languages. Under the patronage of the house of the Medici, he might have acquired not only fame, but wealth; more especially after he had, by taking holy orders, rendered himself capable of holding the valuable preferments in the church, belonging to that illustrious family. But, a total stranger both to covetousness and ambition, Ficinus was content with the appointment of a canonry in the great church of St. Laurentius, in his native city, and some small estates in the vicinity, beloored upon him by his patron. Although now an ecclesiastic, who exercised all the duties of his profession, yet he continued to prosecute physic; the profits from which latter profession he devoted to the use of his nephews and nieces, and other collateral poor branches of his family. The cardinal John de Medici, having been raised to the sovereign pontificate, under the name of Leo X. Ficinus received an acquisition to his fortune. He was appointed professor of philosophy, he became exceeding popular, and his lectures were crowded with students from every country; many of whom, becoming in their turn celebrated, enhanced still higher the professor's fame. He certainly appears to have possessed great merit in the didactic chair, although in his illustrations he adopted the reveries of judicial astrology; but in this he was not flagr? it was a mania that seized most of his contemporaries among the philosophers. He spent much of his time at his country house, Correggio, near Florence, at which agreeable retreat he was visited by numerous friends, who, like him, could relish the refined pleasures of philosophical retirement, and the charms of physical conversation. So respected was he, that Ficinus could number among his friends some of the ablest of mankind, and the most exalted in rank: doctors, philosophers, bishops, cardinals, and even princes; the celebrated patron of every thing great and good, Lorenzo the magnificent, esteemed it an honour to be cloathed in the number. The solitude that he adopted arose from motives of inclination and necessity. Habituallly contemplative, retirement was pleasing; and naturally exceeding delicate, repose from the bustle and cares of public life at times became essential to his existence on earth. Sensible of his infirmity, he endeavoured to preserve his health by means bordering upon ridiculous superstition. He would, it has been observed, charge his calotte, or under cap, six or seven times an hour. All methods, however, proved unavailing, so that he at length fell a victim to a weak constitution, at the age of sixty-six, A.D. 1499. Sweetness of temper, moderation in disputation, and modesty of manners, were features eminently conspicuous in his character; and he was no less distinguished by his extensive learning, that his genuine piety, fave that the former perhaps was too much tingured with the Grecian philosophy, and the latter too strongly shaded with the gloom of superstition.

His works are numerous and diversified; they contain observations upon physical, metaphysical, moral, and religious subjects. Opuscula de Sole & Luna, various translations from the works of Plato, Plotinus, Jamblichus, Proclus, and other Platonists, and the Platonic syllem thus became fashionable in Italy. The translations are not always accurate, and through all a bias is evident in favour of that philosophy. He would seem persuade his readers, the writers of that school must have been believers in divine revelation. His *Theologia Phatonsica* was printed at Florence in 1582; his *Epitole*, in twelve books, at Venice, 1495; and his whole works were collected and published in two volumes, folio, at Bafle, in 1776. Moret, *Grand Dictionnaire Historique*.

**Ficks**, in Rural. Economy, a term signifying to struggle with
with the legs, as a cow in the tie, or a horse in the fetters, &c.

FICTELOW, in Agriculture, is a term which is sometimes applied to the fore-tackle, or carriage which supports the plough-team.

FICOIDEA, in Botany. See Aizoee, species 2d.

FICOIDEE, the 87th natural order in Juciffen's System, or the 5th of his fourteenth class. The name is taken from Ficuidea, applied by Tournefort to the Menzembranthecam of Linnaeus, which is one of this order. The definition of this class is, Cyzadenes two. Flowers polysepalous. Stamps inserted into the calyx, which is of one leaf, superior or inferior, divided more or less deeply. Carpella inserted into the calyx, generally polysepalous, sometimes wanting, rarely monogynous, by a connection, as it were, of several petals into one. Stamps definite or indefinite in number, often distinct, sometimes united by their filaments. German superior, simple or manifold, or rarely inferior and simple. Styles one or many to each germin, sometimes none; stigma entire or divided. Fruit sometimes simple, superior or inferior, of one or many cells; sometimes, but rarely, manifold, superior, each pericarp being of one cell. Sometimes, by abortion, the sexes become separate in different flowers.

The Ficuideal are thus characterized. Calyx of one leaf, inferior or superior, definitely divided. Petals mostly indefinite, inserted into the upper part of the calyx; sometimes wanting, in which case the calyx is coloured within. Stamens more than twelve, often numerous, inserted into the same part; authors oblong, incumbent. German simple, superior or inferior; styles several; stigmas as many. Fruit either a capsule or berry, with as many cells as there are styles, each containing several seeds attached to their inner angle. Embryo incurred, surrounding a farinaeose albumen. Stemon herbaceous or somewhat thrubby. Leaves opposite or alternate, generally fusculent, mostly various in shape. The first section, which has a superior germin, contains Reaumuri, Nitarria, Scenium, Alzoon, and Glans, with Orygia of Furlkall; the second, with an inferior germin, has Menzembranthecam and Tegragoniam. The plants of this natural order are alkalecent, secreting of themselves soda, or soill alkali, independently of soil or situation, though they naturally grow for the most part in maritime places.

FICOIDES. See Menzembranthecam.

FICORONI, Francisco D', in Biography, a learned and celebrated Roman antiquary, author of an excellent treatise on the theatrical masques of the ancient Romans, with engravings from ancient gems, coins, marbles, and bronzes, upon nearly 100 leaves, well executed, and first published at Rome in 1735, 4to. This work is replete with erudition on the subject, and is at once curious, amusing, and instructive. It is peculiarly connected with dancing, satirization, comic verses, and the musical declamation and melody of the ancients. The wide mouth in the form of a shell, says Ficoronit, so common in the ancient masques, served to augment the power of the voice, upon the principle of a speaking-trumpet. "Quella bocca a condughia, che vede in altre mascher, serviva per ingrandire la voce, come succede nelle trombe a proporzione." See MASQUES.

FICTA, Lit. feigned; as Mufica facta, note transposed out of the hexachords to keys that require flats and sharps, used in old times to be thus called. Ficta, f. e.

FICTION. See FABLE.

FICTION of a person in Rhetoric. See PROSOPEIA.

FICTION of Law, Fictio Juris. Fictions are allowed of in law, in several cases, but must be framed according to the rules of law, not what is imaginable in the conceptions of man; and there ought to be equity and possibility in every legal fiction. There are many of these fictions in the civil law; and by some civilians it is said to be an assumption of law upon an untruth for a truth, in something possible to be done, but not done. (Godolphin and Bartol.) The fictions of the connive in a fine is but a fiction in our law; it being an inverted form of conveyance only. (1 Litt. Abr. 612.) And a common recovery is fictio juris, a formal act or declaration, issued without a cause, where a man is directed to cut off an esche tail, remainder, &c. (15 Rep. 42.) The proceedings in ejected men are also grounded on a fiction, or false representation of law, a bond made by a feudal man may be pleaded to be made in the place where made, 42s. 6d. in Flintmgton, in the county of Middlesex, &c. in order to try the same here; without which it cannot be done. (Cor. Litt. 281.) And thus it also is in some other cases; but the law ought not to be satisfied with fictions, where it may be otherwise really satisfied; and fictions in law shall not be carried further than the reasons which introduce them necessarily require. 1 Litt. Abr. 610. 2 Hawk. 325.

FICTIOUS PLAINTIFF, denotes one not in being at all, or who is ignorant of the suit. The offence of suing another in the name of such a plaintiff, if committed in any of the king's superior courts, is left, as a high contempt, to be punished at their discretion. But in courts of a lower degree, where the crime is equally pernicious, but the authority of the judges not equally extensive, it is directed by Stat. 5 Eliz. 2. to be punished by six months' imprisonment, and treble damages to the party injured.

IFICUS, in Botany, an ancient Latin word of uncertain derivation. The Fig-tree. Linn. Gen. 525. Am. Acad. v. 1. 23. Schreb. 746. Vahl. Enum. v. 2. 118. Hoff. 420. Tourn. 1. 422. Curt. t. 91. Mart. Mill. Dist. v. 2. Clas. and order, Dioscoridia Triacidia. Linnaeus placed it in Polygamaia Triacidia, because the Cupricus, or Wild fig as it is called, has entirely male blossoms, while the cultivated figs have on one tree more perfectly male, on another female, flowers. The different structure of the partial calyx in the two flowers, authorizes its being kept in Dioscoridia at least, though Vahl removes it to Triandria Mouyngia. Nat. Ord. Scabridae. Linn. Urtices. Juff.

Gen. Ch. Common Receptacle somewhat globular, flaky, concave, cloaked with several scalefs within the orifice. Its inside is lined entirely with numerous florets; the uppermost, or those nearest the orifice, being males; the rest, more numerous, females; all separately flowered.—Male, Cal. Perianth deeply three-lobed, rarely more, erect, its segments lanceolate, erect, equal. Gen. none. Stam. Thre. leaves three, bristle-shaped, the length of the calyx; authors two-labeled. Pit. a deciduous twinned segment only.—Female, Cal. Perianth inferior, in five deep, lanceolate, pointed, straight, nearly equal segments. Gen. none. Pit. Germen oval, filling the perianth; style aw-shaped, reflexed, lateral; stigma two, pointed, reflexed, unequal. Peric. none, except the perianth enlarged and become papil. Seed one, roundish, compressed. —The male florets are commonly abortive in all the figs of one tree, the female ones on another. Those figs which are entirely male, as above-mentioned, are considered as most essential for propagation, and for constantly improving the fruit of the female trees. Hence the curious history of Capricaman. See that article.

The species of this most natural genus are prodigiously more numerous than Linnaeus had any idea of. This last edition
Ficus.

Section 1. Leaves undivided and entire.
1. F. religiosa. Linnae. Sp. Pl. 1514. (Arculus; Rheed Hort. Mal. v. 1 47. t. 27.) "Leaves ovate or heart-shaped, entire, very long-pointed. Fruit sessile."—Native of the East Indies, where it is treated by the Hindus with superstitious veneration, their God Vishnun having been supposed to be born under it. Christiana calls it the Devil's tree. The leaves are evergreen, smooth and shining, of a fine green, alternate, on long stalks, elegantly pendulous. Fruit the size of a large pea, dry and tadpole-shaped. This tree grows readily in our flaves.

2. F. popolifolia. Vahl. Synth. v. 1 82. t. 22.—"Leaves nearly cordate, acute, Fruit stalked, in pairs."—Native of Arabia, introduced by Forster for the preceding. Fruit-stalks an inch long. Whole plant very smooth.

3. F. Pilafii.—Leaves ovate, somewhat heart-shaped, pointed, very smooth, finely veined. Fruit foliaceous, globose.—Gathered by Dr. Buchanan at Nasin hotty in Nepal, in D. 1802. The Nawars call it Pilafii. It is a tree, generally parasitical. Leaves about three inches long, on stalks one-third their length, resembling the leaves of a Poplar. Fruit smooth, the fize of a black currant.

5. F. nymphaeifolia. Linn. Mant. 395.—"Leaves heart-shaped, roundish, pointed, smooth, glaucous beneath."—Native of the East Indies. Leaves like those of Nymphaea alba in fize and figure, but very glaucous beneath. H. Linn.

7. F. polila. Vahl. Enum. n. 7.—"Leaves ovate, inclining to heart-shaped, pointed, smooth, even, entire."—Found in Guinea by Hert. Leaves two inches or more in length, veryiny. Fruit stalked, smooth, globose, the fize of a hazel-nut.

8. F. Chinn. Forbb. Arab. 219.—"Leaves heart-shaped, rough."—Native of mountains in Arabia, where it is called Chinnas. It resembles F. Sycomorus, n. 85, except in the asperity of its leaves, and like that has an edible fruit. We have specimens gathered by the late sir George Staunton in the island of St. Jago, under the name of Sycomorus, which appear to be the Chinnas.

9. F. cf. palmata. Ait. H. Kew. v. 3 452.—"Leaves ovate, heart-shaped, with a deep narrow sinus; entire, smooth, acute, green on both sides."—East Indies.

11. F. legginga. Vahl. Enum. n. 10. —"Leaves ovate-oblong, somewhat heart-shaped, pointed. Fruit lateral and axillary, stalked, in pairs."—Gathered by Mr. Ryan in the island of Montserrat. Leaves thin, three or four inches long, veiny. Fruit the fize of a pea, with a minute calyx under.

12. F. sebra. Forbb. Prod. 746.—"Leaves ovate, somewhat heart-shaped, oblong, rough beneath. Fruit top-shaped, without a calyx."—From by Forber at Tanna and Namoka. Leaves half a foot long, remotely toothed; roughish above; rough, paler, slightly downy beneath. Vahl.

13. F. citrifolia. Lamarck. Dier. v. 2 404. (Plum. Ind. t. 131 f. 2.)—"Leaves oval, somewhat heart-shaped, sharpish, entire, ribbed, smooth on both sides. Fruit globose, foliary, stalked, axillary."—Salt Indies. Cultivated in the Paris garden. Leaves more heart-shaped at the base than Plumier represents them. Figs bigger than a walnut, green, white within, almost tadpole-shaped. Lamarck.

15. F. scandens. Lamarck. Dier. v. 2 453. (F. stipulata; Ait. H. Kew. v. 3 452.) Leaves heart-shaped, unequal at the base, smooth, reticulated with veins beneath. Stipulas acute. Branches thread-shaped, creeping.—This is supposd to be a native of the warmer parts of America. It is common in the European flaves. The fume creep up the walls, and throw out numerous, alternate, subdivided, slender, leafy, downy branches, making an elegant evergreen tapestry. Leaves alternate, on very short downy stalks, heart-shaped, obtuse, entire, unequal at the base, dark shining green, smooth, reticulated with pinnate veins beneath. Stipulas inerfolaceous, in pairs, as long or longer than the footstalk, brown, membraneous, ovate, pointed. It has never fruited in England or France, but we have received from the flaves in the royal gardens near Lisbon, by favour of Mr. Correa, branches laden with fruit, of a top-shaped form, purple, nearly as big as common figs, but infix, which were positively ascertained to be produced by the plant in question. These branches moreover are thick, firm, and straight, furrowed, bearing leaves ten times as large as those above described, quite coriaceous, exactly ovate or elliptical, equal at the base, exquisitely reticulated with prominent veins beneath, and punctuated between them, as well as a little hairy. The whole, in short, of these speciments accords with F. puniutta, n. 46, hereafter described, and nothing but our perfect confidence in our correspondent's accuracy could induce us to believe there were not some mistake. Lamarck mentions Mr. Correa's information, but had seen no speciments.

16. F. stipulata. Thumb. Diff. 8. —"Leaves heart-shaped, unequal at the base, reticulated with hairy veins beneath. Stipulas acute. Branches round, decumbent.—Native of Japan. Thumb. China. Herb. Linn. The branches are decumbent and creeping, compound, round, minutely downy, reddish brown, often scaly with the permanent stipulas after the leaves are fallen. Leaves much like the leaf, but the veins at the back are stronger, more crowded, and more curiously reticulated, as well as roughish or hairy. Stipulas like the former. Fruit unknown. We are inclined to think it this he differ from the last, of which there is some question, that F. puniutta may be this in a perfect state. —We have other speciments of creeping kinds, which perhaps undergo a similar metamorphosis when they fructify, and
and which ought to teach botanists caution in defining the species of this genus.

17. F. foetida. Vald. En. n. 16. — "Leaves heart-shaped, oblong, acute, rough on both sides. Stem creeping." — Native of Java, where it runs up trees. Herb. Linn. Stem creeping, by roots opposite to each leaf, downy when young. Leaves alternate, two or three inches long, heart-shaped, equal at the base, entire, acute, roughish to the touch, dotted beneath. Fruit stalks downy, near half an inch long. *Sigillus* lanceolate. Our description will be found to differ a little from Vald.'s, but not materially.

18. F. pedunculata. Ait. H. Kew. v. 3. 420. (F. arbor americana, &c. Pluk. Alm. t. 178. f. 4.) "Leaves ovate-oblong, heart-shaped, acute, smooth. Fruit globose, on long twin stalks."—Native of America and the West Indies. Jacquin first sent it to Europe from Martinique, and it was long kept in the gardens for *F. indica. Leaves* from three to six inches long, and one or two broad, smooth; paler and opaque beneath. *Fruit* the size of a pea.

19. F. menzies. Ait. H. Kew. v. 3. 451. (Tsjakela; Rhodee H. Mal. v. 5. 87. t. 69.) — "Leaves ovate, somewhat heart-shaped, acute, smooth, with impressed dots below. Fruit large, globose."—Native of the East Indies. *Leaves* are a span long, two or three inches broad, on long stalks. *Fruit* the size of pepper-corns.

20. F. radicans. Leaves lanceolate, acute, smooth. Fruit in radical clusters.—Gathered by Dr. Buchanan in the East Indies, probably in the Myfory country. Stem shrubby, branched, smooth. Leaves crowded, three or four inches long, scarcely one broad, pointed, paler beneath, minutely dotted, but not rough to the touch. Fruit stalks scarcely an inch long. *Sigillus* longer, lanceolate, deciduous. *Fruit* in clusters from the root.

21. F. neriifolia. Leaves elliptic-lanceolate, pointed, smooth, with parallel veins. Fruit top-shaped, sessile, finely furrowed.—Gathered in Feb. 1805 at Narain betty in Nepal, by Dr. Buchanan. It is called there *Dud Cbuffi*. Stem arborescent. *Branches* furrowed, smooth. Leaves yellowish green, about three inches long, with narrow parallel lines, and numerous parallel, transverse veins. Fruit stalks furrowed, hardly an inch long. Fruit solitary or in pairs, of a hard nut, perhaps larger when ripe of the Guiana.—A tall tree. Leaves from four to eight inches long, coriaceous, with white ribs, and fine reticulations. *Fruit* axillary, scarcely so big as a cherry, yellow, chesnut-coloured when ripe.

23. F. ovata. Ibid. n. 20. — "Leaves ovate-oblong. Fruit sessile, in pairs. Common calyx hood-shaped, deciduous; that of the fruit torn into two parts."—Gathered by Thoning in Guiana. A tall tree, with somewhat whorled branches, often rooting. Leaves from five to eight inches long, rather leathery, with white ribs. Young fruit covered with a soft hairy, cut round at the base as the fruit swells, and deciduous. *Figs* the size of plums, inclining to ovate.

25. F. Granatum. Forst. Pl. Eschul. 37. — "Leaves ovate, entire. Fruit stalks terminal, in pairs, horizontally divaricated. Fruit globose, with a calyx."—Native of the life of Tanna, where it is also cultivated for the sake of the fruit, which is sweetish, but watery and rather thin, larger than common figs, red with yellow spots, and slightly downy; internally purple, soft and pulpy. The tree is tall, with an angular rough trunk, and long ascending branches. Leaves a span long, smooth, dark green above, with a few yellow veins; brighter underneath. *Fruit* on short thick stalks, from the blosom of the uppermost leaves. *Lunds* terminal, sharp-pointed, clothed with brown hairs. *Fecum*.

27. F. Taba. Forst. Arb. 219. — "Leaves in pairs, flaked, ovate, entire."—Gathered by Forstall at Zebul in Arabia, where it is called Taba. The leaves are four inches long. No other botanist appears to have seen this species.

28. F. Ampelos. Burm. Ind. 226. Linn. Dict. v. 2. 496. (Folium politum, Ampelops; Rumph. Amb. v. 4. 184. t. 63. Teregam; Rhodee H. Mal. v. 3. 77. t. 59.) — "Leaves ovate, acute, rough. Fruit solitary, flaked, rough, with an open scaly mouth."—Native of Malabar. The branches, *fruit stalks* and leaves are extremely rough, with minute cartilaginous points; the latter are about a span long, three-ribbed, but the lateral ribs are short, and run into thin transverse veins, as Rumphius describes them. His synonym appears to us more certain than that of Rhodee, whole leaves are too small, and fruit not like our specimens. The latter may possibly be *F. pericarpia* of Loureiro, quoted by Vahl under *Ampelos*, as that is laid to have small leaves. The fruit in our's is like a small gooseberry, rough, the mouth beft with numerous prominent, recurved scales. *Fruit stalks* axillary, filaments recurved, with ribs, half an inch long. The leaves are said to be very useful for polishing fine cabinet work, or toys, of wood, ivory, or coral. They are not, however, to fine a file as Dutch rubres, *Taxifilum bu runners*. The Abricours name, as made into Greek by Burmann, only tends to deceive.

29. F. fisurifera. Burm. Ind. 226. (Itty-alu; Rhodee H. Mal. v. 1. 45. t. 26, according to Vald.) — "Leaves ovate, pointed, fringed."—Native of Japan. *Fruit* East Indies, according to Juffieu's herbarium. *Vall.* The latter describes the leaf quite smooth, two inches long. *Fruit* globose, rather bigger than a pea, rough with elevated points. *Fruit stalks* very short. It seems not certain that Vahl and Burmann mean the same plant, and the former copies the *same* synonym of Rhodee, after Linnaeus, for *F. benjaminia* in his next paragraph.

parts of the East Indies. It forms a tall tree, with innumerable, slender, zigzag, leafy branches, with a rugged bark. Leaves an inch or inch and half long, flaked, exactly ovate, with an elongated point, entire, very smooth and shining, dilated by numerous, transverse, straight, parallel veins, which do not reach the edge. The fruit is axillary, solitary, on a stalk a quarter of an inch long, bearing two or three small round scales about the middle, and several more under the fruit, which, in the very early state now before us, is the site of multiform, smooth, crowned with two or three long projecting scales from its mouth, to like frugus, that if we had not the function of the moss able botanists, we should have great doubt of this being a Ficus.

31. F. infrasolitana. Buch. MSS.—Leaves ovate-oblong, taper-pointed, entire, smooth. Fruit below the leaves, scattered, flaked, globose.—Gathered by Dr. Buchanan in March 1803, by the way side at Lohair in Nepal. This tree has the aspect of F. religiosa. Leaves deciduous, about three inches long, and above one broad, with several parallel transverse veins, and innumerable reticulated ones between them. Fruitstalks an inch or inch and half long, smooth, channelled. Stipulas downy, deciduous. Fruit from about the top of the last year's shoots, globose, smooth, the size of a gooseberry, on short thick stalks, mottily tinctuate.

32. F. macrophylla. Roxb. and Buch. MSS.—Leaves roundish-ovate, pointed, five-ribbed at the base; smooth above; finely downy beneath. Native of the East Indies. Young branches, stipules and fruitstalks downy, as well as the back of the leaves, which are eight or ten inches long and fix or eight broad, wavy at the edge, paler beneath, reticulated with innumerable transverse rectangular veins.

33. F. bengalensis. Linn. Sp. Pl. 1514. Trew. Enl. t. 59. (Pereira; Rheed. H. Mal. v. t. 49. t. 28.)—Leaves ovate-oblong, obtuse, smooth above; somewhat downy beneath; ribs radiating from above the base. Fruit globose, softly, crowded.—Frequent in the East Indies. A tall and stout tree. Leaves coriaceous, rather elliptical, four or five inches long, minutely downy beneath, their five ribs meeting a little way above the base. Fruit generally in pairs or crowded, as large as a bullace plum, red, downy, encompassed with a broad calyx, of several downy leaves, at the base. Our specimen from the Hirta Chloriflorus agrees with one sent by Dr. Roxburgh from Bengal. In both the leaves are decidedly downy beneath, though described as smooth. We have also from Dr. Roxburgh what seems a variety, with rather narrower leaves, very downy beneath, and fruit no higher than peas, equally downy, generally in pairs, and very abundant.

34. F. rubiginosa. Ventenat Jard. de la Malmaison. t. 113. —Leaves elliptical obtuse; smooth above; downy and rubly beneath. Fruit globose, nearly flask. Calyx downy, almost as long as the fruit. —Native of New Holland. Cultivated in the greenhouse at Kew, where it fruits about midsummer. So abundant, with rich downy branches. Leaves three or four inches long, and two broad, coriaceous, evergreen, flaked, clothed beneath, especially when young, with soft, dark, rubly, purplish down, and furnished with numerous transverse parallel veins, of which the lowermost do not grow in a radiating manner like the last species. Fruit axillary, solitary, the size of a floce, reddish, dotted, enveloped, till half grown, in the brown downy calyx.

35. F. callosa. Willd. Diff. 25. t. 4. Vahl. Enum. n. 29.—"Leaves oblong, obtuse, narrower at the base, with two callous dots; rough beneath." —Native of the East Indies. Leaves smooth and shining above, paler beneath. Fruit globose, umbilicated, the size of a cherry. Wildman.

38. F. racemosa. Linn. Sp. Pl. 1515. (Attia; Rheede H. Mal. v. t. 43. t. 25.)—"Leaves elliptic-ovate, acute, dotted on the upper side. Fruit febilis, top flapped, downy." Vahl. Native of the East Indies, in Sandy soil. A tall and spreading tree. Branches downy in the upper part. Leaves flaked, remote, two or three inches long, narrowed at each end, especially the upper, acute, flitted, in a manner, with ribs, somewhat venous, smooth on both sides, dotted on the upper when examined with a microscope. Fruit stalks rather downy. Fruit pear-shaped, flaked, downy. Vahl.—We know this only by the above authorities, having no authentic specimen. The fruit is not febilis in Hort. Malab.

39. F. glomerata. Roxb. Corom. v. 2. 14. t. 123.—Leaves elliptic-ovate, acute, not dotted above; minutely granulated beneath. Fruit clustered, flaked, top-flapped, downy. Generally found near villages, and about rivers and water-courses in Bengal, where the soil is rich and moist. Fruit eaten by the natives, but Dr. Roxburgh thought it disagreeable; purplish, the size of a pigeon's egg, growing many together on the young branches, each on one stalk. Leaves four or five inches long, smooth above; feeling roughish beneath.

41. F. indica. Linn. Sp. Pl. 1514 e. Lamarcck. Diff. v. 2. 394. Cluf. Exot. 1. (F. cotonefolia; Vahl. Enl. n. 34. Catu-alus; Rheede H. Mal. v. t. 73. t. 57.)—"Leaves ovato-lanceolate, coriaceous, downy beneath. Fruit febilis. Branches taking root at the extremity."—Native of the East Indies, where it has been celebrated from the most remote antiquity, for its property of letting its branches droop and take root, so extending itself by that means, that a single tree forms a curiously-arched grove. We cannot therefore approve of Professor Vahl's innovation, in transferring its ancient name to another, which Linnaeus thought a variety, but which is totally distinct. See our note. These leaves are three or four inches long, pointed. Fruit globular, the size of a large gooseberry, reddish, sweet, but not pleasant-tasting.

42. F. Toba. Forck. Arab. 219.—"Leaves two-ranked, rough, ovate, acute, entire, alternate, flaked."—Found by Forckall in Arabia, where it is called Toba, which is all we know concerning it.

43. F. santriata. Thumb. Diff. 9.—"Leaves oblong, emarginate, smooth, dotted beneath. Stem zig-zag, throwing out roots."—Native of the East Indies. Stem parasitical, creeping to a great extent, round, rugged, brown, hardly to thick as a goose-quill, branchless; the ultimate divisions very short. Leaves obtuse, only from half an inch
FICUS.

... to an inch long, spreading or reflected, their margin entire, a little reflexed. **Footstalks** very short. Fruit obovate, almost as large as the common *F. carica* Linn. — We suspect this ought to be placed near *ficus* n. 15, but we are unwilling to disturb Vahl's arrangement. It seems by analogy to confirm the report there given of the fruit of that species.

44. *F. peruviana*. Linn. Suppl. 442; excluding the synonym. — Leaves elliptical, pointed, very smooth. Fruit globose, umblicated, flaked, axillary, in pairs. *Calyx* in two lobes. — Native of Surinam. Whole plant smooth. *Leaves* two or three inches long and one broad, taper-pointed, with fine transverse veins. **Footstalks** half an inch long. **Fruit** the size of a pepper-corn, on a stalk nearly its own length. *Calyx* small, in two deep, recurved segments. Vahl describes the fruit in clusters an inch long, which is altogether unfounded. He also copies from the **Suppl. Plantis** an erroneous synonym of Plummer, t. 132. f. 3, which he had just before similarly applied to *F. americana*.

45. *F. xanthocarpa*. Buch. MSS. — Leaves ovate-oblong, pointed; smooth above; downy and glaucous beneath. Fruit solitary, axillary, ovate, hairy, on flaks as long as the footstalks. Stem trailing. — Gathered, in May 1862, by Dr. Buchanan, in the woods of Upper Nepal, where this and others of its genus are called *Swieflis*. — Stem trailing, milky, as thick as the thumb, branching out, at the top of the tree that supports it, into many spreading, alternate, downy, leafy shoots. *Leaves* about three inches long, reflexed at the margin, very veiny, three-ribbed at the base; their under side whitish, downy, finely reticulated. **Footstalks** half an inch or more in length, hairy. **Footstalks** rather larger. Young **fruit** the size of a hazel-nut, somewhat angular, oblong, very hairy. *Calyx* very small, and a little remote, of three hairy leaves.

46. *F. rumblidis*. Linn. Sp. Pl. 1515, but not SYST. VEG. ed. 14. 922. (F. sylvester procedens, folio liripeti; Kempt. Amea. 803. t. 804.) — Leaves ovate, smooth, very closely reticulated beneath. Stem jointed, creeping. Fruit flaked, nearly as long as the leaves. — The only certain knowledge we have of this Fig. 3 from Kempter, who describes it as running up walls and rocks in Japan, the branches being marked with annular contractions. *Leaves* evergreen, scattered, flaked, about two or three inches long, hard, rigid, exactly ovate, but pointed; smooth and of a rather shining green above; paler, opaque, and most beautifully reticulated with prominent veins beneath, so crowded that there is scarcely room for the point of a needle between them. **Fruit** terebent, on thick, short, recurved, axillary, foliary stalks, the size and shape of a walnut with its coat on, or else pear-shaped, or turbinato with a taper base, hardish, rugged, generally green with a blue bloom, sprinkled with white dots. Nothing can much better accord with the specimens sent us from Portugal than the fruit of *F. scindens*, n. 15. Thunberg's description is still more precise, as he says the leaves are obtuse, and branches furrowed. We have been no authentic specimens of *F. rumblidis*. Linnæus altered the specific character, and added a description, in his *Systema Vegetabilium*, from a widely different plant in his herbarium, the *eritx* of Thunberg; see n. 59.

47. *F. Calabur*. Buch. MSS. — Leaves oblong-obovate, taper-pointed, smooth; very closely reticulated beneath. Fruit flaked, axillary, solitary, globose, hairy. — Native of woods in Nepal, where it is called *Calabur*. Stem bluntish, three or four feet high. **Branches** downy. *Leaves* alternate, four or five inches long, somewhat revolute; very smooth above; whitish and reticulated, like the leaf, beneath. **Footstalks** and **fruitstalks** each about half an inch long, thickish, hairy. **Fruit** the size of a moderate gooseberry, globular, pointed, hairy, slightly ribbed.

48. *F. reflexa*. Tomb. Diff. t. 11. — Leaves elliptical, of life, smooth. Branches recurved. Fruit globular, fleshy. — Native of the East Indies. **Branches** bristled, rugose, sin-coloured, smooth. *Leaves* somewhat obovate, a finger's length, with parallel ribs (or rather veins). **Footstalks** half as long as the leaves. **Fruit** fleshy on the branches, either scattered or crowded, smooth, the size of a pea. *Thunb.*

49. *F. trifida*. Linn. Suppl. 441. (F. folio citri obtuso, fructu sinuoso; Plum. t. 123. t. 132. f. 1.) — Leaves elliptical, smooth, five-ribbed at the base; ribs hairy. Fruit globose, foliary, axillary, flaked; mouth with a triangular border. — Communicated to Linnæus from Surinam. The **branches** are slightly hairy about the extremities only. *Leaves* alternate, three or four inches long, on very hairy footstalks not an inch in length; both sides are smooth and even; the upper minutely dotted; the under scarcely perceptibly reticulated with veins, but furnished with a strong mid-rib, several very straight, parallel, transverse ribs, and at least two radiating ones, on each side, at the base, all hairy. **Fruit** the size of a black currant, on a short thick hairy stalk, minutely downy, with an oblique variously divided calyx, externally hairy, beneath it, and a singular triangular elevated border round the mouth, which is closed. Plummer's figure seems to agree tolerably well, but there is no certainty in his synonym.

50. *F. nitida*. Thunb. Diff. t. 10. (F. microcarpa; Linn. Suppl. 442. Ititi-aracalou; RheeHe H. Mal. v. 3. 69. t. 55.) — Leaves elliptical, bluntly-pointed, somewhat unequal, smooth, with numerous parallel veins. Fruit fleshy, globose, flattened at the top. — Native of the East Indies. Whole plant smooth. *Leaves* two or three inches long, usually oblique or inequilateral, near two inches broad, with a short blunt point; transverse ribs or veins very slender, terminating in one radiating vein within the margin, as in many other species. **Fruit** the size of a pea, enveloped till half grown, in a strong three-clawed calyx; its mouth is always closed with scales folded over each other. — The **footstalks** are short and thick. Vahl overlooked the Linnean synonym, and Lamarck could not ascertain.

51. *F. schleichera*. — Leaves elliptic-oblanceolate, unequal, acute, roughish on both sides. Fruit axillary, flaked, in pairs, globose, rough. — Native of the East Indies, where the leaves are used for polishing ivory, being a very fine file. Every part of the plant is rough with most minute cartilaginous points, hardly perceptible but by the touch. *Leaves* two or three inches long, of a light green, on stalks half an inch long. **Fruit** the size of red currants, with a timid, slightly perforated, mouth. We have some doubt whether Vahl's *roombdulidis*, hereafter mentioned, n. 56, be different from this.

52. *F. composita*. Roxb. Corom. v. 2. 14. t. 125. — Leaves elliptical, pointed, smooth, with numerous transverse veins. Fruit fleshy, in pairs, roundish, with a triangular mouth. — Found by Dr. Roxburgh on the Ceylon mountains. It is called among the Telangas Poota, or Pudda, Jure. A large tree, with flender, often pendulous, branches. *Leaves* two or three inches long, and half as broad; their lateral veins straight and parallel, having numerous reticulations between them. **Footstalks** near an inch long, and rather flender, very different from those of *niitida*, n. 52. **Fruit** when ripe the size of a moderate gooseberry, first purple, then orange.

54. F. aggregata. Vahl. En. n. 43. (V. pandata; Lam. Dict. v. 2. 495.)—"Leaves oblong, obtuse, smooth; dotted on the upper side. Fruit globose, aggregate, feffile."—Gathered by Commeron in the Mauritius, from whose specimens Lamark described it. 

Leaves two inches long, one and a half broad, flaked. Fruit about the tops of the small branches. We know this species only by the above description.

55. F. pulchra. Lam. Dict. v. 2. 520. Vahl. En. n. 44. 

—Leaves elliptic-oblong, with a blunt point, rough with hooked spines. Fruit globose, thick, axillary, solitary, rough.

—Gathered in Madagascar by Commeron, one of whose specimens is before us. 

Leaves about two and a half inches long, scarcely one broad, obtuse, with a little broad obtuse point; pater beneath, with largely reticulated veins; both sides flakey, especially the veins beneath and the edges, are rough with minute white, hooked, rigid prickles; as are the footstalks, fruitstalks, upper part of the branches, and the fruit itself, which is rather larger than a black currant, and purple.

—"Leaves oblong, downy beneath. Fruit axillary, feffile, foliary, downy." Vahl. 

Native of the East Indies. 

Branches round, downy. Leaves two inches long; smooth above; velvety beneath, rather flat; obtuse on downy footstalks, shorter than the leaves. Fruit very small.

Ed. Sciss. Lam. En. n. 66. (V. lepida; Forl. Prod. 76.) 

—Leaves oblong, oblong-ovate, pointed, fruitstalks in pairs, with a small calyx at the top. Fruit warty. Forl. 

Found in the island of Tanna.

57. F. coriacea. Ait. H. Kew. v. 3. 453. 

—"Leaves oblong, smooth, coriaceous; attenuated and heart-shaped at the base; veins faneck."—Grows in the East Indies.

Fruit top-shaped, thick, axillary, solitary, smooth. 

Found in Japan. Stem weak, not perfectly decumbent, round, flitted, smooth. 

Branches scattered or aggregate, erect, straight, leafy. Leaves from two to four inches long, green, and often minutely bristly, above; pale, and reticulated with numerous downy veins, beneath. Footstalks half an inch or more in length, rather downy upwards. Fruitstalks rather longer, erect, with a three-leaved calyx at the top. Fruit the size of a hazel-nut, rather tapering at the base, sweet and eatable.

—"Leaves oblong, fiddle-shaped, smooth. Stem thread-shaped, creeping."—Native of Java. Leaves obtuse, with one side narrower than the other, about an inch long, very finely veined, pale beneath, on very short footstalks. Stem and branches slender, zigzag, brown. This seems to be akin to n. 15 and 16, next to which Thunberg has placed it, and we know not why Vahl, who appears to have seen specimens of the fulvata at least, has removed it to so great a distance.

—"Leaves oblong, pointed, smooth. Fruit ovate, rugged, feffile."—Native of the East Indies. 

Branches round, narrowed, smooth. 

Leaves coriaceous, four inches long, ribbed; green above; 

af-coloured beneath, on thick stalks about half an inch long. Fruit towards the ends of the branches, smooth, as big as plums. Thumb.

62. F. retusa. Linn. Mant. 129.—Leaves oblong, obtuse, very obtuse, quite smooth; three-ribbed near the base. Fruit feffile, globose, smooth. 

Calyx downy. Native of Java. 

Branches smooth, angular. Leaves three inches long, flaked; shining above; opaque, paler and veiny beneath; furnished with a ftraight lateral rib on each side, which vanishes about the middle of the leaf, and several transverse ribs before the fruit. When young, enveloped in a calyx which is externally downy; when full grown the size of a currant, smooth, with broad polished scales at the mouth.

—"Leaves lanceolate-oblong, pointed, dotted beneath. Fruit mostly in pairs, globose, axillary, on wavy smooth footstalks."—Native of the Society Isles. 

Branches smooth. Leaves flaked, three or four inches long, an inch or more in breadth, with very fine nerves, febile, veined, membranous. Fruit the size of a pea, on very short footstalks. Vahl. 

64. F. laurifolia. Lam. Dict. v. 2. 495. Vahl. En. n. 53. (F. virescens; Ait. H. Kew. v. 3. 451.) 

F. indica maxim. folio oblongo, funicularis e funnis ramis deminis radicibus agentibus fe propagatis, fructu minore, fpheroicas, fanguineas; Sloane Jan. v. 2. 142. t. 223.) 

—Leaves oblong-lanceolate, smooth, with a few scattered depressed points above. Fruit feffile, foliary, globose, axillary."—Native of the West Indies. A very lofty tree, according to Sloane, whose upper branches throw out long roots. 

Polynesian of all kinds are fond of the fruit, which is of the size of a hazel-nut, scarlet, sweet, and not unpleasant. The leaves seem to resemble those of the Cherry-laurel.

—"Smooth. Leaves oblong, obtuse, narrowed at the base. Fruit feffile, nearly foliary."—Described by Vahl from Juffieu's herbarium. Its native country is unknown. The branches, according to him, are grey in the upper part. Leaves flaked, three or four inches long, paler beneath, very smooth. Footstalks an inch long. Fruit globose, grey, twice as big as a pea. 

Stipulas lanceolate, attenuated, smooth, as long as the nail. 

66. F. pallida. Ibid. n. 55. 

—"Leaves oblong, somewhat wedge-shaped, smooth, even, obtuse. Fruit axillary, in pairs, on short footstalks."—Gathered by Von Rohr at St. Martha, in South America. Branches greyish. Leaves membranous, two or three inches long, and one broad, bright green, minutely veined, with a yellow rib. 

Footstalks slender, smooth, an inch long. Fruit globular, smooth, the size of black pepper. Vahl.

67. F. extensa. Ibid. n. 56. (Ait. H. Kew. v. 3. 375. t. 58.) 

—Leaves lanceolate, fome obscurely elliptical, acute at one side, and narrower on the other side; at the base. 

Fruit flaked, globose. 

—Native of the East Indies. Branches and leaves smooth; the latter three or four inches long, most veiny beneath, on short footstalks. 

Fruit in pairs, axillary, smooth and even, the size of a pea, on footstalks longer than those of the leaves. Vahl.

68. F. amphisma. (F. indica; Vahl. En. n. 57. F. indica b; Linn. Sp. Pl. 1514. Tejela; Rheed. H. Mal. v. 3. 85. t. 63.) 

—"Leaves broad-lanceolate, long-pointed, smooth. Fruit chaffier, globose, smooth, on short footstalks."—Native of the East Indies. This, according to Rheed, is a tree of vast dimensions, about 70 feet high, and 18 in the circumference of the trunk, with widely-spread branches. 

Leaves flaked; two or three inches long, with numerous, parallel,
parallel, transverse, slender ribs; the point sometimes an inch long. Fruit copious, the size of a pea, inbipid, the food of bats, on which account the Portuguese and Dutch call it the Bat-tree.

69. F. deltisfolia. Vahl. Symb. p. 182, t. 23. (F. indica; Forb. Fl. Arab. 179.)—"Leaves lanceolate, pointed, smooth. Fruit axillary, stalked, in pairs."—Gathered by Forstkall in Arabia, where it is called "Dhab." Of the bark, dried and twisted, matches for great guns are made. The branches, though long and pendulous, do not throw out roots. The whole plant is very smooth. Leaves flaked, from three to five inches long, rounded at the base, dotted beneath, not above an inch broad. Fruit larger than a pea, smooth.

70. F. obliqua. Forbl. Prod. 77.—"Leaves lanceolate, very smooth, with a cartilaginous edge. Fruit-flacks in pairs, very short. Calyx as long as the fruit, deciduous." Forl. A native of the South Sea Islands of Nanoka and Tanna.

Section 2. Leaves undivided, serrated, or toothed.

71. F. semicordata. Buch. MSS.—Leaves half-heart-shaped, slightly serrated, rough; rather hairy beneath. Fruit on wide, flat foot-flacks, stalked in pairs. Hedges in Upnag and Lower Nepal, where it was found by Dr. Buchanan, early in 1822. A large tree, with downy or hairy branches. Leaves above a foot in length, oblong, sharp-pointed, very unequally heart-shaped at the base, paler and veiny beneath, on short, rough, or downy foot-flacks, the larger leaf crossing the branch, and furnished with radiating ribs. Stipulae long, narrow, smooth, deciduous. Flowering branches from the base of the trunk, or even from the roots under ground, drooping, panicked, downy, sometimes leafy towards the extremity. Fruit in pairs from each joint of these branches, globose, hairy, on hairy or downy flacks, with a pair of downy bracteas; when ripe as large as a common plum. The natives eat the figs raw, as well as fried.

72. F. auriculata. Lour. Cochinch. 666.—"Leaves heart-shaped, pointed, somewhat serrated, downy. Fruit auricled, smooth, in terminal clusters."—Cultivated, and probably wild also, in Cochinchina, where the moripe figs are flicid and eaten in balads, instead of cucumbers, which they resemble in flavor. The tree is large, with ample leaves. Fruit turbinate, two inches long, red, in dense, upright, terminal clusters, furnished at its top, besides the usual orifice, with four diametral holes, surrounded with a prominent cartilage, and resembling cars.

74. F. mauritiana. Lam. Dict. v. 2. 499. Vahl. En. n. 62.—"Leaves ovate or heart-shaped, serrated; downy and rough beneath. Fruit globose, somewhat turbinate, flaked, on naked pendulous branches."—Gathered by Commodor in the Isle de Bourbon. Branches, downy, rather bipid. Leaves smooth on the upper side, flat, or less than four inches long, four or five broad, ovate, generally heart-shaped at the base, on foot-flacks two or three inches in length. Fruit larger than a walnut, in pairs. Vahl says, the figure in Hort. Mal. v. 3. t. 67, does not ill accord with this plant. See F. symphylodora, n. 82.

75. F. latiflora. Vahl. En. n. 63. (F. morifolia; Lam. Dict. v. 2. 499.)—"Leaves ovate, somewhat heart-shaped, acute, serrated, smooth. Fruit globose, flaked, below the leaves."—Gathered by Commodor in the Isle de Bourbon. Branches brownish. Leaves resembling those of a mulberry-tree, flaked, green on both sides, scarcely at all rough, about three inches long and wide. Fruit smooth, felted over the naked part of the branches.

76. F. tiliifolia. Lam. Dict. v. 2. 499. Vahl En. n. 64.—"Leaves ovate, sparingly toothed, pointed, unequal at each end, rough on both sides."—Native of Java, and the Philippine islands. Branches, round, rough. Leaves two or three inches long, ovate-oblong, very rough with little tubercles, terminating in a point as an inch long, wavy at their edges, sometimes three-crested, or somewhat pinnatifid. Fruit globose, very rough, rather bigger than a pea, on flalls half the length of the leaf-flacks.

78. F. flacciflora. Burman Ind. 227.—"Leaves flaked, ovate; entire at the base; serrated at the top; yellowish underneath."—Found by Goron at Saramon. The fruit is yellow, resembling a gooseberry, but poisonous. Such is Burman's account, who considers Hort. Mal. v. 3. t. 62. as a variety of this, differing only in having shorter foot-flacks. See F. rufescens, n. 122.

79. F. exasperata. Vahl. En. n. 67. (F. seabra; Willd. Diff. t. 2. Vahl.)—"Leaves oblong-ovate, very rough, pointed, toothed towards the end. Fruit flaked, globose."—Branches rough when young, afterwards smooth. Leaves three inches long, flaked, three-ribbed, downy beneath. Fruit in pairs, rough, the size of a pea, on flalls an inch long.

80. F. symphylodora. Lam. Dict. v. 2. 492. Vahl. En. n. 68.—(Perin-teregam; Rheed H. Mal. v. 3. 81. t. 61?)—"Leaves ovate-oblong, acute, minutely toothed; rough on both sides. Fruit hairy, flaked, somewhat whorled, in long clusters."—Native of Java, and other parts of the East Indies. Lamarch described it from Sonnerat's specimen, and remarks, that the figure in the Hortus Malsbaricus would be tolerably exact, if the leaves were represented without the barks. The leaves are about three inches long, somewhat flaked, with hairy ribs. Fruit globose. Vahl describes the fruit iselible, the size of a cherry. Rheed's plant is a very large long lived tree, laden with fruit, as well as leaves, all the year long.

81. F. maculata. Linnae Sp. Pl. 1515. (F. caffinaria folia, fructu globose mucato; Plante, in 1212. 131. f. 1.)—Leaves oblong, pointed, serrated. Fruit globose, fleshy, in long spikes. Native of America. Plumer's figure, whence the above characters are taken, is our only authority for this species. The fruit is an inch in diameter, besprinkled with spots or warts. Leaves a foot long, regularly and sharply serrated, with innumerable straight, parallel, transverse veins.

82. F. hispida. Linnae Suppl. 443. Thunb. Diff. 13.—Leaves elliptic-oblong, pointed, obscurely serrated, rough on both sides. Fruit turbinate, flaked, axillary, solitary, very brilly. Native of Java. The branches and foot-flacks are nearly smooth, the latter two inches or an inch and quarter long. Leaves near four inches long, rough with minute points, furnished with several unequal, curved, brilly, lateral ribs, and reticulated veins; the edges waved, but feebly serrated. Foot-flacks full half an inch long, covered, like the fruit itself, with numerous rigid, shining, tumid brillies.
Had we not one of Thunberg’s own specimens, we should hardly have recognized the plant by his description.

85. F. oppossimolia. Roxb. Corom. v. 24, t. 124. (F. Daemonum; Vahl. En. n. 71. F. cabra; Jacq. H. Schoenbr.v. 3, t. 24.) — Leaves opposite, oblong, slightly serrated; rough above; more downy beneath. Fruit flaked, angular, very hairy.—Gathered by King and Roxburgh in moist rich soil, about the banks of rivulets, in the East Indies. It is but a small tree, with hollow jointed, hairy branches, which sometimes take root about their extremities. Leaves very unequal in size, from one to five inches long, one or two broad, on thick, hoary stems: the upper side is extremely hairy to the touch; the under hoary, and strongly reticulated. Fruit the size of a large nutmeg, very leathery at the mouth; axillary and solitary on the young branches; on the older ones racemose or clustered; tawny, hoary, seldom eaten. This species being, as far as hitherto discovered, singular in its genus for having opposite leaves: we greatly prefer Roxburgh’s name to any other. The milky juice is said to be poisonous, as in several more.

86. F. montana. Burm. Ind. 226.—“Leaves oblong, with wavy serrations. Fruit very small.”—Native of hills in Java. Known by Burman’s short character only.

Section 3. Leaves angular or sinuated.

87. F. reticulata. Thunb. Diff. 12.—“Leaves elliptical, somewhat angular, toothed, pointed, smooth; reticulated beneath. Fruit globose, foliaceous, slightly leathery.”—Found in the East Indies. Branches erect, smooth, purple. Leaves obovate, tapering at the base, three or four inches long, spreading; paler underneath, on shortish thick stalks.

Ficus. Fruit axillary, smooth, larger than a pen, on a stalk a line in length.

88. F. Sur. Forl. Fl. Arab. 180. Vahl. En. n. 76.—“Leaves lanceolate, waved, very smooth, somewhat heart-shaped at the base. Fruit chaffier on the main stem.”—Native of Arabia, where it is called Sur. This tree resembles the Sycomorus. The young branches, stipules, and under side of the footstalks, according to Vahl, are hairy. Leaves rather coniescent, broad-thin lanceolate, with wavy edge and reticulated at the back. The fruit is described by Forlali as the size of a pigeon’s egg, and eatable.

89. F. aphrera. Forl. Fl. Efcul. 36.—“Leaves unequally heart-shaped, sinuated or toothed, rough on both sides. Calyx obsolete, united to the base of the turbinate fruit.”—Cultivated in the gardens and shrubberies of the island of Tana, for the sake of its fruit, which is sweet and pleasant, as well as of the leaves, which when boiled afford the inhabitants an agreeable drink. Tree four or five fathoms high, with jointed leafy branches. Leaves flat long, on very short stalks, rough and hairy, one side narrower than the other. Fruit axillary, in pairs, fleshy, downy, white; the size of a common fig. Forlali; who cites H. Mal. v. 3, t. 22, as having some resemblance to this species; see rufi—a, v. 102.

90. F. sinaita. Thunb. Diff. 2.—“Leaves elliptical, sinuated or toothed, pointed, smooth. Fruit globose, aggregate, fleshy.”—Native of the East Indies. Branches erect, smooth, green. Leaves oblong, toothed, and somewhat angular towards their points, with a reflexed margin: entire towards the base; pale, ribbed and reticulated beneath, three or four inches long, on stalks the length of the nail. Fruit scattered or aggregate upon the small branches, fleshy, knotty, scarcely to big as pepper. Such is Thunberg’s description, and yet, in his specific character, he calls the fruit flaked.

91. F. jublnfis. Buch. MSS.—Leaves oblong, pointed, hard, naked; here and there jagged. Fruit orbicular, tuberculated, axillary, flaked, foliaceous.—Gathered by Dr. Buchanan on the rocks of Upper Nepal, Jan. 28, 1803. A tree with very numerous, rigid, crooked branches, leafy at the ends only. Leaves two inches or more in length, with a taper point almost an inch long, elliptic-lanceolate, moily entire, but often cut, toothed or wavy in the upper part at one or both edges, veiny, rough to the touch, paler beneath. Footstalks short. Fruit towards the end of each branch, the size of a nutmeg, pointed, covered with prominent warts, not hairy, on stalks twice as long as those of the leaf, thickened above the middle, where there is a small three-angled involucrum.

92. F. rosifera. Lam. Dict. v. 2, 498. Vahl. En. n. 79.—Leaves oblong, unequally angular and wavy, with a linear obtuse point; smooth above. Fruit globose, smooth, on short stalks.—Gathered by Commodore in Java. Branches slender, roughish with minute points when young. Leaves on short rough stalks, two or three inches long, of a singular abrupt and irregular figure, irregularly veiny, reticulated; paler and somewhat harish beneath; the point almost an inch long, rather broadened towards the end. Fruit the size of a pea, axillary, two or three together, on very short stalks. The leaves of this species suggest some idea of the fifth called Cbatoon longroflris, figured in Borlinoet’s Ichthyologia.

93. F. difformis. Lam. Dict. v. 2, 500. Vahl. En. n. 80.—“Leaves oblong, acute, rough, of various shapes; undivided; somewhat angular; sinuated; or deeply laciniated.”—Native of the Philippine islands. We know nothing of it.
it but the above definition of Lamarck, who quotes a
fynonym of Ray which we would rather apply to F.
 heterophylla, n. 99, if that be different from the present,
which we doubt. Lamarck indeed appears to have had two
distinct plants under these names, but his heterophylla is not
that of Linnæus. See rufescens, p. 102.

Section 4. Leaves divided.

Fl. Arab. 179.—Leaves ovate or lobed, serrated, acute,
rough; heart-shaped at the base. Fruit pear-shaped, smooth,
flalked, axillary, solitary.—Native of Arabia. Branches
smooth. Leaves from two to four inches long, sharply fer-
rated throughout, velvety; paler, with purple veins, beneath;
on slender footstalks, full an inch long. Fruit the size of a
hazel-nut, its leaf shorter than that of the leaf, with a small
two-leaved involucrem.

95. F. birta. Vahl. En. n. 82.—"Leaves oblong, un-
divided or three-lobed, finely serrated; somewhat heart-
shaped at the base; smooth above. Fruit small, prickly."—
Native of China. Leaves divergent, three-lobed towards the
extremity; lobes pointed, the lateral ones small; ribs
hairly beneath. Footstalks hairy, an inch and a half long.
Fruit axillary, solitary, the size of a pea. Vahl saw a Java
specimen with some leaves undivided; and two or three
fruits together, twice the above size.

96. F. truncata. Vahl. Symb. v. 1. 83.—"Leaves oblong,
undivided or lobed, entire, rough. Fruit falked, oblong,
abrupt."—Native of the East Indies. Branches angular,
smooth. Leaves above two inches long, on short falked
footstalks, either undivided, or with three, sometimes five,
oblong lobes, the lateral ones blunt. Fruit rough with
minute points, its top as it were cut off abruptly.

97. F. ferrata. Ibid. 83. Forkl. Fl. Arab. 179.—
"Leaves oblong, undivided or palmata, rough, with waty
teeth. Fruit flalked, globose, very rough and hairy."—
Gathered by Forkell in various parts of Arabia, where
the leaves are used to clean and polished rusty iron. Branches
and younger leaves very rough with numerous extremely
minute points. Fruit the size of a hazel-nut, on short
flalks.

98. F. toxicaria. Linn. Mant. 305. (F. toxic a; Thunb.
Dill. 14. F. Padana; Burm. Ind. 226.)—"Leaves ovate,
or heart-shaped, cut and lobed, somewhat toothed; white
beneath. Fruit flalked, ovate, downy."—Found near the
town of Padano in Sumatra, by Garcin, who reports it to
be extremely poisonous. The leaves are a foot long, being
equal in size to those of F. baugherifera. Burman. Fruit
the size of a plum. Thunb.

99. F. heterophylla. Suppl. 42. (F. ducriebula; Vahl.
Symb. v. 1. 93. F. indica sylvestris, inda ifes, &c; Ren
dil. v. 9. append. 5. 12.)—Leaves oblong, undi-
vided, three-lobed and cut, very much toothed; lanth
both sides. Fruit falked, flaked, globose, tuberculated,
rugulose.—Gathered by Reichen in the East Indies, where
it is called Mr. Ait., water 67; from it's inhabiting the
banks of rivulets and other watery places, so overrun with
the prickly ratten, Calamus Ratang, as to be hardly accessi-
ble. The branches are reddish brown, slender, roughish;
angular and downy at their ends. Leaves on short stiff,
rough stalks, green and very rough to the touch, on both sides,
with extremely minute carthaginous points; their shape re-
markably various, some being oblong, undivided, acute,
partly entire, partly toothed for a considerale space, but
quite irregularly; others with a deep wide rounded entire
fult at one, or often both, sides, thus become two or
three-lobed, and are toothed unequally like the former.

Veins pale, forming large quadrangular reticulations. The
length of each leaf is from two to four inches. Fruit the
size of a musquet-ball, pale, covered with very minute
rough points, and with falttered slightly prominent warts,
its mouth obtuse, closed with broad slit flaps. Fruits leaf-
axiliary, thick, shorter than the footstalks, rough with
little prickles, and bearing an involucrem of three small
obtuse coelate leaves, a little below the fruit. The syno-
nym of Linnæus and Vahl are determined by authentic
specimens; that of Ray we can only guess at, but his de-
scription answers exactly to our plant. He says the leaves
are used for polishing wooden furniture, and that the fruit
is mucilaginous, sweet, eaten by children and birds only, but
useful for cataplasm. When boiled and bruised. The inner
rark is given in decoction for the generaha, and to throw
out the measles. We cannot account for Linnæus's de-
scribing the fruit as smooth, nor can we answer for Vahl's
heterophylla being the same as ours, though it is very po-
licable for it might happen to be young fruit only; but ours
in an early stage is rough.

100. F. repens. Ruxb. MSS.—Leaves unequally heart-
shaped, finely toothed throughout, rough on both sides;
undivided; or three or four-lobed. Fruit falked, flaked,
obovate, abrupt, prickly.—Communicated by Lord Viscount
Valentia from the East Indies. Branches slender, downy
when young. Leaves on some branches four or five inches
long and three broad, heart-shaped, with one side of the
base much larger than the other, on slender footstalks two
inches-long; on other branches unequally heart-shaped at
the base in a similar manner, but much smaller, and deeply
three-lobed, one lateral lobe usually divided, their foot-
stalks scarcely an inch long, and more downy; these seem to
be younger leaves than the undivided ones; all are rough with
minute points and bristles, paler beneath, minutely but
sharply toothed throughout, somewhat pointed. Fruit
axillary, the size of a filleted or bigger, tapering at the
base, lopped at the end. Fruit stalk shorter than the foot-
stalk, with a small three-leaved involucrem about the mid-
le, which is close to the fruit when very young. This is
probably nearly related to the following, which we have not
seen, but the descriptions of their leaves can scarcely be
made to agree.

101. F. cannabifera. Lour. Cochinch. 668.—"Leaves of
the stem halfate, cut; those of the branches ovato-lanceo-
late, slightly ferrated. Stem nearly erect."—Native of the
plains of Cochinchina. A furb six feet high, branched, with
a smooth tough and fibrous bark. Leaves flalked, falked,
very rough. Fruit oval-top-flaked, on long, simple, fo-
liary, lateral flalks, with a three-cleft rounded involu-
crum.

102. F. rufescens. Vahl. En. n. 89. (F. heterophylla;
Lamarck. Dict. v. 2. 499. Vahl-tengerat; Rheede H. Mal.
v. 3. 83 t. 62.)—"Leaves ovato-oblong, somewhat toothed,
undivided or lobed, rough. Fruit slightly flalked, hairy
like the flalks and branches."—Native of China, and the
East Indies. Synonym. Leaved green on both sides,
about five inches long, and half as broad, on flalks not
an inch in length; some of them undivided, others with
three or four deep flutes, about as in the common fig-
tree. Fruit clothed with reddish hairs or bristles. Lah-
ara. Rheede says his plant is a climbing furb six or
seven feet high, throwing out long trailing branches in
every direction.

103. F. moripholia. Ibid. n. 90.—"Leaves in three deep
divisions, very rough; their segments lanceolate, angular,
and somewhat pinnaed."—Native of the East Indies.
Branches slender, scarcely rough, a little downy in the
upper part. Leaves flaked, alternate, obtuse at the
bist, three-ribbed; vellums above; slightly veiny beneath;
delicate of pubescence, but very rough on both sides
with minute points, the upper sides appearing under a
magnifier as if covered with small white, membranous
scales. The segments are narrow and tapering. *Vahli.*

104. F. simplicifolia. *Lour. CochinC* 667.—"Leaves
palmarive. Stem perfectly simple. Fruit compressed."
Native of the woods of Cochin China. A shrub five feet
high, with a straight upper tier of delicate of branches.
Leaves large, flaked, scattered, rough. Fruit small, ax-
illary, sessile, solitary, roundish, fawn-coloured. *Leucici-
na.*

105. F. Carica. Common Fig. Limn. Sp. Pl. 1513.
Miller Illust. t. 100. Trew Eebth. t. 73, 74, excell. *a.*
(Tancers and Chamerion; *Ger. em. 1510."
Native of the south of Europe and some parts of Asia, where it is also
generally cultivated, but not bever the severe winters of the north of Europe, nor even our own, without
protection. Stem brached from the bottom, from six to
twenty feet high, with long, twilled, plant, round, grey-
ýh branches, rough when young. Leaves deciduous, a
span long, in three or five deep rounded lobes, of which
the central one is the largest, the outermost much the
smallest; they are of a deep green, scarcely paler, but
rather more hairy; beneath, furnished with radiating ribs,
one to each lobe, and many transverse veins. Fruit foli-
tated. One to three thick flak, tapering at the base, and
furnished with a three-leaved involucrem. Its colour is
generally purplish, its pulp soft, sweet and fragrant.
There are numerous varieties of cultivated figs, of which
the most hardy is the Common Purple. Others are ei-
ther more tender, worse bearers, or less desirable in
flavour. Several excellent kinds however are found in the
southern parts of France, Italy, Spain and the Levant.
In those countries figs are usually brought to table, with
melons and mulberries, in the beginning of the dinner, as
well as at breakfast, and do not in general make a part
of the diet.

The *Carica* in its wild state is a more humble and
distorted shrub, bearing fruit which comes to no perfection
as to flavour, but the parts of fructification are very
perfect, and the seeds are only ripened, even in France.
Such figs as seem to fall off before they arrive at matur-
ity, are commonly those in which the flaminis are most
numerous or effective, and which have therefore attained
their final perfection. These are carefully collected in
the Levant to impregnate the female blossoms of the
cultivated fig, their pollen being probably more perfect
than what is produced by the flaminis of such individ-
uals as have, on the other hand, more perfect petals.
In other words, the plants are incompletely pollinated, like
the mulberry and many others. This will explain the mystery of
Caprification, whether wounding the fruit be useful to
promote its ripening, or whether the perfecion of the pulpy
receptacle be owing chiefly to the vigorous growth of the
female flowers consequent to their impregnation. Though
both causes seem to co-operate, we should lay most stress
on the latter, which the analogy of other fruits confirms. See
Caprification.

All the species of *Ficus* are either trees or shrubs, whose
secreted fluids are milky, more or less acid or acetid, how-
ever sweet and wholesome the fruit of severer, though not
all, may be. The leaves are simple, flaked. Stipulas
lateral, not intrafolaceous, in pairs, membranous, decid-
ous, generally taper-pointed. Flowers more or his poly-
gamous.

We have in the above synopsis of the species added fourteen
to those of Vahli, though we have presumed to reduce
two of his to one; see n. 90. Possibly some of the rest,
which he, as well as ourselves, have been obliged to
adopt upon fruit, may, on a future examination, prove
distinct from each other, while it is probable that nu-
murous undescribed species may still be latent in the wilds of
Asia and America.

*Ficus,* in *Gardening,* a tree of the deciduous fruit kind,
and the fruit cultivated are: the common fig-tree (*F. carica*);
the Egyptian fig-tree, or ficume (F. *sycomorus*);
the poplar-leaved fig-tree (*F. religiosa*); the Bengal
fig-tree (*F. Bengulensis*); and the Indian fig-tree
(*F. indica*).

Of the first species there are several varieties, the chief of
which are the following:

*Brown Ischia fig.*—This is a fruit which has a large fruit,
short, globular, with a pretty large eye, pinched in near the
foot-flake, of a brown or dehnt colour on the outside, and
purple within; the grains large, and the pulp sweet and high-
flavoured; it often bursts open as it ripens, in the end of
July, or the beginning of the following month. This has
its ripening well on standards in warm soils and situa-
tions.

*Black Genoa fig.*—This is a kind which has a long fruit,
that swells pretty large at the top, where it is obtuse; the
lower part is much more slender towards the half; the skin a
cart purple colour, almost black, and has a purple farina
over it, like that on some plums; the inside is of a bright
red, and the flesh very high-flavoured. It ripens early in
August.

*Small white early fig.*—This is a fruit which has a round-
fruit, a little flatted at the crown, with a very short
foot-flake; the skin thin, and, when fully ripe, of a pale yel-
lowish white colour; the inside white, and the flesh sweet,
but not high-flavoured. It ripens in August, as in the pre-
ceding kind.

*Large white Genoa fig.*—This is a kind which has a large
globular fruit, a little lengthened towards the half; the
skin thin, of a yellowish colour when fully ripe, and red
within. It is a good fruit, but the trees are not good
bearers in general.

*Black Ischia fig.*—This, which is a short fruit, of a mudding
size, a little flatted at the crown, has the skin alm-
most black when ripe, and the inside of a deep red; the flesh
very high-flavoured. It bears well, and ripens in August
in this climate.

*Malta fig.*—This, which has a small brown fruit, much
compressed at the top, and greatly pinched towards the
foot-flake, has the skin and inside of a pale brown colour;
the flesh very sweet, and well flavoured. When the fruit is
permitted to hang upon the trees till shrivelled, it becomes
a fine sweetmeat.

*Murray, or brown Naples fig.*—This is a kind which has a
pretty large globular fruit, of a light brown colour on the
outside, with faint marks of a dirty white, the inside
nearly of the same colour; the grains are pretty large, and
the flesh well-flavoured. It ripens the latter end of August
in general.

*Green Ischia fig.*—This is a fruit which has an oblong
fruit, almost globular at the crown; the skin is thin, of
a green colour; but, when fully ripe, darkened through by the
pulp to a brownish cast; the inside purple, the flesh
high-flavoured. It ripens about the end of August.

*Madonna, Brunswick, or Hanover fig.*—It is a kind which
which has a long pyramidal fruit of a large size; the skin brown; the flesh of a light brown colour, coarse, with little flavour. It ripens the end of August, and the beginning of September.

Common blue, or purple fig.—This is a fruit which is oblong, it is a great bearer. The fruit ripens in August in general.

Long brown Naples fig.—This is a kind which has the leaves deeply divided; the fruit long, somewhat compressed at the crown; the foot-tails pretty long; the skin of a dark brown when fully ripe; the flesh inclining to red; the grains large, and the flesh well-flavoured. It ripens in September.

Tillou Ichia fig.—This is a fruit which has a large fruit of a pyramidal form; the skin is yellow when ripe, and the flesh purple and well flavoured. It is not a good bearer, but ripens in September in moist caves.

Small brown Ichia fig.—This is a fruit which has a small pyramidal fruit, with a very short foot-tails; the skin of a light brown, the flesh inclining to purple, of a very high flavour. It ripens late in September. It is not a good bearer.

Gentile fig.—This fruit has a middle-sized globular fruit; the skin, when ripe, yellow; the flesh also inclines to the same colour; the grains large, and the flesh well-flavoured, but it ripens very late, and is a bad bearer.

There are also other sorts, as the beet early white, black Provence, Cyprian, Ford's feeding, green Naples, large black, large blue Marfilles, Milward, small black Ichia, white Ichia, yellow Cesar.

Those which are most proper for a small garden, according to Mr. Forsyth, are; the large white Genoa, early white Murray, small brown Ichia, and the black Ichia.

It is affirmed by the same writer, that in a good season the brown, or chestnut coloured Ichia, the black Genoa, the small white early, the Murray, or brown Naples, and the common blue, or purple fig, will ripen on standards.

The second sort is often here called the lycomore-tree, and mulberry fig-tree. This, and not the great maple, is the right lycomore.

The fifth sort is often known by the name of banyan-tree, and is a native of the East Indies.

Etched of Culture.—The first sort and varieties may be readily increased, either by suckers, layers, or cuttings, but the two last are the best methods, according to Mr. Forsyth, who has had great experience in raising fruit-trees of this kind.

The suckers should be taken off from the roots as low down as possible, and, after being trimmed, planted out in nursery-rows, at the distance of two or three feet from each other, with the tops entire, to take their natural growth, when intended for standards; but when for walls, espaliers, or dwarfs, in the situations where they are to remain. In the latter case, they should be cut or headed down to fix or eight inches in the early spring, to induce lateral shoots to be thrown out near the ground.

The layers should be made from the well-ripened woody shoots of the bearing trees, and be laid down in the autumn, or early in the spring, being protected from frost during the winter by tan or some sort of flaky material. When the plants are sufficiently rooted, as in the following autumn, they should be taken off and planted out in the places where they are to remain, as they do not bear transplanted well, being covered at the roots with dung, tan, or litter during the winter. The cuttings should be taken from the well-ripened, woody shoots of the former year, which, without being shortened, may be planted out in the beginning of the autumn, on beds of loamy earth, in a warm, sheltered situation, to the depth of eight or ten inches, protecting them with tanners' bark and litter during the winter; the litter being removed as the spring advances. When they have broken good root in the following autumn, they should be taken up and planted where they are to grow and remain.

Three sorts of trees are mostly cultivated as standards in warm climates, but in this, in general, against walls or as espaliers; and only sometimes as standards.

The sorts of trees cultivated against walls are those of the blue and white kinds, but several of the others succeed well in this management, where they are duly attended to.

But for espaliers, and as standards, the fifth, second, third, ninth, and tenth varieties are probably the most proper.

In their culture as wall-trees, they should always be placed in sunny situations, and the purpose of the fruit bring the most effectually ripened, as in that of a full southern exposure, but an east or west aspect will answer very well when that cannot be had with convenience.

In the planting them out, where the walls are of considerable height, fifty or sixty feet distance may be sufficient; but in low walls, twenty or more are not too much space. Mr. Forsyth advises from twenty to twenty-five feet, as the most suitable distance for planting these trees at, in general.

Where the trees are planted against fire-walls, they should not be kept too close, be drawn by glades, or have the heat too great; but have at all times, when the weather is favourable, a good share of free air admitted, and if the trees are young, care should be taken that their roots are not extended beyond the reach of the covering; they must be frequently watered when they begin to flower, otherwise it will drop off; but old trees, whose roots are extended to a great distance, only require to have their branches now and then sprinkled over with water. Where these trees are properly managed, the full crop of fruit is greater than upon those which are exposed to the open air, and ripen six weeks or two months earlier, and a plentiful second crop may also be obtained, which ripens early in September, or sometimes in August; but the first should not be allowed to these trees till the beginning of February, as when they are forced too early, the weather is frequently too cold to admit a sufficient quantity of fresh air to get the fruit; but the covers should be put over the trees a month before to prevent the shoots from being injured by the extreme state of the weather.

The management of the trees in the common method after they have been headed down or shortened in the manner mentioned above, whether they be on walls or espaliers, is that of training them horizontally, so as to preserve the branches in an equal and regular manner on each side, at the distance of from five to eight inches from each other, and, for the most part, keeping their full length without any breaking, that as large a proportion of young fruit bearing wood as possible may be preferred. Some, however, advise their not being led to close, considering a foot or eighteen inches as little enough room for them.

And in the pruning of the trees, Mr. Forsyth advises that it should never be done in the autumn or winter, but in the early spring months. The best time for this, it appears, is to be the latter end of April or beginning of May, allowing months, as by this period it may be ascertained what branches have been destroyed by the severity of the winter. And as the ends of these branches, the wood of which has not ripened well in the autumn, will be most injured, they should be...
be cut into the found wood as near to an eye or bud as possible.

In cases where the branches have been permitted to run up, so as to leave the bottom in a naked state, every other branch is advised to be cut out, as near to the ground as it can be done, by which the walls or eipillars will be provided with good young wood, care being taken to stop the ends of the shoots in summer, as about the beginning of June, in order to induce side-shoots to be thrown out for fruiting the following summer; by which time plenty of fine wood will be provided, and then the remainder of the old branches may be cut out as before, pruning their young shoots as in the preceding cafe, constantly pinching off the ends of all the strongest shoots at the top bud, except such as are leading ones.

But in the spring pruning, as the fruit is produced near the tops, the bearing shoots should never be shortened, nor should the fine shoot side and fore right shoots be cut off, except when decayed; as they ripen better than the long strong ones, and are not apt to be destroyed by frosts in the winter season. By this practice, it is contended that the trees will be covered with fruit from the tops to the bottoms of the wall, &c., instead of having a few only at the top, as is the case in the common method of management with these trees.

In summer, as many shoots are sent off, some of those that are irregular and useless may be rubbed off, and the others trained in for the forming of future bearing wood. The proper period for this is about the beginning of June, and in the two following months.

After the fruit has attained the size of small nutmegs, the points of the top buds are recommended by Mr. Forfyth to be pinched or cut off with a sharp knife, some of his powdery material being immediately applied, to prevent the oozing out of the milky juice, and the consequent exhaustion and injury of the tree.

In order to prevent the necessity of cutting the trees down in the above manner, they should be covered in winter before the approach of frost, which would destroy the ends of the shoots before the wood was ripened and rendered hard.

Where fig-trees are greatly injured in the winter, the best practice is to cut them down as near the ground as possible, as in the following year, by the above management, they may be got into a good bearing state.

The best mode of protecting these trees is, according to Mr. Forfyth, to cover them with bentings, or short grafts, from the pleure-ground, which he finds answers the purpose very well; after it is thoroughly dry, it may be put in a cock, covering it with straw, to prevent the rain from penetrating into it, which would cause it to heat and rot; or it may be put into a shed. If grafts cannot be procured, some dry moss may be employed. In performing the work, cover the trees with laurel, yew, fir, or spruce boughs, and then tuck in the short grafts or moss among the branches, beginning at the top of the tree, tucking in the grafts, &c. as you descend, till you come to the bottom.” Fern, when well dried, he says, makes an excellent covering. The trees may be thatched on the outside with the long leaves of the common fern; and where these can be got, there will be no occasion for short grafts. When it can be procured, which it may in most country places, it will, he says, be found preferable to laurel.

They may also be sheltered in winter by wrapping hay or straw bands round the branches of the trees; and then opening the ground, laying in the branches, and covering them over with mould about nine inches deep, leaving the ends of

**Garden Trees.**

Great care, he says, should be taken not to uncover the fig trees too soon in the spring; and it should be done partially, as there are frequently frosts and cutting winds in the months of April and May, which will infallibly kill the young fruit as they make their appearance in the spring.

Thence branches which have been laid into the ground should be taken up in the month of April, leaving the hay or straw-bands taken off, and then nailed to the wall. Some fern leaves, or any other light coverings, may be flung in among the branches, to protect them from the drying winds and frosts till the fruit comes to the size of a large walnut, or rather till the leaves are sufficiently large to protect the fruit.

It is observed, that the Italians, when they wish to forward the ripening of figs, drop in a little sweet oil, from a quill, into the eye of the fruit; but care must be taken not to hurt the skin, which will make the fig burst. This will make a difference at least of a fortnight in the ripening of the fruit.

It is also recommended, as soon as the leaves begin to fall, to brush them off with a broom, but by no means till they will come off easily. If they are forced off before they begin to wither and decay, the trees will bleed at the foot-talks. At the same time the talks should be cleared of all the small late fruit, which, if suffered to remain during the winter, will rot, and injure the tree, so as to prevent it from bearing the ensuing summer. If any milk be observed oozing from the foot-talks, a little of the composition should be used, which will stop it, and heal the injured part. See **Composition.**

By doing this, the ripening and hardening of the wood will be facilitated before the winter frosts set in.

In standard-trees of all sorts little pruning is necessary, only just to take out the very irregular branches and the young shoots, when too much crowded, and the dead ends of the shoots, as well as any dead wood that there may be in them.

Mr. Forfyth, however, observes, that as the branches of standard fig-trees are very liable to be killed in severe winters, it will be necessary to lay them also in the ground, wrapping them up in hay or straw-bands, as directed for wall-trees. It will be sometimes impracticable to lay down the middle branches; they must, therefore, be well covered with hay or straw-bands, and the outside ones laid down, going regularly round the tree, and taking particular care not
not to hurt them with the spade, then to mulch them with rotten leaves, &c.

Where Mr. Forlyth has been under the necessity of cutting fig-trees down near to the ground, after hard winters, he has found, by the use of his composition, that "in the course of two years, the new wood has covered over the old stump, and the branches filled up the former space, bearing also plenty of fine fruit."

The other species are easily propagated by cuttings during the summer season. When the cuttings are taken from the plants, they should be laid in a dry sandy place for two or three days, that the wounds may be healed over, otherwise they are apt to rot; after which, they should be planted in pots filled with sandy light earth, and plunged into a moderate hot-bed, where they should be shaded from the sun, and two or three weeks a gentle refreshment with water, if the season is warm; but they must not have too much moisture, as it would infallibly destroy them. When the cuttings have taken root sufficiently, they should be each planted into a separate small pot filled with undug earth, and replanted into the hot-bed, shading them until they have taken fresh root; then they should have a large share of free air admitted to them at all times when the weather is favourable, to prevent their drawing up weak, and to give them strength before the cold comes on. In autumn the pots should be removed into the house, and be plunged into the tank-bed, where they should contentedly remain, and be treated in the same manner as other tender plants from the same countries, for although two or three of the forts may be treated in a harmer manner, yet they will not make much progress. They may likewise be increased by layers when necessary.

These are shrubs in this climate which afford variety in flower collections.

Ficus, in Conchology, a name given by authors to a peculiar species of sea shell. It is of the genus of the dolium, and has a remarkably depressed calicle. See Conchology.

Ficus, or Ficaria, in Surgery, signifies a tuberecel, or excrescence, about the anus, or pudenda. The term is said to be derived from vi, to produce, or cile from the Hebrew phig.

Fidari, in Geography, a river of European Turkey, in Livadia, which runs into the sea, eight miles N. of Patras.

Fid, an iron pin used at sea to splice or fallen ropes together; it is made tapering and sharp at one end. There are also fids of wood, which are much larger than the iron ones.

The pin also in the heel of the topmalt, which bears it upon the chefs-tree, is called a fidd.

Fid-d hammer, is used for a hammer, the handle of which is a fidd, or tapering into that form.

Fiddes, Richard, in Biography, a learned divine, and polemical writer, was born at Hunmanby, in the county of York, in the year 1671, and went first to study at Cambridge, but afterwards was admitted of University College, in Oxford. Entering into holy orders, he obtained the living of Hullham, in his native county, but the air of the place not agreeing with his health, he was forced to forego all thoughts of residing on his living; having while there left the use of his speech, which he never after perfectly recovered. He was appointed chaplain at Hull, but he spent the latter part of his life at Putney, where he died in 1735.

In 1718 and 1720, he published a Body of Divinity, in two volumes, folio; in consequence of which, the university of Oxford conferred upon him the degree of doctor in divinity. In 1721, he published two letters on the soul's immortality, occasioned by the epitaph on the duke of Buckinghamshire. In 1724, appeared a Life of Cardinal Wolsey, in which the free manner he had treated some opinions induced a belief, that he was favourably inclined to the Catholic tenets. The same year he published a treatise on morality, and he also wrote fifty two practical discourses. His first publication was a prefatory epistle concerning some remarks to be made on Homer's Iliad, addressed to Dean Swift, &c. Gen. Biog. Diet.

Fiddichow, or Fabvchova, in Geography, a town of Hindar Pomernania, on the Odas, 22 miles S.W. of Stargard. N. lat. 53° 13'. E. long. 14° 13'.

Fiddle, probably from Fid, Latin. This is the vulgar name for the violin, which is a modern instrument, as the use of the bow cannot be traced in antiquity. The earliest mention which we have found of the fiddle in England, is in the legendary life of St. Christopher, MS. Vernon. Bodl. Lib. (119) written about the year 1200.

"Christofre him served long.

The king loved the melody of sithele and of longing."

The fiddle, however, did not seem in common use in feasts, mummeries, and processions, for some hundred years after this period. It is mentioned by Chaucer, but was not allowed to be a concert instrument, till the reign of Charles II. who, in imitation of Louis XIV., established a band of twenty-four violins, alias fiddles, which gave birth to Tom Purcell's song of "Four and Twenty Fiddlers all on a Row," &c., a humorous production in which there is a mockery of every instrument, and almost every trade; and which, in our own memory, used to be performed between the acts, or between the play and farce, by some man of humour at benefit. See Violin, Rebec, and Bow.

Fiddle-shaped leaf, in Botany, folium panduriforme, is oblong, broad at the two extremities and contracted in the middle, like a fiddle or some sort of guitar, and not like the ancient pandura or reed-pipe, as the Latin name implies. See Leaf.

Fiddle wood. See Citharexylon.

Fiddler's Elbow, in Geography, a bend of Wood creek, between the outlet of South bay, and the mouth of the creek at the northern end of lake Champlain, opposite to the mouth of East bay. The mouth of Wood creek lies in N. lat. 43° 32'. W. long. 73° 15' 12".

Fide-Jusserand Affili., See Asinusus.

Fiedship, in the Civil Law, is a surety, or one that obliges himself in the same contract with the principal, for the greater security of the creditor or flippuror. See Bail and Cautionary.

Fidei-commisum, in the Roman Law, the appointing of an heir, or bequeathing a legacy to a person on this condition, that he surrender the inheritance or legacy to another person, for whom the same is originally meant; or it is an inheritance left in trust with any one, for the use of another.

Fidei-commissa were much used among the Romans. In the French law the thing is become odious; as being, ordinarily, no other than an expedient in favour of persons to whom the laws forbid any thing to be given. In order to this, some trusty friend is chosen to be made legal heir, under a tacit agreement to deliver the inheritance to the person incapacitated by law. But of later times the same expedient has come in use with regard to persons capable of inheriting; to whom the testator, for particular reasons, does not care to leave the inheritance directly.

As it happened that the fidei-commissioners did not always faithfully restore what was trusted to them, Augustus took
took proper measures to oblige them thereto; this to end a
prator was erected, whose business was restrained to the
single matter of fidei-communions.

As a testament was null without the institution of an heir,
and it frequently happening that the fidei-commissioner re-
fused to accept the trust, upon which the testament fell to
the ground; to engage somebody to accept it from a con-
\federated advantage, the P: galiani fettus confiduum de-
creed, that the fidei-commissioner should be at liberty to
retain a fourth of the fidei-communion.

TIDELES, in Church History. See BELLIVERS.

TIDENA, in FIDENA, in Ancient Geography, a town of
Italy, upon the Tiber, N. of Rome and N. of Veii. It was
founded on the territory of the Sabins, by a colony of Allia,
and seems to have been very powerful before the foundation
of Rome, as it fulfilled a war against it, which lasted from
the year of Rome 170 to the year 327, when the Fidenates
were subdued by the dictator Emilius Manerucus.

FIDENTIA, a town of Gallia Cispadana, situated
towards the S. E.; near which the troops of Carbon were
cut to pieces by those of Sylla.

FIDICULE, in Antiquity, is often used to signify
the same with equus, a kind of punishment used among
the ancients.

Fidicule, in a more proper sense, denotes the cords
wherein the criminals' limbs were diffident on the
equus.

FIDMIN, in Geography, a town of Egypt; five miles
W. of Fayum.

FIDRA, a small island near the coast of Scotland,
at the entrance of the Forth; three miles N.W. of North
Berwick. N. lat. 56° 5'. W. long. 2° 49'.

FIDULEA, a small island in the Grecian Archipelago;
four miles S.W. of Stambelia.

FIE, the fame with fud or far, which see.

FIEP D'HAMBERT, a name given by the Normans, and
adopted by the French, to that species of tenure denomi-
\ated a kniajes-service, which see.

FIEGO, or Fijogo, in Geography, a Sea-port town of
Japan, on the S. coast of the island of Niphon, with a large
harbour in the bay of Oolce; 24 miles S.S.W. of Oolce,
and 34° S.W. of Macao.

FIELD, in Agriculture, is a portion of land mostly included
by some fort of fence, and employed either in tillage or as
pasture. Fields should be proportioned in size to the na-
ture of the husbandry under which they are chiefly man-
ge, where they are of the ample kind, they may be
much larger than where they are of the grazes or grazing
description. (See INCLOSING OF LANDS.) For the method of
finding the contents of a field, see AREA, CHAIN, and
SURVEYING.

FIELD-FALLOW, a term frequently made use of to signify
a common field, which is occasionally cultivated under the
fallow system. See FALLOW.

FIELD-GRAVES, any sort of graves cultivated or grown in
the field. See GRASS.

FIELD-HIGHLAND, those sorts of husbandry or cultivation
which are practised in the field, whether to relate to
tillage or grass. See HUSBANDRY.

FIELD-WELL, the name of a pit or small font of artificial
watering-place for cattle in a field. See DRINKING-FIELD.

FIELD-WORK, that sort of work which relates to the field,
and which is of very different kinds.

FIELD-STAFF, the common name of a perennial weed
often met with in tillage lands. The stem is upright and
branching, rising to the height of a foot or a foot and a
half. It is spotted, rough, and hairy. The lower leaves
are oval, and indented about the edges; but those on the
stalk are divided and pinnated. The flowers are blue, and
of the compound kind, consisting of a great number of
small ones, each divided into four parts, and having one
seed under them. The plant has a bitter disagreeable taste.

FIELD-ALS, or Fieldals, in our Ancient Customs, a kind of
drinking in the field, by bailiffs of hundreds; for which
they gathered money of the inhabitants of the hundred to
which they belonged. But this custom has been long since
prohibited.

FIELD, Campus, in Antiquity, is frequently used for a
public place, or square in a city, &c.

Such were the Field of Mars, Campus Martius; and
Field of Flora, Campus Flora, in Rome; and the Field of
May, Campus Maius, among our ancestors, &c.

Field of Mars was denominated from a temple of that
dity, built therein; it was the scene or place of the assem-
blies called comitia. Tarquin the Proud at length appro-
\rinted it to his own use; but after the expulsion of the
kings, the consuls Brutus and Collatinus restored it to the
public use again, for assemblies and elections.

Originally it was no more than a meadow on the banks
of the Tiber, where horses grazed, and the Roman youth
were exercised to war. But it was afterwards erected into
a magnificent square, adorned with statues, &c. See Campus
Martius.

Field of Flora, was the place where the laws, edicts, and
constitutions, were published.

Field of May. See Campus Maius.

Field Baffi, in Botany. See ClinoPodium.

Field Baffi, American. See Monada.

Field Baffi, Syrian. See Ziziphora.

Field, Clare, was anciently a place enclosed, or raised
in with a barrier, for jits and tournaments to be per-
formed in.

Field, Elysium. See Elysium.

Field, Richard, in Biography, an able champion of the
doctrines and discipline of the church of England, was
born at Hemphied in Hertfordshire, in the year 1561. In
1577 he was admitted a member of Magdalen college, Ox-
ford, where he took his degrees with high reputation. His
great learning and talents pointed him out as adapted to fill
certain useful and important places in the church, till at
length he chose divinity reader to the society of Lin-
coln's Inn. In this situation his services gained him many
friends among the learned members, one of whom presented
him to the valuable living of Burrowclere in Hampshire,
and in a short time after he was offered the still more valuable
benefice of St. Andrews, Holborn, but he chose to adhere
\hat the in the country, as affording him more ample opportu-
nities for study, on which his mind was very intent. In
1588 he took his degree of doctor of divinity, and became
chaplain in ordinary to queen Elizabeth, and was soon after
made prebendary of Windlor. On the death of the queen
he succeeded to the late office of chaplain in her suc-
cessor James; and was entrusted with the management of
some special comunions inned for ecclesiastical canons, and
the exercise of spiritual jurisdiction within the diocese of
Winchell. In 1604 he obtained a prebendary of Windlor,
and when the king went to Oxford to witness the scholastic
exercises at that university, Dr. Field was sent for to take
a part in the divinity act, and the manner in which he per-
formed his part reflect the highest degree of credit on his
learning, and afforded uncommon satisfaction to the splendid
audience.

In 1610 the king bestowed upon him the deanery of
Gloucester, but he continued to reside and labour at Burrow-

 cler's,
clere, only going to Gloucester occasionally to preach when his particular duty required him. Sometimes, in the winter months, he usually spent at Windsor, and was often selected to preach before the king, who exclaimed on first hearing him, "This is indeed a Field for God to dwell in." The monarch held Dr. Field in so high esteem that he was anxious to promote him to the bishopric of Salisbury, but his counsellors prevailed upon him to give it to another. The king, however, determined to raise him to the see of Oxford, which was expected to become vacant in a short time, but before the vacancy occurred, Dr. Field died of an apoptyx, in the year 1616, in the fifty-fifth year of his age. His principal work, as a literary man, was entitled "Of the Church," four books, folio. This was published in the year 1665, and in 1670 the author added a fifth book, with an appendix, containing a "Defence of Such Pages of the former Books that have been excepted against," or wrested to the maintenance of Romish Errors." Dr. Field was universally respected, and at his death generally lamented. "He was," says Wood, "much against disputing about the high points of predestination and reprobation, nor did he like that men should be busy in determining what God's decrees in heaven are. He was one that laboured much to heal the breaches of Christendom, and was ready to embrace the truth whereverof he found it. His dehre, his prayers, his endeavours, were for peace, to make up the breaches of the church; not to widen differences, but to compose them." Gen. Biog.

Field, in Heraldry, is the surface or face of the field, or escutcheon; thus called, as containing the achievements ancienly acquired in the field of battle.

The field is the ground whereon the colours, bearings, metals, furs, charge, &c. are represented. In blazoning a coat, we always begin with the field: he bears sable, &c.

Among the more modern heralds, field is less frequently used than field or escutcheon.

Field of Battle, in the Military Language. The possession of this, after an engagement, is generally supposed to denote which party has obtained the victory; the worsted army, for the most part, retiring with the view to rally, and eventually to make a fresh stand at some advantageous position: But it does not always follow that possession of the field remains with those to whom the greatest merit attaches; we sometimes see an inferior force repel the attacks of partners, and following its route, leaving to the defeated allies that field, on which a large number of them may bury their lair, while the victorious band, though somewhat diminished in numbers, effect a safe retreat. Retention of the field under such circumstances denotes the want of power to follow, and, according to the military phrase, is "a ransom victory": usually to be clasped with those sad effects produced by severe contests on an enemy's country, where the latter are constantly obtaining both supplies and reinforcements, from which the invaders are, or should be, completely cut off. We cannot give a stronger representation of this position than is afforded by the glorious struggle maintained by our Spanish allies, who, though certainly in the first instance by no means competent to repel their invaders, at length were routed to a fine state of their situation, and displayed their national character for loyalty, piety, and bravery, in the most glowing colours.

A previous knowledge of the field on which an army is about to engage, cannot but become an object of great importance, not only to the commander-in-chief, but to all those in charge of divisions of the troops under his authority. An intimate acquaintance with various minutiae, such as broken ground in which cavalry cannot act; swamps in which they as well as artillery would be fixed, or at least be unable to fulfill their intentions; strong situations, such as natural lines made by precipices bordered by banks, or fringed with underwood; elevated spots, on which batteries could be placed to advantage, and behind which large bodies of cavalry might be concealed; bridges within command, by means of which a safe retreat might be made; and all such points, are indispensable towards the successful issue of the day.

We do not mean to assert that every commander has it in his power either to choose the field on which he will make a stand, or that, when he has chosen it, he must be thoroughly acquainted with all localities; but it may be permitted us to observe, that no man, whatever rank he may have attained, or whatever service he may have seen, is competent to be placed at the head of an army, but more especially one acting upon the defensive, whose eye does not most keenly search for natural advantages, or who does not, when those advantages are apparent, profit by them in a suitable manner. We particularize the defensive, because that system rarely fails to afford those highly valuable advantages in regard to the several strong positions every country affords, more or less; but which may not always be sufficiently ascertained by an invading army. Thus, it must be evident, that during the apprehension of invasion, our generals, throughout the country, had the fairest opportunities for most accurately reconnoitring every defensible point, whereby they would have been enabled to act with the greatest effect, and to choose their field on almost every occasion, which could not have fallen to the lot of hostile troops, whose advance must invariably have been attended with some uncertainty, and all its train of mischiefs.

In reviewing the great number of plans that have at times been published, wherein the positions of the contending parties and their several movements have been laid down, one obvious feature appears common to a very great majority; namely, that the party which awaited the attack of its adversary, had its flanks, or at least one of them, covered by woods, rivers, villages, morasses, or broken ground. The great object appears to have been there, to throw impediments in the way of the enemy's horde. Hence we see, that so soon as any part of the centre gave way, the whole were thrown into confusion, bearing down the several lines in succession, and offering opportunities for a dreadful display of the powers of cavalry. It appears rather doubtful how far an equal force should place itself, and is to defend home valley, &c. through which alone the enemy could penetrate into a country.

Field-Fortification relates to the formation of such temporary lines of defence, redoubts, &c. as well as of such batteries, of various descriptions, as may be deemed necessary either for the maintenance of a position, or for driving an enemy from that he may occupy. It would be utterly impracticable to afford instructions suited to every case; there being such varieties of locality, as well as of circumstances, which can only be provided for on the spot, and never could come under any general description. Although we are at to consider the science of fortification, in all its branches, to appertain, rather exclusively, to the corps of engineers, yet no general should be unacquainted with the command of an army, unless possessing either an intimate acquaintance with that science, or such a ready conception of the advantages and disadvantages of every position he may assume, as should enable him, as it were by inspiration, to adopt or reject it without hesitation. We fear that this excellent quality rarely comes, as Dogberry says, "by nature,"
FIELD.

1. A paragraph discussing the role of engineers in fortification and the importance of flanking positions for defending positions.

2. A discussion of the principles of field fortification, including the division of work into offensive and defensive strategies.

3. A detailed explanation of how to create trenches and how to position mortars and other artillery for effective defense.

4. A description of how to create a direct fire from batteries and the importance of these positions in defensive strategies.

5. A discussion of the need to protect the flanks of fortifications and the role of engineers in achieving this goal.

6. A mention of the importance of practice and experience in fortification strategies.

7. A conclusion that emphasizes the importance of training and preparedness in defensive warfare.
can be spared for their occupation. When only cavalry is to be opposed, nothing more is necessary than an abattis, (Fig. 7), formed by felling large trees, and after lopping off the more minute branches, placing them, side by side, in a compact manner, with their stems inwards; and either flaking the whole down, or encircling them together with bines, or ropes, &c. so as to prevent them being easily driven away by an enterprising enemy. It is, in general, found best to make even this kind of defence of such a form as may afford flanking fires; observing to place a few guns along the curtains, so as to fire, as it were, in barbet over the upper boughs that point towards the assailants.

Some situations are naturally so strong as to require nothing more than a breast-work; such, for instance, as the borders of a precipice which cannot be taken by assault, and from which a direct fire in every part affords the best means of defeating any party that should approach. In such very strong places a straight line may answer, but, in most cases, flanks should be thrown out, as in Fig. 8. of which the general tendency must be governed by local circumstances. Whatever may be their direction or form, it is proper that no part of the lines intended to afford mutual defence should exceed what is termed the point blank range of a musket ball; which is generally understood to be about 200 or 250 yards, according to the charge of powder. When within 150 yards, the advantages will be greatly augmented.

Fig. 9. represents a continued uniform line, composed of short curtains, a, a, a, a, with the redans, b, b, b, b; these latter must bear such an angle, or be placed at such a distance from each other, as may allow a perpendicular drawn from their faces, at the point of juncture, as at c, to pass just clear of the faillant angle, d; if this be not attended to, the defenders of one redan will pour their fire into that adjoining. And, if the angle be too great, that is to say, more than 100 or 105°, the defences will be weakened in every part, on account of the great obliquity necessary in directing the fire, both in the curtain and in the redan; which, in the firing of musketry, is always attended with bad consequences.

Fig. 10. shews a line of the same kind as that just described, with independent redans, e, e, e, e, thrown up before the curtains, by which they are commanded. These should be placed at sufficient distance in advance, to prevent the enemy, in case they should be able to carry them, from affailing the curtain under cover of the flanks; which they might easily do but for that precaution. The angles of the independent redans should correspond with those of the intermediate ones, which may be about 60, or 65 degrees, according to circumstances.

Fig. 11. shews a very good mode of making alternately short flanks in a regular order, as to resemble the overlapping of tiles: the usual designation is "en cramailfaire," from the French word cramailfaire, signifying that kind of pot-book which can be lengthened at pleasure by means of ratchets. The termination of this sort of indented line ought to be strong; otherwife it would be subject to assault at the point, A, where the addition of the redan, B, adds greatly to its security.

Fig. 12. shews a line of obtuse angles, called swallow-tails, a, a, which would not afford a sufficient flanking fire; therefore it is expedient to mix them alternately with redans. This is an excellent mode for lines not finished with redoubts, or with advanced redans.

Fig. 13. is a line of swallow-tails, a, a, a, mixed with obtuse bastions, b, b, b, wherein it will be seen there is great strength. The addition of a cavalier, c, in each bastion, with a felce, d, in front of the swallow-tail, e, obviously renders such a line truly formidable.

Fig. 14. exhibits a line of curtains, a, a, flanked with bastions, and having redoubts, e, e, in their centres. This is also attended with great strength, especially as the latter prevent the enemy from following up any advantage. We shall conclude this article with observing, that field-fortification must usually be extremely irregular; therefore, on lines of any extent it may be expected to see the whole of the above-mentioned defences intermixed according as the ground may suit them respectively. In some parts, where deep flaiures or crags may intervene, the line will of course be broken; there it will be necessary to place batteries on the most commanding situations, as well as to scourp, and otherwise add difficulties to the ascent, so as to prevent the enemy from making a push in such situations; which, when well defended, may be considered impregnable.

In carrying field-works over rising grounds, some parts of the defences will sometimes expose their flank; when this happens, an encaissement must be thrown up, of sufficient height to obstruct, not only the point-blank, but the ricochet ranges of the enemy's shot.

Circular bastions have been properly exploded; it being evident that the general tendency of their fire was weakened; while, at the same time, that portion most advanced towards the enemy could not possibly be flanked by any other works.

We shall now offer to the consideration of our military readers a few practical observations derived from a small work possessing considerable merit; these are selected because they furnish, in concise terms, the very elements of that highly important topic now under consideration.

1. The spot on which works are to be constructed should determine their figure; nor should any attention be paid to preserving a regular form, which does not occupy the ground to advantage.

2. Every line must be so disposed, that the slope of hills all round, even to the very bottom, be open to the small arms of the garrison, and every part should be discoverable to the distance of at least 500 paces.

3. Works thrown up for the defence of a defile should always be within musket shot of it; which must not be more than 200 yards.

4. The best defence in works that are flanked, or where one side is defended by the fire of another, is that formed by right angles.

5. A faillant angle should never be less than 60°, nor a re-entering angle less than 90°, nor greater than 120°.

6. The entrance into the work should always be in that part least exposed to attack, and if possible in a re-entering angle.

7. Endeavour to prevent, if possible, a longer front to the enemy than he can occupy in making the attack.

8. Avoid all ground commanded by an eminence, either in front, flank, or rear.

9. Never leave your rear so exposed that an enemy can attack so as to turn it.

10. Always make the angles of a work in the directions least exposed to attack; and consequently endeavour to prevent a front to the enemy's batteries, &c.

11. The garrison should never be drawn up more than two deep; allowing an ordinary pace of two feet for each file, and from six to eight paces for each piece of ordnance.

12. If a work is so large as to be defended by a battalion or two, a reserve should be allowed of about one-sixth of the number.
FIELD.

for the men to move and lie down; every soldier will require at least 18 square feet, and every piece of ordnance about 216.

14. Provided the work be not too extensive, the more inward space there is the better.

15. A parapet, to repair cannon, should never be less than 12 feet thick, and for muskets not less than 8 feet.

16. The height of the parapet must be regulated by the situation of the work, and of the adjoining ground; with this consideration, that the height (of its crest) above the banquette should not exceed $\frac{3}{4}$ feet: if higher, men of rather a short stature will not be able to fire over it.

17. The depth and breadth of the ditch must be regulated by the quantity of earth required for the parapet and banquette.

18. A tete de pont, or any work intended to cover the embarkation of troops, or the passage of a river, &c., should, if possible, be made where the line of the river or coast forms a kind of re-entering angle, that the flanks of the corps, as well as those of the works, may be covered. See Field Fortification.

To carry on the work.—The number of workmen must be proportioned to the time allotted for carrying on the work, the quantity of labour, and the number of hands capable of being employed at the same time. When the ditches are broad, the workmen must be posted in two rows; but, if narrow, only in one. In the first case the earth will be thrown by those who are on the outward edge of the ditch to the second row, and by them upon the parapet: for which reason the second row, to keep pace with the first, ought to be twice as numerous. The workmen should never be placed nearer than two paces, or four feet from each other, and two men with shovels should be preceded by one with a pick-axe. If more than usual expedition be required, one man with a wheel-barrow, or basket, may be added to six or eight with shovels. Another row of workmen should also be placed on the parapet, to spread the earth and level it down as it is thrown up. In fixing the fascines, three men will suffice for every 24 feet of the work; these should be provided with two mallets, one saw, and one hand-bill or hatchet.

To form some idea of the time in which a field-work may be completed, compute the number of cubic feet of earth to be excavated, thus; multiply half the sum of the breadth of the ditch, at top, by the depth, for the number of square feet in the profile; this multiplied by the distance between the workmen in feet, will give the number of cubic feet each man has to dig; or being multiplied by the length of the ditch (in feet) will give the cubic contents of the ditch. Now, one man is supposed to be able to move 216 cubic feet of earth in a day during the summer; but this is not always the case. If a field-work be completed in 24 hours, it will be as much as the most diligent workmen are capable of. This time is generally allowed for the formation of a weak profile; 48 hours for that of a stronger, with a revetment of fascines; and 72 for the strongest.

The different slopes for the works must depend upon the nature of the soil, and the materials of which the work is composed. The interior slope of the parapet, though it be fascined, should be one-third of its height, and the slope of the banquette equal to its height. The slope of the scar, or counter-scarp of the ditch, should be from half its height to its full height, according to the soil. The superior slope of the parapet must depend entirely upon the situation of the work, and that of the surrounding country. The interior slope of the parapet is generally lined with fascines, to keep up the earth; but it is not absolutely necessary to fascine the exterior slope, if the soil be tolerably stiff. The embrasures are commonly made 20 inches wide within, and nine feet on the outside. They must always be lined with something to retain the earth; turf is generally preferred, as fascines are too apt to take fire. The manner in which fascines are made may be seen under that head.

It sometimes happens that the soil is so hard as to render it impossible to throw up works by the means of excavation; and where it is a loose sand, equal difficulty would occur regarding its retention, even when kept up by revetments of fascines. In either of these cases, the batteries, &c., must be formed by placing galions (which are) in such order, and contiguous, as may serve to give a proper form to the merlons. The galions may be either lined with leaves, backing, &c., where the soil is a running sand, or they may be filled with something, or whatsoever stiff soil may be at hand; wool, cotton, chips of leather, bark, or whatever may serve to confine the sand, may answer according to circumstances, observing that, in some instances, the whole interior must be gabioned. It will be evident that on a bad soil, such as above described, no ditch could be rendered both efficient and permanent; if lined with fascines, they might prove the destruction of the whole works, should the enemy throw carriages or shells into it. A battery formed of gabions may be run up with great celerity, provided proper materials for filling them be at hand, and plenty of labourers at command. In very hard, rocky soils, there is great difficulty in fixing gabions, on account of the impracticability of driving the necessary stakes. To retain mudbanks, sand bags are often found sufficient. These are particularly serviceable in situations where the opposing troops are very close, being placed so as to lean towards each other, but leaving a small interval, like a loop-hole, and being again crowned with an entire layer of the same kind; they offer an excellent screen, from behind which the assailants may be galled in the most disheartening manner. Sand bags arranged along the top of a low wall, add considerably to the means of defence, especially where the wall is so irregular as to offer the means of flanking.

FIELD-PIERS, a species of artillery intended for service in the field, in contradistinction to such pieces of ordnance as are appropriated to the defence of fortified places, to naval warfare, and to battering in breach. Field-pieces are in general made of brass, or rather of gun-metal, which consists of from 8 to 10 lbs. of tin to 100 lbs. of copper; the largest proportion of tin being used for mortars. The ordnance under description is usually divided into three classes, viz. field guns, artillery of the park, and horse artillery. The field guns include all light pieces attached to regiments of the line, which they accompany in all manoeuvres, to cover and support them. The following natures of field ordnance are attached to battalions of infantry, by the different powers in Europe:

The artillery of the park is composed of every class of field ordnance. It is intended to form batteries of position, that is to say, to occupy advantageous situations, independent of the movements of the troops, but with the view to support them, and to produce the greatest effects. Sometimes the park is divided into the several parts of the line; sometimes it is advanced under cover of cavalry, which,
which, suddenly retiring, at a proper moment, unmask the battery, and surprise the enemy by the fatal disclosure.

The park should be sufficiently numerous to afford supplies in the event of any pieces being taken by the enemy; but, on the other hand, it is bad policy to burden an army with too large a train, which not only occupies a great length of line, which in some instances exposes the whole to injury, but demands too large a flock of forage for the horses, &c. as to occasion considerable inconvenience on the score of provisions. The common rule is, to attach to the park twice as many field-pieces, of various natures, as there may be battalions of infantry in the army. The most approved proportions are these: 2 fifths of the whole to be 12-pounders; 2 fifths to be 6-pounders, and 1 fifth to be 3-pounders. But in different countries it is found necessary to lower the establishment to the following standard; viz. only 1 fourth to be 12-pounders; 2 fourths to be 6-pounders, and 1 fourth to be 3-pounders. For every 100 pieces of cannon it is supposed that four howitzers should be added; but we generally see a much larger proportion of the latter; perhaps as far as 15 or 20 to the 100: the French even exceed that proportion, and class their field-pieces into 12, 8, and 4-pounders; which, as their pound weight exceeds our's considerably, their ordnance may be rated at about 1 fifth heavier than the British.

**Horse artillery.** — In the French service this consists of 8-pounders, and 6-inch howitzers; a weight of metal requiring the greatest exertions to move with due rapidity, and rather tending to subject this department to delays, or even to capture. With respect to the latter point, the French seem to entertain fewer scruples about relinquishing their ordnance than we do; they rarely make exigence subservient to honour, but look principally to effects; being certain that a few field-pieces may always be supplied from their park of artillery.

The English horse artillery consists of light 12-pounders, light 6-pounders, and light 5½-inch howitzers. It remains to be proved how far this selection is eligible; but, in addition to the foregoing comment on the French establishment, we may perhaps be correct in hazarding an opinion, that, except in the discharge of grape, in which branch the howitzers profess a decided superiority, the French 8-pounders may be considered as very nearly on a par with our 12-pounders; the former weigh only 1 cwt. 3 qrs. 4 lbs.; while the latter amount to 2 cwt. 3 qrs. 4 lbs.; or, upon the new scale now chiefly in use, to 1 cwt. But our medium 12-pounders have only a very small limber-box, lately added, which carries 6 round, and 6 case-shot, with a proportion of small fleurs. They are attended each by two waggons, having the ammunition, generally about 150 rounds, divided equally between them. The light 6-pounders carry 34 round and 16 case-shot in their limbers, and for each pair of guns about 260 rounds of forts in one waggons. The 5½-inch howitzers carry 22 shells, 4 case-shot, and 2 carcas, in their respective limbers, and are attended by two waggons, carrying 24 case-shot, 24 shells filled, and 120 empty, and 4 carcas. The horse artillery pieces have waggons on a peculiar construction, which carry as follow:

<table>

</table>

The British parks of artillery are composed of the following ordnance; medium 12-pounders, 4; Desaguliers's 6-pounders, 4; and light 5½-inch howitzers, 4. These are called brigades, according to their respective calibres, or natures; each brigade consisting of 4 or 6 pieces, with a reserve of about 5th of the whole number, which should be placed behind the front line; but if the front be extensive the reserve must be divided.

All field pieces are mounted on carriages, standing on one pair of wheels five feet in height, and when travelling have their trails, or rear, (which then precedes the gun itself,) hooked up to the rear of the limber, or carriage, on equal fixed wheels, allowed to the conveyance of the ammunition in chests; thence called limber-boxes.

**Field-Staff**, is a staff carried by the gunners, in which they screw lighted matches, when they are on command; which is called arming the field-staffs. See **Linstock**.

**Field-Marshal**, is the denomination of the modern military rank in England, but superior to all others; having the chief command of the whole army.

**Field Officers.** See **Officers**.

**Field of Vision**, in **Optics**, is that conical space indefinitely extended before us, so as to include all objects that can be seen at one view, or without turning the eyes. The precise limits of this space are not easily ascertained. In looking at a small distance, we have an imperfect glimpse of objects through about the extent of a hemisphere, or at least for above sixty degrees each way from the optic axis; but towards the extremity of this space objects are very imperfectly seen; and the diameter of the field of distinct vision does not subtend an angle of more than five degrees at most, so that the diameter of a distinct image on the retina is less than .06 of an inch; but it is probably much less. See **Vision**.

**Field Pigeon, in Ornithology**, the English name of a bird of the thrush kind, called by authors Turdus pilaris, which feé.

It is a bird of passage, and visits us in England toward the end of autumn in small flocks, and leaves us in spring; it is not certainly known where these birds breed. They feed on berries, particularly those of the holly, and are well tailed birds.

This bird is easily taken with water bird-line in the following manner: take out a gun, and kill two or three field-fačes with it; by that time the gun has been discharged two or three times, the rest of these birds will be so frightened, that there will be no coming near them; then tie one or two of those that were shot to the upper branches of a bushy tree, in such manner, that they may seem alive and fitting there. Then prepare two or three hundred twigs, covering them well with the water bird-fare, made warm for that purpose; take a good brochen bough, and in that place all the twigs; tie this fast to the tree, just underneath where the other field-fačes are tied, and let this be in a place
FIELD, ENRY, in Biography, a distinguished writer, was born in 1709 at Sharpnam, near Glaistonbury in Somersetshire. After receiving the rudiments of education at home, he was removed to Eton school, where he laid in a respectable stock of classical learning. From Eton he went to Leyden, where he studied the civil law, but soon after his return he commenced writer for the stage. His first piece was a comedy, entitled "Love in Several Mafks," and the success which he obtained in this instance led him to make numerous efforts in the same way; but his early comedies are all forgotten; many of them were little more than translations from the French.

At the age of about twenty-six, or twenty-seven, he married a young lady of great beauty, and with some fortune, which, with what he obtained by the death of his mother, put him in possession of an estate of rather more than $200 per annum. With this fortune he assumed the style of a country gentleman, with a retinue of servants, horses, and dogs. In three years he had exhausted his property, and involved himself in considerable difficulties. He now resolved to study the law, with a view to future support, and entered himself in the Temple. While he was keeping the terms required, he supported himself and family by his pen. He wrote for the stage, and published many essays which displayed a fond of good sense, and acquaintance with mankind. His first attempt at the humorous and satiric delineation of character, was in the "HisUory of Jonathan Wild," which displays a familiarity with the scenes of low profligacy, which it is wonderful that a person in decent life should ever acquire; but his early courts laid the foundation of too much knowledge of this kind. In 1742 he published his first proper novel, entitled "The History and Adventures of Joseph Andrews, and his friend Mr. Abraham Adams." The scenes introduced in this piece are chiefly those of low life: the grave Cervantian humour is imitated, and the principal character, parfon Adams, is moulded on the Quixote of the piece. His success as a novel-writer was not favourable to his professional pursuits, and he did not attain to any considerable eminence at the bar. He received little emolument from his legal practice, and his other supplies were inadequate to the demands of his family. In the midst of anxious cares and broken health, he had the misfortune to lose his wife. By this stroke he was so far overwhelmed as to be unequal to all exertion. At length, the love of liberty and the cause of Protestantism re-animatéd his soul, and, in 1745, during the rebellion, he wrote and published a periodical paper, entitled "The True Patriot," which was followed by "The Jacobite Journal." These efforts in favour of the government and constitution, obtained for him the appointment to the office of Middlesex magistrate, in the discharge of the duties of which he was very exemplary, and took every method for preventing crime, and for improving the police. In 1749 he published "A Charge to the Grand Jury," containing an accurate account of the administration and particular duties of grand juries. This was followed by an "Enquiry into the Causes of the late insurrection of Robbers," and a letter to the lord chancellor Hardwicke; and by "A Proposal for the maintenance of the Poor," both these pieces were esteemed judicious and useful performances, and as exhibiting much diligent research into difficult subjects. While he was thus employed in the serious avocations of his magisterial office, he found leisure to write his "Tom Jones," which must ever be regarded as a master-piece of art, replete with the most striking delineation of manners, and exhibiting extraordinary skill in managing the intricacies of a plot so as to wind up with the happiest effect. His third novel was entitled "Amelia," which came out in 1751; after the publication of this his constitution began to give way very rapidly, but the powers of his mind were still in high vigour, and he engaged in a new periodical work, entitled "The Covent Garden Journal," which continued with much success for about a year, when the author's ill-health obliged him to suspend his literary labours. As a last resource, he was advised to try the climate of Portugal, but the voyage did not contribute to his recovery: he lived long enough to describe the occurrences which he had witnessed in passing from London to Lisbon, and died October 8th, 1749, in the forty-eighth year of his age. Fielding was possessed of many fine virtues of the heart, and the powers of his understanding were unquestionable. His novels, though liable to objections, afford many valuable moral leons. His manners are often drawn from low life, and display too much of the vices and crimes of mankind, yet they are relieved by a considerable admixture of nobler matter, and contain many affecting pictures of moral excellence. His fame as a writer has not declined since his death. He is still regarded as much at the head of the department of comic romance as Richardson is at that of the sentimental. His father, Sarah Fielding, is known for two novels, entitled "David Simple," and "The Cry," and for a translation of the "Memorabilia" of Xenophon: and his half-brother, sir John Fielding, was long at the head of the public office, London. Biog. Brit.

FIÉLDEWEER, in Geography, an island near the W. coast of Norway, about 22 miles long and 4 broad, with a town. N. lat. 63° 33′.

FIÉLSÅ, a town of Swedish Lapland; 45 miles S.S.E. of Aetsa.

FIÉNA, a town of Persia, in the province of Irak; 5 miles S.W. of Cahan.

FIÉNVILLE, in Geography, a town of France, in the department of the Somme; five miles S.W. of Doullens.

FIÉNS, or FIÉNS, THOMAS, in Biography, a physician of eminence in the sixteenth century, was born at Antwerp, where his father exercised the same profession, on the 28th of March, 1557. He pursued his medical and mathematical studies at Leyden, and afterwards at Bologna, which he visited in 1580. On his return to his native country his talents were soon made known: in 1593 he was invited...
to Louvaine, in order to fill one of the vacant professorships of medicine in that university, in which he took the degree of doctor about the end of that year. He resigned his chair after seven years of residence in that school, and went to Munich, having been appointed physician to Maximilian, duke and afterwards elector of Bavaria; but he returned to his poll at the end of one year. In 1616, he was offered the professorship of medicine in the university of Bologna, with a salary of a thousand ducats; but the archduke Albert immediately increased his salary at Louvaine to the same sum, in order to do away the temptation of leaving that city. Accordingly he remained there until his death, which occurred on the 15th of March, 1617, at the college of Brougham, of which he had been for a long time professor. Fienus has been ever regarded as an intelligent and able physician; he had few equals among his contemporaries in the knowledge of natural history and surgery; not to mention his acquaintance with the Greek, and mathematics. His works likewise contributed greatly to advance his reputation; they were as follows. 1. "De canteribus Libri quinque," Louvaine, 1598. 2. "Libri Chirurgiae XII., de praecipuis Artis Chirurgiae controversiis," Francfort, 1602. This work, which passed through many editions, treats of the principal surgical operations. 3. "De viribus Imaginacionis Traetatus," Louvaine, 1628. 4. "De Cometa anni 1618," Antwerp, 1619. In this tract he combats the opinions of Copernicus regarding the motion of the earth. 5. "De vi formatoric hastis Liber, in quo ostenditur animam rationalism infundii tertiis die," ibid. 1620. This work was attacked by Louis du Gardin, a professor of Douai, who maintained the better ground in the undeterminable argument. Fienus replied in a. "De formatoris hastis adversus Ludovicum du Gardin, &c.," Louvaine, 1624. His opinion was at last impugned by Santa Cruz, the physician of Philip IV. which produced, 7. "Pro fun de animacione Fictus tertii die opinione Apologia, adversus Antonium Ponce Santa Cruz, Regis Hispaniarum Medecim Cubilecumare, &c.," Louvaine, 1629. 8. "Semiotics, sive de signis medicis Traetatus," Leyden, 1664. The father of the preceding, Dr. John Fienus, published a treatise at Antwerp in 1582, entitled, "De Platibus humanum corpus molellantibus Commentariorum novus ac fingularis," which passed through many editions. Eloy. Dict.

FIERAS, in Geography, a town of Sweden, in the province of Aebland; twelve miles N.N.W. of Wardberg.

FIERI FACIAS, in Law, a judicial writ, which lies at all times within the year and day, for him that hath recovered in an action of debt and damages; it is directed to the sheriff, commanding him to levy the debt and damages on him, against whom the recovery was had. This species of execution is called fieri facias from the words in it which command the sheriff, quod fieri facias de bonis, that he cause to be made of the goods and chattels of the defendant the sum or debt recovered. This lies as well against privileged persons, peers, &c., as other common persons; and against executors or administrators with regard to the goods of the deceas'd. The sheriff may not break open any outer doors (5 Rep. 92.) to execute this writ; but must enter peaceably, and may then break open any inner doors, belonging to the defendant, in order to take the goods. (Palm. 54.) And he may fell the goods and chattels, even an estate for years, which is a chattel real (8 Rep. 171.) of the defendant, till he has raised enough to satisfy the judgment and costs: first paying the landlord of the premises, upon which the goods are found, the arcents or rent then due, not exceeding one year's rent in the whole. (Stat. 4 Ann. c. 14.) If part only of the debt be levied on 2 fieri facias, the plaintiff may have a copy of satisfacientium for the residue. (1 Roll. Abr. 904. Cro. Eliz. 344.) See Execution.

FIESCO, JOHN LEWIS, in Biography, count of Lavega, a noble Genueso, was born in 1525. He became possessed of a large estate at the age of eighteen, and, surrounded with flatterers, began, at their suggestions, to aspire after that power and distinction in the state to which his birth and opinion formed to entitle him, but from which he was precluded by the superintendency of the Doria family. (See Doria, Angelo.) Fiesco, who possessed all the talents proper to ingratiate himself with a party, resolved to attempt a revolution in Genoa which might raise him to the station that Doria now occupied. His courteous manners rendered him a favorite with the people. He obtained the interest of the court of France, and the concurrence of the Pope, who accommodated him with some galleys. Notwithstanding the preparations that he was making, Doria did not, and would not, suspect anything to the prejudice of Fiesco, though the destruction of himself and family formed an essential part of the conspiracy. The day fixed for the bloody enterprise was January the 2d, 1547, and, on the preceding morning, Fiesco prepared a galley under the pretext of a cruise against the corsairs, and then paying a visit to Doria, he requested permission to depart early from the harbour, and took his leave with much apparent respect, and every demonstration of affection. In the evening he assembled his adherents, and having exhorted them to join him in an attempt to free their country from its oppressors, he went to make known his project to his wife, who, distraught with the idea of the impending danger, entreated him, on her knees, to desist from his desperate undertaking. He had, however, made up his mind, and was immovable; rushing from her apartment, he exclaimed, "Madam, you shall never see me again, or you shall see every thing in Genoa beneath you." In the dead of night he sailed forth at the head of 50 armed men, surround'd by his fellow conspirators. He dispatched parties to all quarters, and proceeded himself to secure the dock in which the galleys lay. In pulling over a plank, placed between two veldts, it gave way and he fell into the water. The weight of his armour fink him to the bottom, from whence he never rose, and thus, at the early age of twenty-two, his life was sacrificed at the shrine of ambition. The confederates had gone too far to recede with safety; they determined therefore to strike the desperate blow, but the death of their leader was fatal to the attempt. Doria escaped unhurt; the senate recovered its authority, and the family of Fiesco paid the penalty of the crimes of their leader by ruin and proscription; Mod. Unit. Hist.

FIESCO, in Geography, a town of Italy, in the department of the Upper Po; 4 miles E. of Crema.

FIESOLE, GIOVANNI DA, in Biography, 2d historical painter, who was born at Fiesole, in 1507. His real name was Montoroli; from his excellence in painting the expressions of saints and angels, he was also called Giovanni Angelico. He was first placed as a disciple with Giottino; he afterwards became a Dominican friar. His first works of confluence were painted at Florence, by order of Cosimo di Medici; who having built the church and convent of St. Mark, commissioned Fra. Giovanni to paint the Chapter-house, in which he represented, in fresco, on the walls, three subjects. 1st, The Pallion of Christ. 2d, All the Saints, Founders of Religious Orders, weeping at the feet of the Cross, and on the other St. Mark the Evangelist with the Virgin, the three Marys, and Saints Cosimo and Damiano, present at the Crucifixion. Under these, by way of fresco, 

R
he represented a tree, at the foot of which was St. Dominici
co supporting the branches, which in their turn upheld
portraits of all the popes, cardinals, bishops, saints, and
doctors in theology, who were of the Dominican order.
His fame procured him an invitation to Rome from pope
Nicholas V., who employed him to paint his chapel and or-
nament manuscripts. He became so warm an admirer
Giovanni, that he offered him the see of bishop of Florence,
which his humility and poverty of his art, led him to
deny him for himself, and the person whom he re-
commended was installed in his stead. He generally painted
his pictures smaller than life: Vafari speaks of them with
great delight, but they are not of a grand clafs, and are
often defective. He died in 1445, aged eighty-six, hav-
ing been exceedingly industrious, and leaving behind him an
immense number of works, principally at Florence and
Rome.

FIESOLI, in Geography, a town of Etruria, the see of
a bishop, suffragan of Florence, three miles N.E. of
Florence. This is the ancient 
Fezola, one of the twelve cities of
Etruria.

FIFE, a small shrill flute, blown at the side, like a Ger-
man flute. It is in almost every musical band, and in the
labor and pipe driven the dance, the fife and drum animate
the soldiers, particularly in the quick step. The fife has fix
notes, and families two octaves from the lowest D in the
treble, to D in alt. The Swiss fife brought this instrument
into France, after the battle of Marengo under Francis I.;
since which it has been admitted into regimental music,
in preference to the common octave flute, having made its
fife falls from its having a key which the fife 
has not. Lab-
barde.

The fife is an instrument, particularly intended for the
use of regiments, and, in conjunction with the drum,
the only music with which many corps are provided. This
little shrill tube is usually about fourteen inches in
length, and of one piece, though some are made to take
to pieces; but such are not suited to military use: it may be
considered a small kind of flute, especially if provided, as
some are, with a key; but such are rare, the generality
being confined to only fix finger holes, and an embouchure,
or mouth-hole. The want of a key necessarily occasions a
difference in the fingering of many notes; but the compas,
or extent, is about the same as that of the German flute;
namely, from D below the treble staff, to D in alt.; but
all beyond B in alt. are more or less harsh, and cruelly
piercing to a feeble ear. Fifes are made of three several
sizes, denominated A, B, and C, respectively: A being the
largest and deepest toned, and one minor third below concert
pitch; the next size is made to correspond with the B b
of the musical scale, and is generally used when playing with
military bands, using what are called B b clarionets. The
C fifes are those at concert-pitch, and are chiefly used for
the ordinary service of these instruments. Such an affor-
ment requires some vehicle or receptacle; accordingly we
find that where such a diversity is allowed, each fife is pro-
vided with a

Fifes-cafe, which is a tin tube, about twenty inches long,
and three in diameter, having two diaphragms of tin pierced
for the several fifes to pass through, so as to be kept sepa-
rate. There is a tin lid which falls down, and either
locks or is fixed by a spring pin. This case is generally
painted to conformed with the ornaments on the drums of the
regiment, and is slung over the shoulder by means of a cord
with tassels. Though certainly decorative, we cannot but
view this appendage as both useless and extravagant.

Fife-rail, in a Ship, are those that are placed on banisters
on each side of the top of the poop, and so along with
hances or falls. They reach down to the quarter-deck, and
to the flair of the gangway.

FIFE'S Passage, in Geography, a channel in Broughton's
Archipelago, about eleven miles in length and two in breadth.
N. lat. 59° 50' E. long. 233° 11'.

FIFENESS, a cape of Scotland, on the E. of the
county of Fife, with a village of the same name, a ridge of
rocks, called the Cor rocks, extending a considerable
way into the sea, renders the passage of the cape dangerous
to leaven. N. lat. 56° 15'. W. long. 2° 39'.

FIFER, a person who plays on the fife: of these one is
generally appointed to each company of infantry, who, in
company with the drummer, plays to the corps while March-
ing for the relief of guard, or when the arms are carried;
also at the times of beating the reveller, the assembly, the
retreat, the tattoo, and other regular or incidental duties.
The most disagreeable part of the duty of the fifiers and
drummers, consists in the infliction of such punishments as
offenders are sentenced by courts-martial to undergo; in pre-
ference of their companions in arms, occasioning this class
of persons to be often treated with marked odium, and to
receive the opprobrious designation of "Bloody Thumbs."

This term is derived from the stains of blood attaching
to their hands, in consequence of their occasionally firstrate
the several cords of which a cat-o-nine-tails is composed,
and which in the act of floggings are apt to become ent-
tangled, so as to fall heavily upon the delinquent's
shoulders. We cannot let pass this opportunitv of expres-
ing our conviction, founded on the bold authoritv, that
personal punishments are as unnecessary as they are dis-
greecful; and that it is not only very practicable, but has
in many instances been found very effectual, to substitute
moderation for severity, and an attack on the pride of an
offender, for one on his flesh. Under the existing sys-
tem we can never be led to envy the feelings of the fifiers
and drummers of a regiment; nor can we entertain the opinion
that this class of our foldvry will be exempted from these
opprobrious epithets, and these facetious reflections, which
affix a stigma of the most obnoxious description.

FIFESHIRE, in Geography, is a county of Scotland,
almost surrounded by the rivers Forth and Tay, the friths
or estuaries of which nearly form it into a peninsula. The
former river on the south divides it from the Lothians; and
the latter separates it from the friths of Perth and Angus;
on the east it is bounded by the friths of Kinrooth and
Clackmannan; and on the west by the German ocean. The
length is 60 miles by 18 in breadth, comprising about 485
square miles. The rivers by which it is watered, besides
the two already mentioned, are the Eden and the Leven.
The Eden has its rife on the borders of Perthshire, between
the towns of Strathmiglo and Abernethy; and taking a
course of 17 miles due east, falls into the sea in the bay of
St. Andrew's. Though a tide river, its frith is compar-
atively placid, and its fine salmon fishery is greatly annoyed
on this account with the notorious enemies of that fish, the
ploice or seals, which is elegantly alluded to by the poet
Johnstone.

"Arva inter nemoralique umbras, et pescena lata
Lene fluen, vitreis fabritur Eden aquis."

The Leven flows out of Loch Leven, a beautiful lake
of nearly 12 miles in circumference, partially included in the
friths of Fife and Kinrooth, the fertile plain of which forms
its well and northern boundary, and to the east and north
it is overlooked by the towering Lomond hills. These and
other interesting surrounding objects, particularly the royal
residence
residence of the ancient line of Scotch or Pictish kings, will be noticed in their respective places. This river, after running 17 miles in an easterly direction, falls into the sea near the village of Leven. It has frequently been confused, by the admirers of Smollett for his beautifule ode on Leven Water, with a river of the same name in the flight of Dumbarton.

This district anciently formed part of the province invicta Caledonia which name the Romans had given to the country north of the river Tay, previous to their taking possession; for Camden observes, the Tay was the utmost northern boundary of the Roman empire in this part of Britain. Julius Agricola, the last of generals under the world of emperors, Domitian, though he was enabled to penetrate further by inductive invasions, even into the heart of the highlands; yet sagaciously perceiving no benefit could arise by conquering a country, naturally unproductive, and thinly peopled, wisely withdrew his army from what he termed the Barbarians; and to redress retaliations erected a chain of forts across this part of the island, and established the Tay for his hostile frontier. Some Roman remains have been discovered northward in Fife, but many more in those parts of ancient Fifeshire, which now constitute the counties of Clackmannan and Kinross. The face of this part of the country is agreeably diversified; towards the west, it is mountainous, and a ridge of hills extends north-southward nearly the whole of its length, dividing the country into two natural districts; on each side the country gradually falling to the respective friths of Forth and Tay. The low lands exhibit a fine fertile country, the high lands most extensive and beautiful prospects; and both are tolerably well wooded. The two conical hills, called the Lomonds, stand very conspicuous, and are visible out at sea to a great distance. The eastern Lomond, the most regular and beautiful in its shape, is about 1650 feet above the level of the town of Falkland, which stands at its base. On the summit of this hill is a small lake, which has the appearance of a volcanic crater, similar to those described by Spallanzani in his travels through Sicily. The western Lomond is less regular in its form, but has greater elevation; and on the summit is a heap of loose stones, denominated by antiquaries a Cairn.

The natural productions are numerous and varied. The whole of the south side of the county abounds in coal, and the pits are numerous. The western and midland districts produce iron; lead has been discovered in the eastern Lomond, and mines of zinc are profitably worked in the parish of Kembrock. Limestone is abundant, and of an excellent quality; there are valuable freestone quarries, and plenty of marble. The pebbles, much admired for the high polish they take, have been discovered in different places; and various kinds of agate, with rubies of a fine water, highly valued by lapidaries. Agriculture appears to have only occupied the attention of the inhabitants of Fifeshire; and its artificial productions vince a spirit of industry and improvement, topsailed in few parts of Scotland. The property is pretty equitably divided; there being few large estates, and the proprietors in general reside and cultivate their own. From this kind of equitable distribution of land, its value is increased, falling from 25 to 30 years purchase. To enumerate the seats of the nobility and gentry is not a part of our plan; but those of Abergour, Leith, Melville, and Ely, are particularly deserving notice. In several parts of the county are the remains of royal seats; at Dunfermline, Falkland, Kinbourn, and St. Andrew's. These ruins will soon eace to be interesting; for in the words of lord Rochester, "they are in the full perfection of decay." Almost surrounded by the sea, this county is supplied with several good harbours; particularly Dunblane, in the frith of Forth, opposite Leith, which is inferior to none in the island. From the circumstance of the towns principally lying upon the coast, king James VI, compared this county to a grey mantle with a gold fringe. These towns were rewarded by that monarch with peculiar attention, who endeavoured to make them full-fertile to Sit gran and wife design of raising Scotland high in the scale of commercial nations; a rank her natural capabilities enabled her to hold. For this purpose he granted the inhabitants. The priviledges and immunities; and by every inducement encouraged them to cultivate their local advantages. And though many of those priviledges by the nation have been rendered unimportant, yet they remain a standing monument of the just distribution and political ingenuity of the royal gracor. The county lends one member to the British senate. The number of royal burghs or parliament towns, as they are usually called, is thirteen, viz. Cupar, the county town, St. Andrews, St. Andrews, Dunfermline, Dunblane, Kinbourn, Kirkaldy, Dornoch, Peterhead, Auchterarder, Kirkcaldy, Earlsferry, and Craik. Several other, formerly privileged with elective franchise, have lost it, from having been unable to defray the expense of representation, by sending a commissioner to the Scottish parliament. Among this number may be mentioned, the towns of Auchtermuchty, Strathmiglo, Newburgh, Falkland, Kilconquhar, Elie, Earlsferry et al., which, though not very large places, derive notice from their former importance. The county is divided into sixty-three parochial districts, and by the enumeration returned to parliament in 1821, the number of houses was 17,065, and inhabitants 93,744, being 196 upon every square mile; a much greater population than is to be found in any other part of Scotland. In its ecclesiastical distribution it contains one final and four seats of prebendary. The people are variously employed. Many in the salmon, herring, and especially what is denominated the white filthery, which is very productive on this part of the coast; others in digging coals, great quantities of which are carried coalwise, and by the Caledonian canal, to other parts of Scotland. The iron mines employ numbers, the ore of which supplies the Calder, Carron, and other iron works; and still more are engaged in manufacturing linen and cotton cloths; with a kind of the latter, under the name of green cloth, the London calico printers have been long supplied from the markets of Fife. This county anciently constituted an earldom, and the honour was possession by the family of Macduff; a title conferred on the thane of Fife, by Malcolm II. For the services the former had done that monarch, in restoring him to the throne, which had been previously possessed by the usurper Macbeth. This title having become extinct, was recently revived in the Dulls of Braco, lateral descendants of the ancient family. General Statistical Account of Scotland.

FIFTEENTH, Septima, or Quinzieme, an ancient tribute or impost of money, laid upon any city, borough, or other town, through the realm; not by the poll, or upon this or that man, but in general upon the whole city or town.

It is so called, because it was supposed to amount to a fifteenth part of that which the city had been valued at of old; or to a fifteenth part of every man's personal estate, according to a reasonable valuation.

This was imposed by parliament, and every town through the realm knew what a fifteenth for themselves amounted to, because it was always the same; whereas the subsidy, which
was raised of every particular man's lands, or goods, must needs be uncertain.

The fifteenth seems to have been a rate anciently laid upon every town, according to the land or circuit belonging to it. Camden mentions many of these fifteenths in his Brit. ves. p. 171, "Bath geldbat pro viginti hidas, quondo sechra geldbat, &c." And p. 181, "Old Sarum pro quinquaginta hidas geldbat, &c." Which rates are according to Doomsday. But in after-times the fifteenth came to be understood as imposed only on goods and chattels, not on lands. It was first granted by parliament, 18 Edw. I. ves. "Computus quintus de repo regii, an. 15. par archiepiscopos, episcopos, abates, priores, comites, barones, & omnes alias de regno, de omnibus bonis mobilibus concebente." The city of London paid that year for the fifteenth 2860l. 172. 8d. and the above of St. Edmund's 666l. 13s. 4d. which was by computation; and thereupon had all the temporal goods of their district discharged of the fifteenth.

In the 8th of Edw. III. it was reduced to a certainty, when, by virtue of the king's commission, new taxes were made of every township, borough, and city, in the kingdom of England. Westminster, London, and the other great cities, which were, at the time, the fifteenth part of the value of every township, and the whole amounted to about 29,000l; and, therefore, it still kept up the name of a fifteenth, when, by the alteration of the value of money and the increase of personal property, things came to be in a very different situation. So that when of later years the commons granted the king a fifteenth, every parish in England immediately knew their proportion of it; that is, the same identical sum that was assessed by the same aid in the 8th of Edw. III.; and then raised it by a rate among themselves, and returned it into the royal exchequer.

The way of collecting it was by two assessors appointed in every county by the king, who appointed twelve more in every hundred to make a true valuation of every man's personal citate upon which the fifteenth part was levied.

**Fifteenth, in Music, is an interval whose ratio is 14th, or the double octave or replicate thereof = 1224 l. 24 l. + 16 l.; see table of Concord.**

Fifteenth Mot. In an Organ, is a range of pipes, so called because each note therein is tuned a double octave or fifteenth above the diapasons, which are reckoned the standard. In accompanying choral parts in a concert, or in church singing, this fift, the twelfth, the principal, and the two diapasons, are generally used together.

**Fifteenth-Mile Creek, in Geography, a river which rises in Pennsylvania, and runs into the Potomack, in Maryland.**

**Fifth, in Music, is a perfect concord, the next in perfection to the union and octave; in the division of the monochord its ratio is 3:1, that is, the third part of a string is a 5th to the octave of the whole string. (See Monochord and Fundamental Bass.) The 5th is a principal found in the triad or common chord. It is made a discord by the 6th; the 5th is a discord in itself, and must be prepared and resolved. The perfect 5th is seven half notes above the base. It is so perfect a chord that no succession of 5ths with the base, or any of the other parts, can be borne, ascending or descending together.**

R. Peguche has given all the warrantable means of preparing and resolving it as a discord, and for the unwarrantable success of 5ths, see Padre Sacchi delle quinte successe. The 5th of a key, falling to the key-note on the base, being regarded as a full cadence or close, has given birth to France to the denomination of dominant, as it governs or leads to the key-note or tonic of every key. Thus, G is regarded as the dominant of C, and D of G, &c.

The **fifth, or major Fifth, is one of its most important intervals, and the most perfect or agreeable in its harmony of any other interval within the octave; it is usually marked V in writings on the theory of music, and consists of seven of the half-notes of keyd instruments, which have 12 founds in the octave. Its ratio is \( \frac{3}{5} = \frac{37}{5} \times 7^h + 31 \); its common logarithm is .82920574004, and its binary log. = .584962, which is its decimal relation to the octave (1) of which it is nearly the 1/2; it contains 15.635526 major commas, is composed of a major and minor third, and is the complement of a minor fourth to the octave; it is equal to the sum of a major tone and minor fourth, a semidiatonic and a medius femitones, a tritone and major femitone, three major tones and a humor, three aportones and four humors, two major tones, one minor tone, and a major femitone also compose it, (see Quint.) Two circumstances have concurred to render this concord the most proper to be used in the tuning of keyd and figured instruments, first, its great perfection, by which much facility is gained in tuning, and it being the only concord which will bear repeating 12 times in succession (with, or without descending octaves) and each time produce a note answering nearly to the 12 notes in common use, and on the 13th repetition fall very nearly on an octave of the note first started from: which circumstances occasion this concord, tempered in different degrees, to be almost exclusively used in the tuning of instruments. Besides the above, various other intervals bear the names of fifth, as

**Flat Fifth, the semidiatonic of the ancient, or false fifth of some, being less than a tone or major-fifth by the medius semitone, and consists of six half-notes; its ratio is \( \frac{45}{64} = \frac{311}{2} = \frac{311 + 6 f + 27 m}{2} \); its common logarithm is .847035979; its binary log. = .708418, and it is 28.5334 major commas. It is the complement of a tritone, is equal to a minor fourth and a major femitone, a tritone and minor comma, to the difference between two minor thirds and a major comma; a major, a minor, and two major femitones also compose it; and it is the difference between two 4ths, and a III, whence it may be tuned on an organ.

**Sharp Fifth, or diesis defective minor fifth, the superfluos fifth of Tartini, consists of eight half notes; it exceeds the true fifth by a minor femitone; its ratio is \( \frac{24}{25} = \frac{394}{3} + 8 f + 34 m \); its common logarithm is \( 5 \times \log 394 + 8 \times \log 2 + 34 \times \log 3 \); its binary log. = .64 886, and it is 35.02654 commas; it is the complement of the flat fourth; it is equal to two major and two minor tones, and is equal to the difference of a minor fifth and enharmonic diesis, also to 2 VIII - 2 Gtis, 2 5 - 2 3, 2 VI - 2 4ths, or to 1 IIIl; whence it may be tuned.

**Comma deficient Fifth, or lesser Fifth of Holder, and deficient Fifth of others, is less than a true fifth by a major comma, as its name imports; its ratio is \( \frac{37}{35} = \frac{347}{3} + 7 f + 32 \); its common logarithm is .82920577283, and its binary log. = .567024; it is 31.69924 major commas. It is equal to one major, two minor, and one major femitone.
F I F

tone, and to a minor fourth and minor tone; it is also equal to the difference between two 4ths and a 3d, whence it may be tuned.

*Comma-deficient flat fifths,* is an apotome less than a true fifth; its ratio is $\frac{729}{1024} = \frac{3}{2} = 300 \times 6 + 5 + 26$; its common logarithm is $0.3324757 + 0.67$; and its binary log. $= 0.900238$; it is $= 27.5^\pm 0.49028$ major commas. It is the complement of three major tones; is equal to two comma-deficient minor thirds; to two major tones and two limmas; and is also the difference between four Vths and two 4ths, whence it may be tuned.

*Comma-redundant flat fifths,* or greater fifth of Holder, is a major comma larger than a true fifth; its ratio is

$$\frac{539}{405} = \frac{25}{35} = 369 \times 7 + 5 + 85 m;$$

its common logarithm is $0.818735.0905$, and its binary log. $= 0.602881$, it is $= 32.6350.120$ major commas, three major tones, and a major limma; and is the difference between two Vths and a 3d and two 4ths, whence it may be tuned.

*Comma-redundant flat fifths,* or tritome maximum of Euler, also the diminished fifth of four, is a minor limma less than a true fifth; its ratio is $\frac{25}{35} = \frac{5}{2} = 322 \times 6 + 36 + 28 m$; its common logarithm is $0.840375.0920$, and its binary log. $= 0.526068$; it is $= 29.35340$ major commas; it is equal to two major tones and two major limmas, also to two 3ds, whence it may be tuned.

*Disphiclima-deficient fifths,* is a disphiclima less than a true fifth; its ratio is $\frac{25}{35} = \frac{5}{2} = 346 \times 7 + 5 + 30 m$; its common logarithm is $0.829738.7996$, and its binary log. $= 0.565417$; it is $= 31.54068$ major commas; it is equal to the difference between four minor tones and a chromatic clisma; to the sum of a minor fourth and two limmas, to live limmas and two apotomes; to the difference between seven octaves and eleven fifths, or seven minor fourths and four fifths, whence it may be tuned. It is the reducing fifth, or that between the hearing notes, when eleven successive perfect fifths are tuned in an octave.

*Double deficient fifths,* is two major commas less than a true fifth; its ratio is

$$\frac{2189}{3024} = \frac{3}{2} = 355 \times 7 + 7 + 29 m;$$

its common logarithm is $0.549078.7942$, and its binary log. $= 0.549122$; it is $= 30.63512$ major commas, and to a major tone, two minor tones, and a limma; and it is the difference between two Vths and two 4ths, and three Vths, whence it may be tuned.

*Double superperfect flat fifths,* is an apotome greater than a true fifth, and two major commas greater than a flat fifth; its ratio is

$$\frac{4796}{6801} = \frac{3}{2} = 416 \times 8 + 3 + 46 m;$$

its common logarithm is $0.7953899.1241$, and its binary log. $= 0.675695$; its major commas, also to four apotomes and four limmas, to two major thirds and two minor commas; to four major tones; to the difference between eight Vths and four Vllths, or between four Vths and four 4ths, from either of which last, this interval may be tuned.

*Minimum fifths* of M. Henfling, or extreme diminished fifth of home, is exceeded by a true fifth, the quantity of two minor semitones and a major comma: its ratio is $\frac{375}{275} = \frac{25}{18} = 2.75 \times 7 + 5 + 24 m$; its common logarithm is $0.8254763.0675$, and its binary or Euler’s logarithm $= 0.949253$; it is $= 25.06728$ commas; it is equal to the difference between a XTH and three ITDs, whence this interval may be tuned.

Fifth-reduction. Men, in Ecclesiastical History, the denomination of wrong-headed and turbulent enthusiasts, who sprang up in England during Cromwell’s usurpation; and who expected Christ’s sudden appearance on earth to establish a new kingdom, and, acting under the influence of this illusion, they aimed at the subversion of all human government, and were far turning all things into confusion.

*Fig.* In Botany. See Figs.

*Fig.* Indian. See Cactus.

*Fig.* Infernal. See Arumumone.

*Fig.* Pharesobt. See Ficus and Musa.

*Fig.* Marygold. See Mesembryanthemum.

*Fig.* tree. Covinham. See Cactus.

*Fig.-wort,* the common name of a plant of the weed kind, which is frequently met with in pasture lands. The roots are of the oblong knobly kind. The leaves are heart-shaped, cornered, and placed on foot-stalks. The flowers have much resemblance to those of crown-foot, but differ in having the cup divided into three parts only, the petals being about eight in number, and narrower. It is a low plant, which runs very much by the roots, choking up most others which are near it. It has likewise the names of pilewort, leffer centuary, &c. See Scrophularia.

*Fig.* Petrified, in Natural History. Among the numerous pyritic indurations of Shelly island, Mr. Jacob collected two which he thought to be figs; which Dr. Parson afterwards referred to a recent fungus, but perhaps with not much better reason.

*Figs,* in the Materia Medica. They are moderately nourishing, grateful to the stomoch, easier of digestion than any of the other sweet fruits, and soften the appetites of the blood, &c. and accordingly are used in medicine, to make gargariams against disorders of the throat and mouth; and as an ingredient in pectoral decoctions, and in minister electurias. They are also applied externally to soften, digest, and promote maturation.

Figs are dried either by a furnace, or in the sun, having first dipped them in scalding hot lye, made of the ashes of the fig tree. The Latins call them carica; or ficus pallas, when thus dried.

In this condition they are used both as medicinse and food; being both the whole, and cather of digestion, when thus clarified of a quantity of their aqueous and viscous parts.

*Figs,* in Common. The best figs are the produce of Turkey, Italy, Spain, Proponese, &c. The islands of the Archipelago yield figs in great abundance; but they are much inferior in goodness to those of Europe. Yet the Greeks in those islands cultivate them with wonderful care and attention: as making the principal food, and a considerable part of the riches of the country.

They
They have two kinds of fig-trees: the first, called \textit{orquus}, or the wild fig-tree; the second, the \textit{domestic} fig-tree.

The method of cultivating and ripening these figs makes a peculiar art, by the ancients called \textit{caprification} ; often spoken of among them in terms of admiration. Some of the modern naturalists have looked on it as a chimera; but Monst. Tournet has assured us of the contrary, and given us that proof, as he learnt it upon the spot. See \textit{Caprilication}.

\textbf{Figs.}, \textit{in antiquity}, were used in divination. See \textit{Sycomoria}.

\textit{Fig}, in the \textit{Manu.}, is a sort of watt, or spongy excrecence, on the trunk, and sometimes all over the body of a horse. The figs that appear in the trunk or sole make an evacuation of blithing malignant humours, that are very hard to cure. The only effectual remedy for these excrecences is excision.

\textit{Fig.}, \textit{Infal}, in \textit{Natural History}, a name given by the English to the creature called by the French, after Mr. Reaumur, the \textit{fons puceron}, or \textit{false puceron}, from its very much resembling the puceron in external appearance, but being extremely different from it when nearly examined. These insects are, when at full growth, of the bigness of the head of a pin of the largest size, but there are usually found among them several that are smaller, down to such as are scarce peas in size, or even one on a pin. They are found in great plenty on the back, or under-side of the leaves of the fig-tree, but they never are seen in clusters like the puceron.

The body and brest of this insect are green, and the edges of the wings are white, and befit with hairs. This creature has two antennae or horns, which it can exert at pleasure; but they usually are lodged under the furrows of the wings, and are not to be seen, unless the animal be turned belly upwards; the head also is bent downwards, and the eyes seem directed to look at objects only placed under them.

It has six legs, and a fine small trunk issuing from the extremity of the head; this is but short, and is of a lively green; it is terminated by a sharp point, and has a fine brown filament like a hair, which it thrusts out of the body of the trunk at pleasure, and which forms a sort of engine or organ destined to convey into the body the juices extravasated by the wound and fission of the trunk. The creature usually remains in perfect quietness on the leaf on which it is found, but has this peculiarity, in its position, that it is always found with its head reposing upon one of the ribs of the leaf, and its body on the plain part; by this means, the anterior part of the head is raised above the surface of the plain part of the leaf, and the creature can, by that advantage, move its trunk about at pleasure, and fix it into different parts of the leaf, while its body is perfectly still at the time.

These creatures throw off their skins many times in their growth, the furrows marking the places where their wings are, and the protuberances made by their cales are always seen, however young they are examined.

In the months of May and June these insects all become winged, and afford a peculiar species of a four-winged fly, which is remarkable for hopping; but as its hinder legs are not greatly larger than the rest, it leaps but a little way at a time. The body of this fly is green, its wings are bordered with yellow, and its legs are white; it has a touch of the same nature with that of the creature before its winged state, and with this it continues to suck the juices of the leaves of the fig-tree as it did before.

The manner in which these animals propagate their species is not yet known. The puceron, to which they more approach in figure than to any other animal, have always young ones found within them; but these, if examined in whatever state, never have any such appearance, not even as much as eggs being found in them; it should seem that their eggs are too minute for our inspection, but that they are vigorous, not viviparous animals. Reaumur's \textit{Hill.} vol. vi. p. 535.

\textit{Fig.} or \textit{Field.} See \textit{Dolium}.

\textit{Figs.} or \textit{cloth of Othoche.} In the South sea, is a coarse and harsh cloth, of the colour of the darkest brown paper, made of the bark of a tree which resembles the wild fig-tree of the West Indies. This cloth has the quality of retarding water; and the greater part of it is perfumed, and worn by the chiefs as a morning dress. For the method of manufacturing and colouring this cloth, see \textit{Oudia.}

\textit{Fig.} \textit{wood Worm.} In \textit{Natural History}, the name of an insect which feeds on the leaves of the scrophularia, or fig-wort, and which is usually esteemed a caterpillar, but is one of those insects called by the French for \textit{fige} \textit{chenilles}.

\textit{Fig.} \textit{eater.} In \textit{Ornithology}, a name given by Albimus and Latham to the \textit{Motailla nova}, which see.

\textit{Figurolo}, \textit{cape}, in \textit{Geography}, a cape on the coast of Epire, at the entrance of the gulf of Acta. N. lat. 39° 29' E. long. 25° 34'.

\textit{Figurulo}, an island in the gulf of Venice, near the coast of Libria. N. lat. 45° 10' E. long. 13° 43'.

Also, a town of Italy, in the department of the Lower Po, 13 miles N.W. of Ferrara.

\textit{Figeac}, a town of France, and principal place of a district, in the department of the Lot, situated on the Solle; 46 miles N. E. of Montauban. The place contains 6452, and the two cantors 23,800 inhabitants, distributed on a territory of 275 kilometres, in 23 communes. This was originally a Benedictine abbey, founded by Pepin, A.D. 755, and secularized by Paul III. It was formerly a place of some strength, but falling into the hands of the king, during the religious war, A.D. 1612, its citadel and fortifications were demolished. N. lat. 44° 37' E. long. 2° 8'.

\textit{Figer}, or \textit{Fiaju}, a rich and extensive province of Japan, on the W. coast of Ximou.

\textit{Figging}, in the \textit{Manu.}, a kind of east term among dealers in horses for thrusting "a corn" (as they call it) of ginger into the fundament of a horse, or vagina of a mare, at the time of their being led out for flour, for the purpose of producing irritation, and causing them to lift up the tail. The London dealers, it is said, are in general so much in the habit of recurring to this artifice, that they permit no servant to flay a horse without having previously figged him, under a certain forfeit.

\textit{Fighig}, in \textit{Geography}, a town of Africa, situated on the south side of the Atlas, in the country of Biedulgier. The women manufacture woollen cloth of exquisite fineness, much valued in Barbary, and sold at a high price. The inhabitants carry on a great trade with Fez and Morocco, and with the negroes: 240 miles E. S. E. of Mequinez. N. lat. 32° 5'. W. long. 1° 5'.

\textit{Fight}. See \textit{Battle and Engagement}.

\textit{Fight}, in a ship, are the wattle-cloths which hang round about her in a light, to hinder the men from being flayed by the enemy.

\textit{Fight}, \textit{cloaks}, denote those bulk-cloths afo or abaft the ship, which are put up for men to stand secure behind, and fire on the enemy, in case of boarding. See \textit{Close}.

\textit{Fight},
FIGHTING, in the Military Art. Under the head of ENGAGEMENT, we have given a description of the incidents, occurrences in both military and naval warfare, and we have endeavoured to give a popular idea of those fluctuations which must ever be expected to attend every conflict, even where the superior numbers of one party should seem to threaten the other with complete destruction. We shall, in this place, add, that every circumstance tends to render the conclusion of a fight the most awful and most decisive. The cannonade, which generally whets in the conflict, is rarely very destructive, though, as approximation takes place, and that ease or grape-shot are substituted for round-shot, the carnage is certainly increased beyond all proportion. It is nevertheless curious to observe, that even in those late battles in the neighbourhood of Vienna, wherein not less than 800 pieces of ordnance, and full 250,000 men were engaged, for at least 30 hours, in which it is ascribed the Austrians alone discharged more than 5,000,000 of milket ammunition, the killed and wounded (letting the prisoners apart) did not amount to 80,000 men. Consequently not one is forty of the latter took effect; even if we suppose the vast trains of artillery attached to both armies to have remained inactive. But when we consider that a very large portion, commonly two-thirds of the whole number killed and wounded, are struck with cannon-shot of some description, and that of the remainder many are wounded by the bayonet only, we must feel our astonishment excited to the highest pitch at the comparative insignificance of musketry. Such, however, is the fact.

Buff-fighting, which relates to a more delusive and secret mode of opposition, is far more destructive. In this, each individual acts independently as a ruffian; he conceals himself under bunks, behind trees and bushes, and either fires at the enemy, or assaills him with the bayonet, or sword in hand, according as circumstances may demand, the great art being to destroy without being seen. To this kind of hostility all uncivilized nations at first resort, using spears, thongs, swords, and clubs of various descriptions, and particularly using their bows with great dexterity. In general, regular troops are not much employed in buff-fighting, except in close countries, where banditti—harbour, and especially when popular insurrections take place. It is a species of service very trying both to the courage and the constitution, and though even performed in the highest style by our gallant soldiery, is considered by them as a most arduous and hazardous duty.

Prize-fighting, however much it may be upheld by amateurs, as conducive to the support of a certain kind of courage among the lower classes, cannot be noticed by the more enlightened, as tending with barbarity, and often with the most wanton acts of cruelty. The man who, merely for pastime, or as a speculation, can encourage two of his fellow-creatures to enter the lists, and to do all in their power to main, or even to murder each other, must in his heart be a complete ruffian. That every individual should, in these days, be able to defend himself, will not be denied; but, in admitting thus much, we pass a most severe censure on the dispositions of those who are too often indiscriminately termed peaceable citizens, and who, we are apt to think, if left induced by a certain kind of emulation, towards which prize-fighting greatly contributes, might perform their several duties in life, and pass each other in the streets without either provoking others, or pretending to have received insults from others of a more praiseworthy disposition.

Without attempting to enter on their merits in other respects, as we relieve ourselves for a full exposition of their principles in its proper place, we cannot refrain from remarking that the policy, as well as the good policy, of refraining from blows, is conspicuously proved by that clafs of difcuttents generally called quakers.

FIGHTING ISLAND, in Geography, called by the French "Grofl lile aux Dindes," lies about four miles below Detroit (which see); it is valuable for pasture, but has very little wood. In the summer the Indians make it a place of encampment, and some of them plant a little corn.

FIGHTWITE, FITHWITA, in the Saxon times, signified a mulet for making a quarrel, to the disturbance of the peace. "Multa ob commodiam pugnam in perturbationem pacis, quae in exercitu regis 10 foldorum erat." Blount and Jacob, in transcribing this passage, have inserted 120 foils.

FIGI, in Geography, a town of Japan, in the island of Xano; 10 miles N. E. of Funai.

FIGIN, a river of Norway, which runs into the North sea, to miles S. of Stavanger.

FIGLNAE, in Ancient Geography, a town of Gallia Narbonensis, marked in the Itinerary of Antoinette between Valence and Vienne.—Alfo, a town of Gaul, belonging to the Allobroges, situated upon the left of the Rhone.

FIGMAN, in Geography, a town of France, in the department of the Upper Garonne; 7 miles N. N. W. of Toulouse.

FIG-TREE BAY, a bay on the N. E. coast of the island of Jamaica. N. lat. 18° 18'. W. long. 76° 29'.—Alfo, a bay on the W. coast of the island of St. Christopher, near Sandy Point.

FIGUERAS, a town of Spain, in Catalonia, containing 4000 inhabitants, where the Spaniards, in 1176, began to erect a fortress, which they designed should be impregnable. It was to contain quarters for 150 companies of infantry, with 500 horse, apartments for 60 officers, with suitable accommodations; one long range of magazines for provvisions, and four for powder. The works were made bomb-proof. The glacing is for the most part formed of the rock, and the whole is protected by proper bastions. It is said that 12,000 men are sufficient to defend these works. Nevertheless, the place was taken by the French in 1794; three leagues from Janquera, and seven from Gerona. The adjacent country is agreeable; the hills are shaded with evergreen woods; the plains are well cultivated, and divided by hedges of aloes and wild pomegranate. The road from hence to Gerona is diversified with gentle eminences and fruitful plains. Two of these hills exhibit some volcanic appearances.

FIGUERO-DOS-VINHOS, a town of Portugal, in the province of Eltrcumadura, situated near some lofty mountains, on a small river, which runs into the Zêzere; celebrated for its wine: 20 miles north of Thomar.

FIGURA, in Mystic. See Figure.

FIGURAL, or Figurate numbers, such as do or may represent some geometrical figure, in relation to which they are always considered; as triangular, pentagonal, pyramidal, &c. numbers. See Numbers.

FIGURATE, or Figurative, that which has a relation to figure, or that teaches under some obscure resemblance. Thus a figurative style is that which abounds in figures. (See Figure and Style.) The figurative style, F. Bouhours observes, is neither the most just, nor the best. For this reason Cicero directs us to the ancients, who not having yet be thought themselves to use figurative expressions.
but keeping to the most proper and natural way, have almost all wrote well. "Sunt enim illi veteres, qui nondum ovare potentat et, quae dicibant, omnes prope praelae locuti."

Long since, say the grammarians, renders that proper in all languages, which at first was figurative. The same thoughts appear more lively when expressed by a figure, than when in simple terms. The reason is, that figurative explications denote not only the principal matter, but also the emotion and passion of the person who speaks.

**Figurative is also much used in speaking of the mysteries and figures of the old law.** In this sense manna is said to be figurative of the eucharist.

**Figurative is also used in the Greek grammar for what we otherwise call characteristic, viz., a letter that characterizes certain tenses of the Greek verbs; or that distinguishes and specifies them.**

In the first conjugation of the barytonous verbs, the σ is characteristic, or figurative of the prater tense, and the ἄ of the future.

**Figurative, or Figurative counter-points, in Music, is that wherein there is a mixture of discordants along with the concords.**

See **Counter-point and Supposition.**

Where the discordants are used as a solid and substantial part of the harmony, the counter-point is properly called the harmony of discord.

**FIGURE, FIGURA, in a general sense, denotes the surface of terminating extremes of a body.**

All bodies have some figure; whence figurability is generally ranked among the essential properties of body or matter. A body without figure would be an infinite body.

The corporeal philosophers account for every thing from the figure, bulks, and motions of the atoms, or primary corpufcles of bodies.

For the figure of bodies, considered as objects of sight, see Vision.

The schoolemen dispute whether or no the quality of figure be the same with that of form; and if they differ, what it is that constitutes the difference? Boethius will have figure only predicated of inanimate bodies, and form of animate. Others extend figure to all natural things, and form to all artificial ones; whence the verbe, "Ferman viventis, piæti dic esse figuram."

Others apply figure indifferently to all kinds of bodies, but not in all relations. If only the bare circumference, or circumference, be considered, they call it figure; but if the circumference be considered as endowed with colour, they then call it form, which see.

**Figure of the Earth and Planets.**—This subject has been so fully treated under **Degree and Earth,** that very little remains to be said in this place. The general spherical form of the earth seems to have been known in ages of the most remote antiquity, but this knowledge was often concealed only to philosophers and mathematicians, during the middle ages, the doctrine was even disputed, and the spherical figure denied by some of the fathers of the church; and it is only since the revival of learning in modern Europe that it has been universally received and acknowledged by every class of people. It is now nearly 200 years, that the first mathematicians of Europe have directed their particular attention to the exact determination of the real figure of the earth; an historical account of these labours, and of the refult obtained from them has already been given under the articles above mentioned. Since these were written, the measurement of the arc of the meridian has been continued in our own country, and our continental neighbours have likewise occasionally published some additional documents, relative to their great survey. Nothing however has occurred to alter any of the principal refults which we have given; every thing seems to confirm the opinion, that though the mean figure of the earth approaches very nearly to the spheroid, whose ellipticity is 1/240, yet that the irregularities in the densities of the different masses are very great, so as to render all the partial measurements entirely unsatisfactory. Europe, in general, appears to be much flatter than according to the general form; other parts of the globe must of course be more protuberant; but observations are still wanting to enable us to pronounce in what manner these irregularities are distributed, so as to compensate each other; nor can we flatter ourselves this question will soon be determined, considering the uncivilized state of the great portion of the globe, compared with that requisite to conduct the operations necessary for these investigations. It appears that the project, once entertained, of determining the exact difference of latitude and longitude by geodetical measurement, must now be abandoned, or at least confined to very small tracts of country, as the errors of astronomical observation, when well conducted with perfect instruments, are less than those which arise from the irregularity of the earth's figure. This observation, however, only applies to particular cases, where extreme accuracy is required; for, in general, the situation of places, determined by national survey, is always extremely near the truth, and the limits of error may almost always be known. Our knowledge of the natural history of the earth has not yet been very materially improved by the investigations which have been made relative to its figure. It does not appear that the earth has ever been in a state of entire fission or fluidity, for then it would probably have taken a more regular figure; yet it approaches much nearer to the figure ascribed by theory than could have arisen from the crumbling of its solid particles, as some have supposed. This intermediate state seems consistent with the information derived from our chemical knowledge, and other sources of information. Though a satisfactory solution of these difficulties is at present beyond our reach, yet science is advancing towards this object with rapid strides, and many years will not probably clasp before the mystery is removed, that at present obstructs our searchings into the original nature and constitution of the earth.

**Figure of the Planets.** See the planets respectively.

**Figures, in Architecture and Sculpture,** denote representations of things made in solid matter; thus it suits, figures, &c. Thus we say, figures of brass, of marble, of itouco, of plaster, &c.

But, in this sense, too, the term is more usually applied to human representations than to other things. Thus we say, an equestrian figure, for a man on horseback. Daviler observes, that these, either represented sitting, as popes, &c. or kneeling, as on monuments, &c. or laid along the river, &c. are more properly called figures than statues.

**Figures, in Architecture, are said to be detached, when they stand singly, in opposition to those compositions which are called groups.**

**Figures, in Arithmetic, are the numeral characters; or the characters whereby numbers are expressed, or written.** Thus the number of four hundred and fifty is written, or expressed, by three figures, 450.

The figures in arithmetic are the nine digits; 1, 2, 3, 4, 5, 6, 7, 8, 9, and 0.

These figures were first brought into Europe by the Moors of
of Spain, and into England, as Dr. Wallis apprehends, about 1150. See Arithmetic and Character.

However, from some ancient dates, supposed to consist wholly or in part of Arabian figures, some have concluded, that these figures originally Indian, were known and used in this country at least as early as the tenth century. The most ancient date discovered by Dr. Wallis was that on a chimney-piece at Holmwood, in Northamptonshire, M 133, i.e. 1153. Other dates discovered since, are 1090, at Colchester, in Essex; 1016, with the Roman M for a thousand, at Widgel Hall, near Huntingford, in Hertfordshire; 1011 on the north front of the parish church of Runfold in Hampshire; and 975 over a gate-way at Worcester. Dr. Ward has urged several objections against the antiquity of these dates. As no example occurs of the use of these figures in any ancient manuscript, earlier than some copies of Johannes de Sacro Butofo, who died in 1256, he thinks it strange, that workmen should have made use of these figures to long before they appear in the writings of the learned; and he also disputes the fact. The Helmond date, according to him, should be 1333; the Colchester date 1490; that at Widgel Hall has in it no Arabian figures, the 1 and 6 being I and G, the initial letters of a name; and the date at Worcester, he supposes to consist of Roman numerals, and to be really 1503. Martyn's Abridgment of Phil. Trans. vol. ix. p. 420, &c.

Figure, in Astrology, a description, or draught, of the state and disposition of the heavens, at a certain hour; containing the places of the planets and stars, marked down in a figure of twelve triangles, calledハウス.

This is also called a horn-cup and thence.

Figure of an Eclipse, in Astronomy, represents a representation of the path or orbit of the sun, and the moon, during the time of the eclipse, upon paper; with the number of digits eclipsed, and the beginning, middle, and end, of darkness. See Eclipse.

Figure, or Delineation, of the full moon, such as viewed through a telescope with two convex glasses, is of considerable use in obervations of eclipses, and conjunctions of the moon with other luminaries. In this figure of the moon are represented the macula, or spots, of the moon, marked by numbers; beginning with the spots, which usually enter first within the shade at the time of the great eclipses, and also emerge the first.

Figure, in Copics, denotes the rectangle made under the latus rectum and transversum, in the hyperbola and ellipsis.

Figure of the Diameter. The rectangle under any diameter, and its proper parameter, is in the ellipsis and hyperbola, called the figure of that diameter.

Figures of Plants, since botany became a study, have come into general use to promote a knowledge of the various species and genera of the vegetable kingdom. The oldest drawings of plants of which we have any knowledge, are in a manuscript of Dioscorides, in the Imperial library at Vienna, of which we have already given an account. (See Dioscorides.) These are supposed to be as ancient as the third century of the Christian era, and serve at least to show what was understood concerning the plants of this writer at that period. After the invention of printing, figures of plants were very soon introduced into botanical or medical books, and were at first cut on wooden blocks, and printed in the pages of letter-press. Fabius Columnus, in his Phytobosanum, published at Naples in 1592, gave the first copper plates of plants. We know not exactly how from the practice began of colouring the figures in books; but from some copies of Dodoens and Tragus in our possession, it appears to have been usual about the middle of the 16th century. The above-mentioned drawings at Vienna are coloured, but in the rudest possible style. Engravings in botanical books were not coloured till the early part of the 17th century. Boller's Hortus Eystettensis, published in 1615, was perhaps one of the earlies; but it is always difficult to say whether such works were actually published coloured, or whether, as often happened, they were painted subsequefly by some of their possessors. All these old works were painted by hand, and not printed in colours. This last method was first introduced, we believe, by the late professor Martyn, in his splendid Historia Plantarum rariorum, published at London in 1728, the drawings of which came from no less a hand than Van Huysem. But the execution of the plates in mezzotinto, and the colouring, are far inferior to the apparent merit of the drawings. The French at present excel in this art of printing in colours, as may be seen by the exquisite publications of Redouté and Ventenat, to mention others of birds and quadrupeds. Bullard led the way in his Herbariæ de France, which is now far excelled by other similar works in this respect. Nor are the French less eminent at present in their engraved uncoloured botanical figures. Some admirable performances of this kind appeared in the reign of Louis XIV. In our days the works of Hérault have justly been admired, and are now even excelled.

In Germany and England the greater part of botanical plates are fine engravings, coloured by hand, though some of Dr. Thornton's figures, and those very well executed, are printed in colours. The German figures are usually altogether deficient in picturesque beauty, or colouring, properly called, but are expressive, and tolerably cheap, so as to be useful to the science. This however can only be said of their best works, some, the second-rate, though popular, ones, being coloured not much unlike the varnished Dutch toys seen at a fair. On the other hand, Germany has produced some exquisitely delicate botanical works in colours, as the Planta Liechensee of Hoffmann, and the cryptogamic works of Schrader and others.

It is much to be wished that the public were not burred with repetitions of the same plant over and over again, at least by authors who publickly profess to publish new ones only. In books defined to exhibit the entire plants of any one country, or exclusively the exotic plants of any particular garden or garden, such a scheme being avowed, there is no imposition. But still the most valuable and respectable are such as figure only entirely new plants, or at most what are badly or erroneousl figured before. If this were attended to, the representations of all known plants might in time be accessible somewhere or other. However perfect the science of botanical definition may have become, few persons are competent to keep it up to its highest standard, who yet may be able to speak to the eyes by a picture. No painting indeed, however excellent, ought to supercede, or be unaccompanied by, descriptions and definitions, which alone render botany a science; for who can argue from a picture? Language is the current coin of rational beings. Nevertheless, the two modes of instruction may advantageously go hand in hand. If every known plant were to be found delineated in some work or other, the study of botany would be much facilitated, and even such an attempt as that of Schilniur of Wittenberg, to furnish an universal set of botanical figures in as compendious a form as possible, merits great praise, though it may be doubted whether the rude colouring of such a work adds any thing to its value, though unfortunately too much to its price. It has often been remarked that the uncoloured wooden engravings of
Brunfelsius, Fuchsius, and a few here and there in other authors, express the plants intended better than many minified plates. Hence outlines of Plummer and other botanists have been published in imitation, but none come near the merit of their prototypes. The truth is, that to make one of those admirable outlines, requires the skill of a first-rate painter, if not a spark of the genius of a Grecian satirist. Hence they are likely to remain unrivalled, as they have hitherto been. Of exquisite precision, without that sublime degree of art, Leers's figures of griffons in his *Flora Hibernica* are matchless examples.

Some persons have attempted, and even published, figures made by an imprefion taken from the dried plant, with printer's ink on paper. These might be supposed likely to prove peculiarly accurate, but they generally fail in execution. They may indeed give the unnatural stiff outline of a dried specimen, but the prominent parts of the surface being necessarily what give the dark and imprefion, they of course totally mislead the eye, and all but the most flender and expanded subjects produce a mass of confusion and deformity.

As we are on the subject of figures of plants, we beg leave to correct an error in our account of *Doreana japonica*. A plate of that shrub is extant in Thumberg's *Flora Polonica, vol. 3*, a work which however indifferently executed, ranks very high for the originality and rarity of its contents.

**Figure.** In *Dancing*, denotes the several steps which the dancers make in order and cadence; confidered as they mark certain figures on the floor.

**Figure.** In *Fencing*, are the divers guards, poftures, attitudes, or dilpofitions, of the body, arm, or fword. See Fencing.

**Figure.** In *Fortification*, is the plan of any fortified place; or the interior polygon, &c.

When the fide and angles are equal, it is called a regular; when unequal, an irregular figure.

**Figure.** In *Geometry*, is applied to the extremities of points, lines, or numbers, thrown or cast at random; on the combinations or variations whereof the fages of this art found their fantatical divinations.

**Figure.** In *Geometry*, denotes a surface inclosed, or circumfcribed with one or more lines.

Such are triangles, figures, polygons, circles, ellipses, &c.

Wolfius defines figure a continuum terminated by a perimeter. In which fente figure is applicable both to superficiies and folds. In the former case, the perimeter is of lines; in the fecd, of surfaces.

Figures are either rectilineal, curvilineal, or mixt, according as the perimeter consists of right lines, curve lines, or both.

The superficial parts of a figure are called its sides; the lowest side, its base; and the angle oppofite to the base, the vertex.

The height of a figure is the dilance of the vertex from the base.

**Figure.** In *Grammar*, is an expression that deviates from the common and natural rules of grammar; either for the fake of elegance or brevity. The best grammarians only reckon four figures; the ellipse, pleonasm, fyllipse, and hyperbation. Others add two more; viz. antipofhip, and enallage.

**Figure.** In *Heraldry*, a bearing in a shield. Of these figures there is almost an infinite variety: some are natural; such as the celestial figures of the sun, moon, stars, &c. and their parts; the effigies of men, women, &c. and their parts: animals, as lions, flags, foxes, boars, &c. and their parts; birds, as eagles, swans, birds, pelicans, &c. and their parts; fishes, as dolphins, whales, griffins, trouts, &c. and their parts; reptiles, and insects, as tortoises, serpents, graffhoppers, &c. and their parts; vegetables, as trees, plants, flowers, herbs, &c. and their parts; and flowers, as diamonds, rubies, poftebles, rocks, &c. These charges, as well as ordinaries, have divers attributes or epithets, which express their qualities, positions, and dilpofitions. Thus, the sun is faid to be in his glory, eclipsed, &c.; the moon in the complement, in crescent, &c.; Animals are faid to be rampant, pajfive, &c. Birds have also their denomi- nations; fishes are decribed to be bountift, natioit, &c.; Befides these natural figures, there are also artificial figures; the principal of which are warlike instruments, as swords, arrows, battering rams, gauntlet, helmets, spears, poleaxes; ornaments used in royal and religious ceremonies, as crowns, coronets, mitres, wreathe, crofiers; towers, caille, arches, columns, plummets, battlements, churches, columes, curtains, borrowed from architecture and fortification; and ships, anchors, rudders, pendents, fins, oars, masts, flags, gallows, lighters, &c. derived from navigation; all these figures have different epithets denoting their position, structure, &c.

There are likewise chimerical or imaginary figures used in heraldry, that are the refult of fancy and caprice: fuch as centaurs, hydras, philomacs, griffons, dragons, &c. Ponies, p.v. *Elen* Herald, p. 131, &c. 172, &c.

**Figure.** In *Logic*, denotes a certain dilpofition of the terms of a fyllogism; particularly of the middle, with regard to the extremes.

Hence it follows, that there are as many figures of fyllo- grims, as there are different connections of the extremes with the middle; so that, though the schoolmen ordinarilv only reckon three, yet a fourth might be admitted.

In the first figure the medium or middle term is the sub- ject of the major proposition, and the predicate of the minor. This contains four moods, and applies to the proof of all sorts of questions, whether universal or particular, affirmative or negative. In the second figure the middle term is the predicate of both the premises, and this con- tains four moods, admitting only of negative conclusions. The third figure requires that the middle term be the sub- ject of both the premises, and has fix moods, admitting only of particular conclusions. The special rules of these three figures are the following: in the first, the major proposition must always be universal, and the minor affir- mative; in the second also the major must be universal; and one of the premises, together with the conclusion, must be negative; in the third figure the minor must be affirmative, and the conclusion always particular.

In the fourth figure, called by the Peripatetics the inde- close, and by others the Galenical figure, as varying too much from the natural form, the middle term is predicated to the major proposition, and subjected in the minor. Some logicians will allow this to be nothing else but a mere inverion of the first figure. It has five moods. Watts's *Logic*, part iii. chap. 2. 3.

**Figure.** In *Manufactures*, is applied to the various defigns represented or wrought on velvets, damasks, taffete, laces, catties, and other flufs and cloths.

The most usual figures for such defigns are flowers, imi- tated from the life; or grotesques, and compartments of pure fancy. Representations of men, beasts, birds, and landscapes, have only been introduced since the tafle for the

Chinice
Chinese stuffs, particularly those called furnes, began to prevail among us.

It is the wool of the fluff that forms the figures; the warp only serves for the ground. In working figured stuffs, there is required a person to move the workman how far he must raise the threads of the warp, to represent the figure of the design with the wool, which is to be paffed across between the threads thus raised. This fome call reading the design, which fee.

For the figures on tapestry, brocade, &c. See Tapestry, &c.

For thofe given by the calenders, printers, &c. See Calendar, &c.

Figure, in Muft. In general, figure includes all the characters used in music to express sounds, their place in the scale, with their duration and equivalent reffs: whence contrapunto figurate, to dilftime it from contrapunto fimplices, plain counterpoint, which Zarlino defines common chords of note against note, all of the fame length, and without difcourfe. Figurative harmony, fome times called florid counterpoint, is that in which the chords are broken into melody, and exprefied by figures or notes of different lengths. See Time-table.

Figure, Mute; mute figures, in Italian mute, imply reffs, or characters denoting silence.

Figure, Apparent, in Optics, that figure, or fhape, which an object appears under when viewed at a distance, being often very different from the true figure; for a straight line viewed at a distance may appear but as a point; a furface as a line; and a folid as a furface; and each of these of different magnitudes, and the two last of different figures, according to their situation with regard to the eye. Thus an arch of a circle may appear a straight line; a fquare or oblong, a trapezium, or even a triangle; a circle, an ellipsis; angular magnitudes, round; a sphere, a circle, &c.

Alfo any fmall light, as a candle feen at a distance in the dark, will appear magnified, and farther off than it is. Add to this, that if several objects are feen at a distance, under angles that are fo small as to be inappreciable, as well as each of the angles subtended by any one of them, and that next to it; then all thofe objects will appear not only to be contiguous, but to confitute and feme but one continued magnitude.

Figure, in Painting and Sculpture, is used to fignify the form, the contour, or outline of the furface of bodies of whatever kind they may be. In conformity with this, we speak of a drawing, as representing the figure of a tree, a house, a book, a horfe, &c. &c. And in sculpture we fpeak of figures of bronze, of marble, of paffer, &c. As however man is the principal subject on which artists who purfue the study of the higher branches of thofe arts are called to exert their talents, the human form is therefore by way of pre-eminencc called the figure.

A picture wherein the representation is given of a great number of men, women, or children, is faid to be full of figures. On the contrary, a landscape wherein there is only the representation of mountains, trees, &c. and not of human beings, is faid to be without figures. For further illuftration fee Human figure.

Figure, is also applied to representations, or images of things in prints, &c.

Some readers chufe to have the figures, efpecially the mathematical ones, in wood, for the convenience of having them immediately annexed to the matter they refer to; others rather chufe to be at the pains of turning over, and having recourse to another part of the book, that they may have the figures more neat and accurate on copper.

The author of a collection of differtations, printed at Paris in 1715, fays, in the firft difertation on the Hebrew medals, p. 66, that the Jews were allowed to make any kind of figures, or images of trees, plants, buildings, flowers, &c. but not thofe of animals, or of the fun, moon, and fars.

Figure, Similar. See Similar.

Figure, in Rhetoric, is a phrase, or turn of speech or difcourfe, more beautiful and emphatical than what is used in common or ordinary speaking. Accordingly it implies some departure from simplicitie of expression; but at the fame time this deviation from what may be reckoned the molt fimple form of speech, by no means supposeth any thing uncommon or unnatural; the cafe is fo far otherwife, that, on many occasions, figures are the molt natural, and the molt common method of uttering our sentiments. Nor should it be imagined that every alteration from the common manner ought to be efteemed a figure, or deviating of that character. It muft contain some beauty, or express some paflion, to merit a place among rhetorical figures, and be marked out for imitation.

Figures, by the Greeks called σχήμα, σχεμα, are the encrements of difcourfe, and we only ufe them when raised and moved with the consideration of something extraordinary.

The term figure, as Dr. Ward obferves, feems to have been borrowed from the flage, where the different habits and geltures of the actors, fuitable to the several characters they fuffixed, were by the Greeks called σχήμα, and by the Latin ftgura. Nor is it unufual with us to fay of a perfon, both with refeft to his drefs and actions, that he makes a very bad, or a very graceful figure. And as language is the drefs, as it were, of our thoughts, in which they appear and are represented to others; fo any particular manner of speaking may, in a larger fense of the word, be called its figure, in which latitude orators fometimes ufe it (see Cic. De Orat. i. iii. c. 52.) but rhetoricians have reftored the fense of the word to fuch forms of speech, as differ from the more common and ordinary ways of expreffion; as the theatrical habits of actors, and their deportment on the flage, are different from their usual garb and behaviour at other times. Or, as the figure or fhape of one body diftinguishes it from another, fo figures are forms of speech, having, each of them, a caft or turn peculiar to itself, which both diftinguishes it from the reft, and diftinguishes it from fimple expreffion.

Simple expreffion juft makes our ideas known to others; but figurative language, more than this, bewows a particular drefs upon that idea; a drefs which both makes it to be remarkead, and adorns it.

Some have erroneously imagined, that figures of speech should be claffed among its chief reneuement not invefted till language had advanced to its later period, and mankind were brought into a polished flate; and that, then, they were devised by orators and rhetoricians. Whereas the contrary to this is the truth. Mankind never employed fo many figures of speech, as when they had hardly any words for expressing their meaning. For, firft, the want of proper names for every object, obliged them to ufe one name for many; and, of course, to expreff themselves by comparison, metaphors, allusions, and all thofe substituted forms of speech.
FIGURE.

Those of the second kind, or such as are fitted for moving and influencing the passions, are Epanorthosis, or correction; Paralepsis, or omission; Parrhesia, or repetition; Anaphora, or enumeration; Exposition, or exposition; Hypothemosis, or imagery; Aspera, or doubt; Aporia, or catachrest; orateis, or Interrogation; exclamation, or Exclamation; Paradoxa, or acclamation; Apeorop, or assertis; Prosopoeia, or the fiction of a person. See each under its proper head.

Of Figures of words, some are tropes, i.e. transitions of words from their proper significations, to some more remote and extraordinary one. See TROPE.

Others are figures of words, more properly so called, and not tropes; being fixed inherent in the words, that upon changing of the words, or sometimes only their situation, the figure is delivered: as in animos pro animis, where the figure would be lost, if not all instances you should put forth.

Thus, to the all figures of life, is in effect to life life; this is lost by changing the order of the words: as, to life all figures of life, is in life life in effect.

The principal of these verbal figures may be arranged into three classes: such as consist in a deficiency of words, in a redundancy, in a repetition. To the first class belong the Pleonasms and Polysemy. The third kind of verbal figures includes those by which the same word in found, or first, is repeated; or one of like found or unit is, or both. Of the second kind in this division there are ten, called Anapadosis, Pneusis, Epanapadosis, Epexegesis, Anadidymia, Epanapadosis, and Epanapadosis. To the second class belong the Paronomasia, the Homoiotetics, the Synonymia, and Derivatio; the two last of which respect words that are similar in sound only, the third in sense, and the last in both.

With regard to the proper use of figures, we may observe, that they should always be accommodated to the sentiments, and rise in proportion to the ideas designed to be conveyed by them; it is also better, in general, to be nervous than copious; that the images, by their closer union, may impress the mind with greater energy, though in such figures as are designed for ornament or illustration, a more diffusive way of painting is sometimes agreeable. The too frequent use of figures should be avoided; and they should be so interwoven in a discourse as not to render the style rough and uneven, sometimes high and at other times low; now dry and jejune, then pompous and florid. In every case they should seem to rise more from nature than art, to offer themselves rather than to be the effect of study. Finally, it should be duly considered, that neither all the beauties, nor even the chief beauties of composition, depend upon tropes and figures. For a further account of the use and effects of figures on language, see Style. See also Mr. Taphor, and each of the articles above noted. Ward's Ont. Lect. vol. i. p. 34.

FIGURES of PROSE comprehend the Syntopha, Ecythelips, Crasis, Syntheses, Diarizes, Systoles, and Diastole. See each article.

FIGURE is used, in Theology, for the mysteries represented or delivered obliquely to us under certain types or actions in the Old Testament.

Thus, anna is held by fome to be a figure or type of the eucharist; and the death of Abel a figure of the suffering of Christ.

Many divines and critics contend, that all the actions, histories,
tories, ceremonies, &c. of the Old Testament, are only figures, types, and prophecies, of what was to happen under the New. The Jews are supposed to have had the figures or shadows, whilst we possess the substance.

Fig. 5. Receptacle cylindrical, clothed with the calyx-leaves. Seed-down none. Female florets among the calyx-scales; perfect ones four-cleft, in the disk.

Fig. 4. Linn. Sp. Pl. 1311. C. f. 1. 36. (Gnaphalium umbellatum minimum; Buhl. Hill. v. 3 p. 162. Exv umbellata; Gartn. v. 2. 393.) Found in the south of Europe, in waste sandy ground, particularly in places occasionally inundated. The root is annual. Stems either entirely wanting, or more or less elevated, solitary or numerous, simple or branched, at most three or four inches high. Whole plant clothed with a white cottony tenuous web. Leaves scattered, ovate or spatulate, entire, many of them surrounding the little heads of flowers in a radiating manner, and making an elegant rosaceous appearance.

Professors Williams now rightly retain this as the only species of Filago, the root being called referred to Gnaphalium. It is also the original one.

FILAMENT, Filamentum, a word though not of classical authority, yet well supported by analogy, is technically applied to the usually flinder thread-like part which unites the anther of a flower; see ANTHER. This part, however, is not essential to all species of flowers, though the anther itself, being the male organ, is so. But the latter in some cases is immediately affixed to the corolla, receptacle, or pilil, on which it is seporate, without any filament.

The filaments differ in number, from one to several hundred, in different genera, or even species of the same genus, though the latter case is rare. They, however, vary in this respect occasionally, in the same species or individual. They differ also, but very slightly, in their insertion, or origin, with respect to other parts of the flower, proceeding either from the receptacle, as in the Poppy; the calyx, as in the Rose; or the corolla, as in the Jasmine. Their form is usually simple, each filament bearing one anther; but in the Orange and St. John's Wort many filaments are united into one, and in most of the Papilionaceae family one filament only is separate, nine others being united from their base almost to the summit. In the natural order of Rutaceae, see Diosma and Eriostemon, the filaments are more elaborate in structure than usual, being tuberculated and glandular, and sometimes bearing their anthers on a sort of appendage, or pedicle. Indeed the extremity of each filament, in many instances, tapers into a fine flexible point, like an additional style, allowing of a free or rotary motion in the anther; witness the Papilion flavum and White L. Such flowers are said to have vertebrate anthers. Filaments are extremely different in proportion, some being prominent far beyond the verge of the blossom, exposing their anthers to the wind and weather, while others lie concealed in the bottom or tube of a flower, carefully protected from wet. Some are long and capillary; others short, broad, or thick.

A very curious circumstance respecting filaments is, that in some flowers they appear enfolded with a frangipanaceous motion, as in Ruta (Rut) Seksyreja and Parnassia. In these flowers the filaments bend in their turn over the stigma, that the anthers may more certainly drop their pollen upon it, and subsequently retire. In the Barberry blossom the same thing is accomplished by an epistylar iridacium in the inner side of each filament at the base, in consequence of which it contract when touched, and the pollen over the stigma, and after a while, retaining its original position, makes way for others. Some filaments are very little hygroscopic, as in the Crock's comb, Cel. f. s., contracting in dry weather, and approaching the stigma, and re-
tiring for shelter under the corolla in wet. See Recumbence of Plants.

The word *filamenta* is also used for the fronds of the genus *Coniferous*, which are; these being of a fine thread-like, or rather capillary, form and size. Roth contends that, to avoid ambiguity, *filo* should be used in the latter case, which expresses the same thing still more correctly. This is certainly an improvement, though it is scarcely possible that the ambiguity in question should cause any confusion. S.

*FILAMENT*, in Medicine, Anatomy, Natural History, &c. a term used in the same sense with fibre for those fine threads whereof flesh, nerves, skins, plants, roots, &c. are composed.

• *FILANA*, in Geography, a river of Benin, which runs into the Atlantic; lat. 4° 40'. E. long. 5° 22'.

*FILANDERS*, in Falconry, a hawk's, &c. confiding of filaments or threads of blood coagulated and dried, occasioned by a violent rupture of some vein, by which the blood extravasating hardens into the figures above-mentioned, to the great annoyance of the reins, hips, &c.

The word is French, *filandre*, formed from *fil*, thread.

Filanders are also a sort of fine small worms which greatly incommodate the hawk in the gorge, and about the heart, liver, and lungs; but which, on some occasions, are supposed to be of service, and to feed on the superfluities of certain parts. See Black Worm.

There are four kinds of these filanders or vermiculi. The first, in the gorge or throat; the second, in the belly; the third, in the reins: the fourth are called needles, on account of their exceeding fineness. The symptoms that discover the difcase are the bird's gaping frequently, straining the fret or perch with its pounces, crotching in the night, ruffling its train, rubbing its eyes, wings, nostrils, &c. As the worms are very relifsfs, the bird is frequently endeavouring to exit them up; and in opening its mouth you will readily discover them. From the throat, &c. they will ascend to the larynx, brain, &c. and finally over the whole body.

The ordinary cause is bad food. The proper remedy, they say, is not by killing them, for fear of impositions from their corruptions; but chiefly by flupifying them, that they may be offensive but feldom.

This is best effected by making the bird swallow a clove of garlic, after which it will feel nothing of the filanders for forty days. Others use rix, worm-feed, aloes, vervain, faffron, &c.

*FILANGERI*, Gaetano, in Biography, a celebrated political writer, was born at Naples on the 18th of August 1752. His parents intended him for the army, but his own genius pointed out to him the sciences as most adapted to his future pursuits. Politics, moral philosophy, and legislation engaged his mind, and seemed to absorb all his attention. He soon discovered the defects of the existing laws by which most of the European nations were governed. In 1771, he drew up the plan of a tratce on private and public education, which, however, he never completed. In 1774 he published a small work, in which he defended a new law against the arbitrary decisions of a judge, with great judgment and the noblest enthusiasm. After this he determined to retire from public life, in order that he might prepare himself for important duties, by diligent and uninterrupted study. But in 1777 he entered into the service of the court, and was appointed a gentleman of the bed-chamber, and an officer of the marine. These avocations did not prevent him from devoting many of his days, and frequently whole nights, in philosophical research. In 1788 he published the first part of his work "On Legislation," which was intended to consist of seven books, but of which only four, and a part of the fifth, made their appearance during the author's life. The early parts of this work were received with the warmest approbation; and the celebrity of the author continued to increase; but as he had indulged in liberties which were new in Italy, he was open to the attack of vocal and bigoted writers. His work was opposed by professor Joseph Grippo, who published a letter under the title of "Scienza della Legislazione Vindicata," with obervations against Filangeri's proposal respecting feudal and criminal laws. Soon after a decree was issued by which the treatise "On Legislation" was declared among the number of prohibited works, on account of the advice given in the second book, to abolish ecclesiastical property, and the proposal promulgated in the fifth for reforming abuses in the power of the church. Filangeri was, however, protected by the court, and various distinguished marks of favor were conferred upon him. In 1783 he married an Hungarian lady sent to Naples by the empress Maria Theresa, as governness to the second of the princes. With the permission of his sovereign, he retired from civil and military employment, that he might devote his whole time to the completion of his work at his country house near the town de la Cava, a few miles from Naples, where he resided till March 1787, when he was appointed to a place in the royal college of finance. In this situation he appeared with great advantage as a statesman, and many wise and useful establishments were formed in consequence of hints which he suggested. Scarcely had he arranged his plans of economy and reform, when he was arrested by the hand of death. He died in July 1787, in the 37th year of his age. His death was lamented by the monarch, who settled a pension on his infant family, to be employed in their education. The demand for his great work on legislation was so great, that it went rapidly through ten editions in his own country, and was translated into the German and French languages. Gen. Bug.

*FILARIO*, in Zoology, a genus of intestinal worms, which have the body round, filiform, equal, and quite smooth; the mouth dilated, and furnished with a roundish concave lip.

The genus filaria, as now established, unites some few of the Vermes, formerly referred to the genus Afacris, and according to its more extensive application in the Gmelinian edition, some of the Gordius tribe may be included also in the same genus. The vermes, which are truly of the filaria genus, seem to be abundant throughout the animated nature; they are not found in man, nor has their presence been hitherto determined in the higher class of domestic animals, the horse excepted; but there are few of the unmedicated quadrupeds, and scarcely any of the bird tribe that have been attentively examined, in which they have not been discovered; they are observed in the fish and reptile race, and infects are infected with them in incalculable numbers. As these are the most simple of intestinal worms, the different species may not perhaps have hitherto been discriminated with sufficient accuracy; they do not seem to afford any very decisive characters by which the species may be readily distinguished; and it is no doubt for this reason that systematic writers describe and class them merely according to the respective animals in which they are observed. Gmelin infers that highly dangerous creature, the hairworm of the Indies, at the head of this genus, because it infests man: in this influence he deviates from the example of Linnaeus, who considered that kind of vermes as a species of gordius, and not without reason. The two genera,
genera, filaria and gordius, are indeed analogous, and correspond in every essential particular, except the structure of the mouth, and the difference in this respect is not expressed with due precision either by Linnaeus or Gmelin; the filaria genus have the mouth terminal, and more or less perceptibly dilated, of a simple form, and furnished with a rounded tip; to the Gmelinian character of the gordius we should add that the mouth confits only of a dent or incision, and is so very minute as to be imperceptible to the naked eye.

Species.

* Infilging the Mammalia.*

Found in the cellular membrane of horses. Linn. In the hoof. Redi.

Martes. In the Martin. Redi.

Lepores. In the cellular membrane of hares. Pallas.

** Infilging Birds.**

Falconis. In the cellular membrane about the abdomen and thighs of hawks. Redi.

Syriavis. In the cellular membrane about the head and ears of owls. Pallas.

Corvocis. In the crop and lungs of crows. Pallas.

Ciconis. In the cellular membrane of the foot. Redi.

Gallinae. In the smaller integuments of poultry. Goeze.

The body is capillary, and about two inches long.

*** Infilging Insects in their perfect State.***

Scarabaei. In the scarabaeus funerarius. Phil. Trans.

Sphynx. In the sphinx obscura. Goeze.

Calipri. In the carabus. Litter.

Grylli. In the Gryllus. Redi.

Monoculi. In the monocus apus.Walch.

*** Infilging the Larvae of Insects.***

Lepidopterorum. Tail hooked. Schrank.

Papilionum. In butterflies. Werner.

Sphynx. In the sphinx euphorbe. Roefel.

Phalanx. In the phalana. Mannigf.

These creatures are found under the skin of the larva, sometimes solitary, from four to seven inches long, and very destructive.

Tenthredinis. Found in the larvae of the tenthredo. A.D. Stokck.

Phyryganei. Found in the larvae of the phyryganei. Dogger.

FILAWS, among the modern Egyptians, villages inhabited by the original natives of the country.

FILAZER, FILAZER, FILAZER, an officer in the court of common pleas, so called because he files the writs whereon he makes out process.

Of these there are nine in the several divisions and counties.

of England. They make out all writs and processes upon original writs, issuing out of chancery, as well real as personal and mixed, returnable in that court. In actions merely personal, where the defendants are returned summons, they make out purs or attachments, which being returned and executed, if the defendant appears not, they make out a dehiman, and so ad infinitum, or till he does appear.

If he be returned nisi, then proceed of capias infinite, if the plaintiff will, or after the third capias the plaintiff may proceed to outlawry in the county where his original is grounded, and may have an exigent with proclamation.

The filazer like wise make out all writs of view in real actions where the view is prayed; and upon pleas and records, writs of retorno hankendo, second deliverance, and writ of withersam. In real actions they make out writs of grand and petit cape before appearance.

They enter all appearances and special bail upon any process made by them. They make the first fier facias upon special writs, of habeas corpus, disfrazas, non recusation vel hallucum, and due stecans; and all superedefus, upon special bail or appearance, &c. writs of habeas corpus cum causa upon the sheriffs return that the defendant is detained with other actions, and writs of adjournment of a term, in case of pestilence, war, or public disturbance.

Tell an order of court made 14 Jac. I. which limited the filazers to all matters and proceedings before appearance, and the prothonotaries to all after, they also entered declara- tions, impariances, judgments, and pleas, whereto a serjeants hand was not requisite, and made out writs of execution, and divers other judicial writs after appearance. The filazers of the common pleas have been officers of that court before the flat. 16 Hen. VI. c. 4. in which they are mentioned; and in the kings bench, of later times, there have been filazers who made out processes upon original writs returnable in that court on actions in general.

FILBERT, a common name frequently applied to the bell fruit of the hazel nut. It is often written filberd, and sometimes filbard.

FILBERT, the name of the tree from which the filbert nut is obtained. It is the low, thrubby tree usually planted out in gardens, orchards, and other places. See Corby.

These trees may be raised by planting the nuts, by layers, by suckers from the roots, and by grafting upon hazel stocks; but the best methods are those of layering, and planting the off-frets or suckers. The layers should be laid down in the early autumnal season, and when they are become fully rooted, be taken off, and planted out in rows at the distance of two feet and twelve inches apart, in the rows. After they have attained sufficient growth in their rows, they may be carefully taken up and planted where they are to remain.

The off-frets or suckers may be taken off with good radical fibers, and be immediately planted out where they are to remain.

They answer well where the soil is of the light, meallow, fertile kind, but will succeed in most, when well protected from cold winds.

They may be planted in the standard method, in rows, at ten, fifteen, or twenty feet distance, by twelve feet in the lines; or be trained to single stems, to the height of four, five, or six feet, with full branches, spreading leads, and in the hedge manner, either in single or double rows, ten or twelve feet between; but the standard mode is most probably the best, as producing the finest nuts.

In Kent they never suffer these trees to rise higher than
FILE.

fix feet, regularly proung them in the manner of the gooseberry bush.

There are two sub-varieties of this tree, namely, the white-skinned, and the red-skinned, the former being in general the moat esteemed.

Filberts, Petrifed, in Natural History, and filbert-trees also, have been described by different authors, as found in the strata of the earth. Mr. John Ray mentions such as being found under the city of Modena and its neighbourhood, at twenty-six feet beneath its surface; but Mr. Whitehurst, who quotes this passage at length, in his Enquiry concerning the Earth (till ed. p. 172.) observes, that these are not original strata, but modern accumulations of alluvial soil, which have buried the beans, corn, filberts, &c. in the alterations which the superficial parts of the ground about Modena have undergone; and similar remarks might, we believe, be applied to every other instance of real filbert-trees or nuts being found beneath the surface of the earth, or in accumulations of calcareous tufa, (see Nuts;) and the same will be found to belong to the class of recent fossils, mentioned in our article Coal.

FILE, an instrument used for reducing, and for giving shape and smoothness to a number of articles made of wood or metal.

It is divided into two varieties from the form of their teeth, namely, files and rasps. The former are cut upon the surface with a shap-edged chisel. In the latter, the tooth is railed with a triangular punch. The file is adapted for working metals, but the rasp is more fitted for wood, bone and horn.

Files again are distinguished by being single or double cut. The single cut file is simply cut once over, and is employed for filing brads, and the softer metals. A second course of teeth is cut to form the double cut file, crossing the grit diagonally. This kind is best suited to iron and steel.

Files are also called by different names, from the various degrees of keenness of their teeth, as smooth, second cut, ballard cut, and rough files.

And again, from their shape, they are called flat, half-round, square, three square, round, and some having two round sides.

The file employed for files requires to be very hard, and in consequence undergoes a longer process in the conversion: it is said to be double converted.

The very heavy files, such as smiths' rubbers, are made of the inferior marks of blistered steel: the more delicate kind, such as watch-makers' files, are made of cast steel. The file is previously drawn at the till, into rods of suitable size.

Forging of Files.—The flat and the square files are made wholly with the hammer, and the plain anvil. Two workmen, one called the maker, and the other the chaser, are required in the forging of heavy files; the smaller being forged by one person only.

The anvil is provided with a gate, or groove, for the reception of certain boisters, or dies, which are used for the purpose of forging the half-round and three-angled files. The half-round boists contain a hollow which is the segment of a sphere, much less than half a circle. That used for the triangular files has a large or hollow, consisting of two files, terminating in an angle at the bottom.

In forging the half-round file, the file is first drawn out, as if intended to make a flat file. It is then laid in the boists and hammered, till the under side becomes round. The file for the triangular file is tilted into square rods. The part to form the file is first drawn out with the hammer, as if intended to form a square file. It is then placed in the boists with one of the angles downwards, and by striking upon the opposite angle, two sides of the figure are formed into one, and consequently a three-sided figure produced. By successively presenting the different sides to the action of the hammer, the figure is rendered still more complete.

In forming the tangs of most files, it is necessary to make the shoulders perfectly square and sharp. This is performed by cutting into the file a little on each side with a sharp file or aggeron, and afterwards drawing out the part so marked off, to form the tang.

After forging, and previous to being ground and cut, the files require to be annealed. This process is generally performed by piling up a great quantity together, in a furnace for the purpose, and heating them red hot; suffering them afterwards to cool slowly. This method of annealing files, or indeed any other articles, in which great hardness is requisite, is very objectionable, since the surface of steel, when heated red hot in the open air, is too liable to oxydation. Too evils result from this circumstance, besides the loss by waste. First, the fey oxyd is very hard, and difficult to remove; and secondly the file, particularly on the surface, is deprived of a portion of its carbon, and thereby rendered less susceptible of hardening.

A superior method of annealing is practiced by some file makers, and since hardnefs in a file is so essential a property, the process ought to be generally adopted.

This method consists in placing the files in an oven or trough, having a close cover, and filling up the interfaces with sand. The fire is made to play on every side of this vessel, as gradually, and as uniformly as possible, till the whole mass becomes heated red hot. The fire is then discontinued, and the whole suffered to cool, before the cover is removed from the trough. Another evil may however arise from keeping steel red hot even in a close vessel, for too great a length of time. It assumes a kind of crystallization under which its tenacity is much impaired. Hence, it will be proper not to anneal too many at once, and not to heat them too hot. Steel, annealed in this way, is perfectly free from that fey surface acquired in the open air; and if each corticle be perfectly surrounded with the sand, and the cover not removed before the file is cold, the surface will appear of a fey white colour.

If the file be suspected to be too kind, from containing too little carbon, powdered charcoal may be employed instead of sand, or sand mixed with charcoal. In this case the files should be stratified alternately with the charcoal, in order that the extra-conversion may be uniform.

The next thing is to prepare the files for cutting, by making the surface, to contain the teeth, as level as possible. This was formerly effected by means of files; and the process is called tripping. The fame is still practiced by the Lancashire file makers, and by others not having convenience for grinding. The greatest quantity of files, however, are ground to prepare them for cutting. The stone employed for the purpose is of the sandstone kind, the texture of which is compact and sharp, but rather rough. They are of as great diameter as can be used with convenience; and about eight inches broad over the face. When used, the surface is kept immered in water. The grinder fits in such a position as to lean over the stone, while its motion is directly from him. Its surface moves at about the same speed with those used in grinding cuttery. Since the object in grinding files is to make the surface as even and flat as possible, and as this cannot be done to completely upon a small stone, the stones of the file-grinder are laid aside when they are reduced to a certain size, and are employed for grinding.
F I L E.

grinding other articles. Though grinding is by far the most expeditious method, it does not give that truth to the surface which can be effected by filing. If the price of the articles would admit, however, it would be well to render the surface more even by the file after grinding. If the surface be not flat, it is obvious, that when the file is used for filing a large surface, those teeth in the hollow parts of the file will not be brought into action. It is from attention to this circumstance, and to the care in annealing and hardening, that the Lancashire file-makers have generally excelled. They have, however, confined chiefly to the small articles, since the larger files would not pay for the process of filing.

Cutting of Files.—If the vast number of teeth contained in a file, and their requisite uniformity are considered, a machine capable of effecting a purpose so apparently mechanical, may be considered a deodatam.

Though many attempts have been made to accomplish this object by machinery, and several varieties of machines have been constructed for the purpose, no one has yet been sufficiently general in its application, to render the projection of such an object very desirable. Among those who have distinguished themselves in this enquiry, Mr. Nichollson, the publisher of the Philosophical Journal, we believe, invented the most likely machine for file cutting, for which he took out a patent. We do not know, however, that either Mr. Nichollson’s, or any other machine, is at present used for the purpose. A file, which is of the same breadth and thickness throughout, of any form, may be cut by the machine, because the same magnitude of strokes is required for every tooth; but if the file be conical, it is obvious that a machine capable of giving all the varieties of strokes required in cutting even one side of a file, would be too complicated to be of any great utility. Again, the chisel employed for cutting a file is frequently liable to snap, or be otherwise out of order. This the workman, in the common way of cutting, can easily feel, and immediately stops to repair it. A very great evil would arise from this source, in cutting with the machine; and this evil would be greater in proportion to the number of chisels which one person had to overlook. It has also been said, but we cannot affirm the fact, that the teeth raised by machinery are not so full and sharp as those formed by hand. Till the above inconveniences can be obviated, in all probability the common method will be continued; the different apparatus and mode of performance of which we will endeavour to describe.

The tools of the file-cutter consist of an anvil placed upon a block of such a height, that the man fits to his work. He has also a piece of lead, or lead clayed with tin, on which he lays the file when one side is cut. The chisel and hammer are of such size, as the file and cut of the file require. He is also provided with a leather strap, which goes over each end of the file, and passes round his feet, which are introduced into the strap on each side, in the same manner as the fitters are used. The file-cutter, therefore, fits as if he were on horseback, holding his chisel with one hand, his hammer in the other, at the same time he secures the file in its place by the pressure of his feet in the fitters. A, fig. 1. (Plate XII. Nifeehany.) is the block; B, the anvil; a b, the file, laid upon the piece of lead; C, C, the fitters passing over the ends of the file; D, the feet on which the workman fits. Fig. 2. is the form of one of the chisels for cutting the files. Fig. 3 represents the chisel or punch for raising the teeth of the file. Fig. 4. the hammer used to strike the head of the chisel. These people have found by experience that there is an advantage in having the head of the hammer hooked inwards. This is easily accounted for, when we observe that the stroke will be made pretty near the centre of percussion. Great pains ought to be taken in preparing the edge of the chisel. It is, in the first place, hardened and tempered by heating it gradually till it appears of a yellowish brown. It is next ground very true to form the edge, which is afterwards washed upon a Turkey stone, with oil. It is not required to be very sharp, the bottom of the tooth requiring to be rather open, to prevent the file from clogging with the substance to be filed. The edge is also required to be very smooth, in order that it may slip easily upon the surface of the file; this is also facilitated by slightly greasing the surface. From this advantage, the worker, after making his cut file, is enabled, by feeling only to form, at its proper distance, the cutting tooth, by filing the chisel close up against the back of the preceding one. All these motions are performed with astonishing rapidity, first the chisel and then the hammer. We observed a boy, in cutting three-sided files of five inches long, bastard cut, make 225 strokes, which produced as many teeth, in one minute. And the whole file being double-cut, contained 1350 teeth, or six times the above quantity. The second cut file, of the same size, contains 2025 teeth, and the smooth file 2500, consequently, the difference in labour between the bastard-cut and the smooth files is about as two to one. Larger files, from the greater surface, require a much greater stroke to raise the tooth, and consequently fewer strokes will be made in the same time.

In the double-cut files, the first set of teeth, which the workmen call up-cuttings, are, previously to cutting the second course, filed lightly upon the face, in order to allow the chisel to slide freely.

The single-cut file is more durable than the double-cut, and ought to be preferred for all purposes, excepting for iron and steel.

The same method is employed in cutting the rasp. The workman is however guided completely by his eye, in regulating the distance of the teeth from each other. The rasp ought to be cut in such a manner that no one of the teeth may stand opposite to another. This not only allows the rasp to cut faster, but makes the surface, either of wood or other substance, much smoother.

Hardening of Files.—This is the last and most important part of file making. Whatever may be the quality of the steel, or however excellent the workmanship, if it is not well hardened, all the labour is lost.

Three things are strictly to be observed in hardening:—first, to prepare the file on the surface, so as to prevent it from being oxydized by the atmosphere, when the file is red hot, which effect would not only take off the sharpness of the tooth, but render the whole surface too rough, that the file would, in a little time, become clogged with the substance it had to work. Secondly, the heat ought to be very uniformly red throughout, and the water in which it is quenched fresh and cold, for the purpose of giving it the proper degree of hardness. Lastly, the manner of immersion is of great importance, to prevent the files from warping, which in long thin files is very difficult.

The first object is accomplished by laying a substance upon the surface, which, when it fuses, forms as it were a varnish upon the surface, defending the metal from the action of the oxygen of the air. Formerly, the process consisted in first coating the surface of the file with salts, and then covering it over with pulverized common salt, (muriat of soda.) After this coating became dry, the files are heated red hot, and hardened; after this, the surface is lightly brushed over with the dust of cokes, when it appears white and metallic, as if it had not been heated. This process has lately
lately been improved, at least so far as relates to the economy of the salt, which, from the quantity used, and the increase of duty, had become a serious object. Those who use the improved method are now consuming about one-fourth the quantity of salt used in the old method. The process consists in dissolving the salt in water to saturation, which is about three pounds to the gallon, and stiffening it with ale grounds, or with the cheapest kind of flour, such as that of beans, to about the confidence of thick cream. The files only require to be dipped into this filtrance, and immediately heated and hardened. The grounds, or the flour, are of no other use, than to give the same confidence, and to that means, allowing a larger quantity of salt to be laid upon the surface. In this method, the file forms immediately a firm coating. As soon as the water is evaporated, the whole of it becomes fixed upon the file. In the old method the dry salt was so loosely attached to the file, that the greatest part of it was rubbed off into the fire, and was sublimed up the chimney, without producing any effect.

The carbonaceous matter of the ale-grounds is supposed to have some effect, in giving hardnes to the file, by combining with the flour, and rendering it more highly carbonated. It will be found, however, upon experiment, that vegetable carbon does not combine with iron, with sufficient facility, to produce any effect, in the short space of time a file is heating, for the purpose of hardening. Some file makers are in the habit of using the coal of burnt leather, which doubles produce some effect; but the carbon is generally found prepared for the purpose, and the time of its operation so short, as to render the effect very little. Animal carbon, when properly prepared and mixed, with the above hardening composition, is capable of giving hardnes to the surface even of an iron file.

The carbonaceous matter may be readily obtained from any of the soft parts of animals, or from blood. For this purpose, however, the refuse of shoe-makers and curriers, is the most convenient. After the volatile parts have been distilled over, from an iron fill, a bright shining coal is left behind, which, when reduced to powder, is fit to mix with the salt. Let about equal parts, by bulk, of this powder, and muricit of soda, be mixed together, and brought to the confidence of cream, by the addition of water. Or mix the powdered carbon with a saturated solution of the salt, till it become of the above confidence. Files which are intended to be very hard, should be covered with this composition, previous to hardening. All files intended to file iron or steel, particularly few files, should be hardened with this composition in preference to that with the flour or grounds. Indeed, we are of opinion, that the carbonaceous powder might be used, altogether, in point of economy, since the ammonia or harthorn, obtained by distillation, would be of much value and remainder the coal of no expense. By means of this method the files made of iron, which in itself is infusceptible of hardening, acquires a super usable hardness, sufficient for any file whatever. Such files may at the same time be heated into any form, and, in consequence, are particularly useful for sculptors and die filers.

The next point to be considered is the best method of heating the file for hardening. For this purpose a fire, similar to the common smiths’ fire, is generally employed. The fire is held in a pair of tongs, by the tongs, and introduced into the fire, confining of very small coals; pulling it more or less into the fire for the purpose of heating it regularly. It must frequently be withdrawn for the purpose of observing, that it is not too hot in any part. When it is uniformly heated, from the tang to the point, of a cherry red colour, it is fit to quench in the water. At present an oven, formed of fire bricks, is used for the larger files, into which the blast of the bellows is directed, being open at one end, for the purpose of introducing the files and the fuel. Near to the top of the oven are placed two crofs bars, on which a few files are placed, to be partially heated. In the hardening of heavy files, this contrivance affords a considerable saving, in point of time, in addition to which they are more uniformly and thoroughly heated.

After the file is properly heated for the purpose of hardening, in order to produce the greatest possible hardnes, it should be cooled as soon as possible. The most common method of effecting this is by quenching it in the coldest water. Some file makers have been in the habit of putting different filiances in their water, with a view to increase its hardening property. The addition of the sulphuric acid to the water was long held a great secret in the hardening of saw files. After all, however, it will be found, that clear spring water, free from animal and vegetable matter, and as cold as possible, is the best calculated for hardening files of every description.

In quenching the files in water some caution must be observed. All files, except the half round, should be immerged, perpendicularly, as slowly as possible, so that the upper part shall not cool. This management prevents the file from warping. The half round file must be quenched in the same steady manner, but at the same time it is kept perpendicularly to the surface of the water, it must be moved a little horizontally, in the direction of the round file, otherwise it will become crooked backwards.

When the files are hardened, they are brushed over with water and powdered cakes, when the surface becomes perfectly clean and metallic. They ought, also, to be washed well, in two or three clean waters, for the purpose of carrying off all the salt, which, if remaining, will be liable to ruin the file. In addition to this, they should be dipped into line water, and rapidly dried before the fire, after being oiled, with olive oil, containing a little oil of turpentine, while still warm, and they are deemed finished.

File is also a thread of wire wherein writers or other exhibits in courts or offices are fastened or filed, for the more safe keeping and ready turning to the fame.

A file is a record of the count, and the filing of the proceedings of a court makes it a record of it. 1 Lil. 112.

File, or Label, in heraldry, a bearing, sometimes of more, and sometimes of fewer points, being the difference or distinction of the eldest son.

It is sometimes also borne as a charge in a coat armour, of which Gwilliam gives many instances; but it is oftener the difference or mark of distinction which the elder brother bears in his coat during his father’s life.

Some distinguish file and label, calling the file the upper horizontal line, and the label the points which issue from it.

File of three, or more labels. See Label.

File, in a Military Service, is a row of men standing one behind another, as a rank, on the other hand, includes any number drawn up before each other: whether, in either respect, they be in close or open order.

Or file is a line or series of soldiers, placed one before another, and thus composing the depth of a battalion; and it is thus distinguished from the rank, which is a line of soldiers, drawn up file by file, forming the length of the battalion. A file is two or three deep; hence, a battalion or regiment drawn up consists of two or three ranks, and of as many files as there are men in a rank. Files of cavalry
are generally two deep. A file on horse-back occupies in the ranks about two feet eight inches; a file on foot occupies in the ranks twenty-two inches.

Close files in cavalry are at the distance which was taken before dismounting, when each man's boot-top touches, without pressing, that of his neighbour.

Open files, in cavalry movements, are six inches distant from boot-top to boot-top, being calculated for the gallop as well as the walk of a squadron.

In the covering of files on horse-back, the same directions hold good as on foot. Besides, it must be familiarly observed, that every man's horse stands exactly straight to the same front as that of the man before him. Both in the horse and foot drill the men should be often practiced in covering. The former are thus taught to place their horses straight under them.

Close files of infantry are soldiers standing in rank, contiguous to one another, upon any given depth of line or column. Whenever a regiment marches in front, every man should feel his next man in whatever way he drestes; but he must not lean upon him, nor must he move his arms from his body to feel him: so that arm close files mean merely that soldiers in the ranks should lightly touch each other, without crowding or pressing. Open files are soldiers standing in rank at given distances without touching one another.

The formation at open files is only practised as a preparatory drill for forming at close files (which is the order for action). In order that every man may be taught to stand and move in a proper position, without getting a habit of leaning upon his neighbour. On this account, every intelligent officer who has the management of recruits, will form them sometimes at open files, and march in that order. Soldiers that have been regularly drilled should likewise be occasionally practiced in advancing by open files. Double files are formed by the left files in each rank stepping to the rear of the right files. Indian files denote a line of men advancing or retreating from either of the flanks, from the centre, or from any proportion of a line in succession to one another. They are sometimes called "goose-files," a term vulgarly used among soldiers, and derived from a lack of grace, which generally follow a leader one by one. We say, close the files; that is, bring the men nearer each other. Double the files; that is, double the depth of the battalion, and diminish its breadth or front by one half. The halt or hindermost person is laid to bring up the files. To file, that is, to advance, or from any given point by files; as to file to the front, to file to the rear, to file from the right or left flank, or to file from any given company. To file off, is to wheel from marching in a parallel front, and to march in length by files. See Drill.

File-leader is the soldier placed in the front of any file, or the man who is to cover all those that stand directly in the rear of him, and by whom they are to be guided in all their movements. File-leaders should be very careful to preserve their proper distances, from which ever hand they are to drest to, and the followers of each file must only be careful to cover, and be regulated by their proper file-leaders. In file the rear rank invariably drestes by, and is regulated by the front rank.

File marching on foot. According to the printed regulations, all recruits must first face, and then be instructed to cover each other exactly in file, so that the head of the man immediately before may conceal the heads of all the others in front. The men should move with the lock-step. The front-rank men should cover exactly, and the rear-rank men keep close and drested to the front rank. File-marching may be performed to the front, to the rear, and to either flank; in all which cases the men must be taught to cover well. When recruits are at drill, on the word march, all are to step off together, gaining at the first step thirty inches, and so continuing each step, without increasing the distance between each recruit, every man looking or placing his advanced foot on the ground, before the spot whence the man who preceded him had taken up his. Marching by ranks in front, open files, is when any body of men advance by ranks at close order, and drest to some given object without touching one another. The file-man of the flank to whom the soldiers drest, must be a non-commissioned officer, and he must take care that his heel be kept quite straight to the front, and his body erect, and that he advances without deviating in any the least degree to the right or left. In order to execute this essential part of the drill accurately, two perons should be present, one in the front, and the other on the flank, to observe the dreasong. Marching by ranks in front, close files, is when any number of men advance by ranks at close order, and drest to some given object, each man lightly touching his next man, without crowding or pressing. The march in front at close files is much more easy than that at open files, because every man feels his next man, which ever way the rank drestes, and into whatever direction the rank or column moves.

FILEFIO, FRANCIS, in Biography, a distinguished Italian writer, was born at Tolentino in the year 1398. He studied at Padua with so much success, that he was invited to open a school of eloquence at Venice in his 20th year. In 1410 he went to Athens, where, under the direction of John Chrysostom, for Manuel, he applied himself so vigorously to the study of the Greek language, as to be sent ambassador to Sultan Amurath I., in whose service the emperor Sigismund. In this latter embassy he received an invitation from Ladislaus IV. King of Poland, to assist at his martials, and on that occasion he recited an epiation at Cracow, in the presence of the emperor and princes. Returning to Constantinople, he occupied himself in literary concerns, and in 1427 he revisited Venice on the express invitation of many of the nobles. From Venice he removed, in 1428, to Bologna, where he was received with extraordinary honours, and appointed professer of eloquence and moral philosophy, with an ample stipend. Civil affairs obliged him in a few months to quit Bologna, and from thence he went to Florence, where he soon collected four hundred scholars, and was admitted to the rank of citizen by a public decree. Here his life was sometimes in danger from his enemies, among whom he reckoned the chief to be Cosimo de Medici. In 1433 he accepted of a professorship at Sienna, where he was attacked by the same affiai from whole malice he had formerly escaped at Florence. The villain was detected, and punished with the loss of a hand. The reputation of Tilefio was now so high, that he was invited,
invited, at the same time, to the performance of important duties by the pope, the Greek emperor, the duke of Milan, and the universities of Perugia and Bologna. He accepted the latter, where he re-opened his school for a few months only, when, repairing to the court of the duke of Milan, he was retained by him in his service, and treated with great favour. The death of the duke, in 1447, deprived him of a powerful patron, but he was, after a considerable interval, received by the successor to the dukedom, Francis Sforza, who assigned him an honourable stipend. He next went to Rome, where he experienced the liberality of pope Nicholas V. Proceeding to Capua, he was treated with extraordinary regard by Alphonso king of Naples, who conferred upon him the honour of knighthood, allowed him the privilege of using the royal arms, and placed on his head the poetical crown of laurel. Upon his return to Milan, he learnt that his mother-in-law, the widow of Chryfoloras, and her two daughters, were made slaves in the capture of Constantinople by the Turks; at the earnest request of Filelfo the duke dispatched two messengers to Constantinople, with a letter and an ode addressed to Mshonett II., who restored the female captives without a ransom. At the same period Filelfo became reconciled to Cofno de Medici, and ever after remained in friendship with that illustrious family. On the election of pope Pius II. in 1458, he settled a pension on Filelfo, which being paid only one year, gave him an occasion to decline against the court of Rome and the pontiff, a liberty which was punished with imprisonment. In 1469 he presented pope Paul II. with his translation of the Cyropædia, for which he received a present of four hundred ducats. This donation was handson, and perhaps unexpected, and he felt it his duty to go to Rome and return thanks in person. In the course of his journey he was honourably received and treated at Florence, by Peter and Lorenzo de Medici. He continued to reside at Milan till 1474, when he obtained leave, on the invitation of pope Sixtus IV., to become professor of moral philosophy at Rome. After this he removed three times to Milan, and back again to Rome, till at length, in the eighty-third year of his age, he accepted an invitation from Lorenzo de Medici to a Greek professorship at Florence. In the performance of the duties of this office he died, in 1481, a very short time after his arrival. He left behind many books, which consist of orations, moral discourses, poems, and familiar epistles, that afford much curious anecdote relative to the times. As a man of letters, he is more to be admired for his industry, and the great compass of his attainments, than for peculiar excellence in any one branch. Nevertheless he was a good historian, well skilled in classical learning, and a profound grammarian. Morei.

Filer un son, Fr. in Musæ, implies the conduct of the voice in singing, in such a manner as to be able to prolong, swell, or run rapid divisions of many bars, without taking breath. The French verb fîler, literally means to string, thread, or wire-draw any substance; and, applied to the voice, it means almost every perfection of a great finger. Millicu used to say that the voice, by practice, should be rendered as dulcet as wax when worked by the hand till it will receive any impression. Roucoub says there are two ways of managing the voice which come under the term fîler les fons: the first is what we have been describing; the second, that of sustaining a tone steadily, and perfectly in tune, in a long note, while the accompaniments are busily employed. When the Gabrielli was here, during the time that the Aguiari sung at the Pantheon, after she had finished one of her bravura airs, with long and difficult divisions, and such high notes as had never been heard in England before, the Gabrielli said to a gentleman in our hearing "mais messieurs, ce n'est pas filer les fons;" one finger is never to prate another. Aguiari was however a very great finger in a different style from that of the Gabrielli; who, when at her best, had very singular vocal abilities. We have just now recollected that Aguiari was forgotten in the alphabetical order where she ought to have had a niche, for which we beg pardon of her name, and shall try to deserve it, by doing her justice here.

Lucretia Aguiari was a truly wonderful vocal performer. The lower part of her voice was full, round, of an excellent quality, and its compass, after she quitted its natural register, which it was to be wished she had never done, beyond any one else had then heard. She had two octaves of fair natural voice, from A on the fifth line in the base, to A on the fifth line in the treble, and beyond that, in alt, she had in early youth more than another octave; as Sacchini told me (Sayburn) he had heard her go up to B B in altissimo. Her voice was open and perfect, her intonation true, her execution marked and rapid, and her style of singing, in the natural compass of her voice, grand and majestic; though the pathetic and tender were not what her manner or figure promised, yet she had expressions sometimes that were truly touching, and she would have been as capable of exciting universal pleasure, as admiration, if she had been a little less violent in the delivery of her passages, and her looks had been more tempered by female softness and timidity. She sang hardly any other music while she was here but her husband's, Signor Colla, which, though often good, was not of that original and varied cast which could supply the place of every other master, ancient and modern.

At this time there was no male singer in England with irresistible attractions; Rauzzini indeed was here, who more frequently pleased than surprized his audience; but it was during this period that the proprietors of the Pantheon ventured to engage the Aguiari at the enormous salary of 100L. a night, for singing two songs only! And yet, however exorbitant the demand, or imprudent the compliance with it may seem, the managers of this most elegant and superb building, which would have done honour to Greece as a performance splendid period of taste and magnificence, have, since that period, by going a more economical way to work, involved the proprietors in disgrace and ruin. Indeed in subsequent undertakings, previous to the fatal destruction of the building by fire, they have more frequently had money to pay than receive; for, notwithstanding so much was disbursed to the Aguiari, much was likewise cleared, and the dividend was more considerable than it has ever been since that memorable era. The admirable Aguiari, as Sacchini told us, was in her youth called "la Baffardella;" and being lame it was said, that, as soon as born, she had been abandoned on a dunghill by an unnatural mother, where a pig was beginning to devour her, when she was unexpectedly discovered, and humanely protected, adopted, and so well educated in music, as to become the wonder of her age and country. This admirable singer died at Parma in 1783.

FILEY, in Geography, a small fishing town of England, on the E. coast of the county of York, in a bay on the German sea, to which it gives name; near it is a ledge of rocks, called "FILEY BRIGG." In 1801 the inhabitants were 605.

FILIAL, something belonging to the relation of a son, filius.

The divines usually distinguish between a fervile and a filial fear. The most abandoned have a fervile fear of God, such...
such as that of a slave to his master; but not a filial fear, i. e. a fear resulting from love and respect.

**FILIAL**. See **CUSTOM of London**.

**FILICAIA, VINCENZO DA**, in Biography, an elegant Italian poet, was born at Florence in 1642. He studied and took his degrees at the university of Pisa. He married at the age of thirty-one: he was fond of retirement, occupying himself in poetical composition, and in the duties of domestic life. He was first brought to public notice by his fine canzonet composed on the raising of the siege of Vienna. For this he received the most flattering and complimentary letters from several crowned heads; from the emperor Leopold, the king of Poland, the duke of Lorraine, and the queen of Sweden. By the latter he was adopted into her own academy, and she took upon herself the charge of maintaining his children; at the same time commanding him to conceal her bounty, as being inadequate to the merits of so great a man. He was created a senator by the grand duke, and employed in some important duties by that prince, which he performed with so much credit, as to gain the esteem of the prince, and affection of the people. He died universally lamented, at Florence, in the year 1707, at the age of sixty-five. "He was," says his biographer, "one of the principal ornaments of modern Italian poetry, displaying, as well in his canzonet as his sonnets, great splendour, animation and dignity, and scarcely surpassed by any in vigour of sentiment and energy of style. He also wrote Latin verse with elegance, and some of his orations and epistles are inserted in the "Profe Fiorentine," He was member of the academies of La Crusca, and the Arcadi. His son Scipio gave a compleat edition of his Italian poems, under the title of "Prose Tofane di Vincenzo da Filicata, Senator Fiorentino," 1707, 4to." Moreri.

**FILICES, in Botany.** Ferns, a very distinct and natural order of the class Cryptogamia of Linnaeus. The name is supposed to be derived from flum, a thread, in allusion to the slender segments, or rather stalks, of these plants, whence also they are termed capillary plants, and some of them have the name of Maidenhair. They constitute the fifth natural order in the first class of the Physiella of Jussieu, and the first order of the twenty-fourth class of the Linnaean artificial system.

Their herbage is a frond, or leaf bearing frutification, rarely arborecent, involute when young, the flake more or less fealty; the root perennial, and generally very long-lived. Frutification most commonly on the back of the leaf; sometimes at the edge; sometimes, (by a transformation, as it were, of a leaf or its lobes,) spikied and terminal, or foliar and axillary. Capules usually of two valves and one cell, mostly flat, and bound with a contrary elastic ring; sometimes fidele and aggregate; very rare of many cells. Seeds extremely minute and copious.

The flowers of ferns are as yet altogether unknown, except what Hedwig has described in *Equitum;* see that article. The same admirable investigator thought he discovered anthers differed about the rib of the leaf in some common ferns, and piliills under the cover of their young fruit, see his *Thoria Generationis et Frutificationis Plantarum Cryptogamicarum, 43; 5. 6. 7;* but others have not adhered to this theory. Bernhardi has suggested another, equally hypothetical, that impregnation is performed on the upper side of the leaf, the pollen being secreted by small membranous anthers situated near the margin, and the stigmas placed directly over the point of attachment of each dot or mass of capules. See Sims and Konig's *Annals of Botany,* v. 1. 107; but this is not better supported by facts than the doctrine of Hedwig. Some have imagined the ring which embraces the capsule in most dorousferous ferns, might perform the office of an anther; but such a theory will not account for the impregnation in genera where no such part is to be found.

The seeds of ferns, independent of poetic fancies, were early known to naturalists. Giseke points out a passage in Cordus, denying them seeds indeed, but afferring that all ferns are propagated by the dust at the back of their leaves. Morison tells us he raised from seed the Harts-tongue and the Osmund-royal; see his *Historia, v. 3. 555 and 593.* Microscopic observers, about the same time, readily ascertained the structure of the capsules, and appearance of the seeds. Ehrlath observed the germination of *Asplenum spinulatum;* and Mr. Lindsay of Jamaica raised many ferns of that island from seed, as recorded in the *Transactions of the Linn. Soc.* v. 2. 93, carefully attending to, and delineating the progress of their growth. Mr. Fox of Norwich first raised a *Lycopodium* from seed; see *Tr. of L. Soc.* v. 3. 314. Similar experiments have been repeated by various other persons, and in hot-houses, where the larger kinds of *feres* are cultivated, young seedlings, of a feasty pellicul appearance, like an *Asphondylia.* Many often be seen scattered over the moist earth, or round their bark. Some seeds, in the hands of collectors, in his letters on Cryptogamous plants, translated by Mr. Konig, and published at London in 1807, that the cotyledons of these plants are not always simple, and this raises another difficulty respecting a natural classification by those parts. See *Cotyledones* and *Dicotyledones.*

The possible increase of ferns, if we consider the abundance of their seeds, is beyond computation. A single leaf will often bear one hundred millions of seeds. Yet we have no reason to think the countless numbers, that turn to no account as to propagating the species, afford food for animals of any kind, or serve any other secondary purpose.

Besides the feminal mode of increase, a few ferns produce gemmae, or buds, on their fronds or leaves, as *Woodwardia radicans;* and some take root at their points, as *Asplenium rhoicophyllum.*

To the botanical arrangement of ferns, much attention has been paid of late years, and with considerable success. The systematic writers of the 17th century touched this subject only lightly. Müller's *Historia Plantarum* distinguishes the spikied from the dorousferous ferns, and purposed to divide the latter according to the situation of the seeds on the edge or middle of the leaf, and according to the round or linear shape of the mass which those seeds compose. He then distinguishes them further into larger and smaller, owing, at the same time that he was not well satisfied with such a principle of arrangement; and finally subdivides them into such as have simple leaves, and such as have them simply, doubly, or triply pinnate. What concerns the situation of the seeds, or capsules, in this system is excellent, and is justly claimed by Ray as original. It forms, indeed, the basis of the Linnaean arrangement hereafter mentioned. But the shape or structure of the frond leads to no true generic distinctions, and yet Ray, loyalist of his original principles, distributes ferns according to these faulty ones, secretly observing how inconvenient they are, and retaining old names, without attempting to new-model them, or the genera which they had hitherto so imperfectly described.

Tournard, so lucidous of the genera of plants, attempted to distribute ferns according to the form of their fronds, but even this he performed in a most fundmental and imperfect way. His genus *Filix* indeed is tolerably characterized, after his principles, as having a pinnate leaf, and pinnatifid leaflets; his *Lenochitrus* has auricled leaflets; and his *Trichomanes* "generally roundish ones;" while his *Pteridophyta*...
Polypodium has a simple pinnatifid leaf. But his Ruta
muraria is strangely defined "with leaves somewhat
resembling garden rue;" his Filicula "with leaves somewhat
resembling those of Filis;" and his Adiantum "with leaves
known from other plants by their peculiar appearance," 
without indicating what that appearance is. Such a loose
mode of definition indicates a truly barbarous state of science.
He paid no attention to the situation of the fructification in
the different plants. Plancher, a very famous collector and di-locutor
of the species of ferns, followed his countryman Tournefort
implicitly in their generic arrangement, if it deferves to be so called, nor were any improvements in this line at-
ttempted till the time of Linneaus.

The system of the learned Swede would of course have
been imperfect, had he not undertaken to characterize all
the genera, even of his class Cryptogamia, as much as possible
by their parts of fructification alone, as far as such could be detected. Unfortunately, however, not only the essential organs of impregnation of ferns were then, as they still are, undetected, and the accessory parts of their
flowers nearly as obscure; while the structure of the fruit in
différent ferns was so much the same, in all known to
Linneaus, that it was useless for the purposes of generic
distinction. He was therefore obliged to have recourse to other principles, which, in the arrangement of plants with
evident flowers and variously-formed fruits, he had rejected as
unphilosophical; these were deduced from the situation of
the fructifications, and their aggregate figure, according to
the scheme indicated by Ray, but still carried into execute
by Linneaus.

Thus its genera appear differentiated in the first edition
of its Genera Plantarum.

Pteris. Fructifications disposed in a line, running along
the margin of the leaf on its under side.

Lunaria. Frut. in little crescent-shaped lines, under
the siphons of the leaf.

Adiantum. Frut. in oval spots, collected under the
reflected siphons of the leaves.

Asplenium. Frut. in straight lines, arranged on the
under side of the leaf.

Polypodium. Frut. in roundish spots, or dots, dif-
dered over the back of the leaf.

Acrolychnum. Frut. accumulated into one mass, en-
tirely covering the back of the leaf.

In the second edition of the same work two other genera
are added.

Hemionitis. Frut. in lines running into or interfetcting
each other, or branched.

Tricksmann. Caiax turbinated, solitary, erect, from
the margin of the leaf itself. Style bristle-shaped, ter-
minating the capsule. This last definition is incorrect in
terms, there being no authority for the use of the words
dyle and capsule in this case, and the former being indeed
merely a column, or elongated receptacle, to whose lower
part several capsules are indeed attached, but whose siphum
we are not warranted, by any analogy, to term a file, howerver appearances may be in favour of such a supposi-
tion.

In the 5th edition of Gen. Pl. a ninth genus is added,
while the arrangement of the former is a little altered.

Blechnum. Frut. disposed in lines, parallel with, and
near to, the rib of the leaf.

Nothing new on this subject occurs in the 6th edition of
the same work, the hall to which its author himself lent any
affinity, nor did he leave any thing relative to it in manu-
script.

Belcher, in his edition of the Gen. Pl. had added three
new genera, Marattia of Swart, Canoptera of Bergius,
and Menzies one of his own.

It is proper to notice what has been done by some contem-
poraries of Linneaus towards obtaining satisfactory
genetic characters of ferns.

Adanson, in his Familles des Plantes, published at Paris
in 1763, has noticed the membranous involucrum which
covers the fructification of most ferns; as has Gleditch in
his Système Plantarum, published at Berlin in 1764; but
they have detected this part in very few genera, and have
erred in several of their remarks concerning it. Thus in
the common brake, Pteris Linnaeus (Thebyteris of
Adanson, Cincinnia of Gleditch) whose involucrum is
manifest to the most careless observer, the former properly
describes that part as of one valve, in the shape of a pent-
house, while Gleditch absolutely denies its existence.

They both judiciously observe that the involucrum of Asplenium
Scrofulosum of Linneaus consists of two valves, but did not
say a word of its form in Blechnum. Hemionitis, or Lunaria.

"They have totally altered the Linnaean genera, but being
ignorant of any true principles, have made every thing
worse than they found it; and as to nomenclature, they have
gone counter to every maxim and all sorts of authority.

Both these writers have observed the pleated ring, which
binds together the capular valves of ferns, but they have
alike both equally erred, in denying the existence of any
such part in Polypodium vulgare!" It appears that both
these authors, who profess great originality, are not original
even in this error, for the slightest inspection of this very
common fern would have prevented it, none having a more
evident ring; they therefore could only have adopted it from
Tournefort, whom they do not quote, but who in his
figure and description has fallen into this unaccountable
mistake. Scopoli in his Flora Camioca has made use of
the remarks of Adanson and Gleditch, without correcting
the above faulty particulars, which he adopts on their
authority, though so very easy to be ascertained or refuted.

Haller and most other writers have made use of the Lin-
nean characters, with some occasional variations of no great
moment, either with respect to nomenclature, or the dif-
pollition of the species.

Indeed those who were conversant with European ferns,
or a few well-known exotic ones, only, would fearily find
any necessity of looking further than the Linnean generic
distinctions. But the writer of the present article was in-
dered only to consider the subject with attention, in con-
sequence of the vast collection of unsettled ferns of which
he became possessed in the Linnean herbarium, and
which were subsequently much increased by the unbounded
liberty of his friend Sir Joseph Banks. Many of these
could not be reduced to any known genus, and others,
tho the writer's technical characters possibly referable
to some, were yet too novel in habit as to require to be kept
generically separate. Many of these novelties were first
published at the celebrated Hedwig in 1756, in hopes of his
assistance; but nothing has transpired from him respecting any generic
reformations, though he or his son have since published a
few of the species.

The result of a general review of all the known as well
as nondescript ferns that could be got together, was a Latin
efay, communicated to the Royal Academy at Turin, and printed in the fifth volume of their Mémoires
in 1795, under the title of Tentamen botanicae de filicum
generibus dorserasum, autore J. E. Smith. In this the in-
volucrum, or membranous cover of the spores of capules,
was first brought into use for generic discrimination, and
particularly the direction in which it opens, whether out-
wards,
wards, that is, towards the margin or extremity of the frond, or inwards, towards the rib, nerve, or base, of the frond or its segment. This easy principle is found to lead to the most natural and distinct genera, without any exception. It does not overturn nor change one of those established by Linnæus, but more clearly defines them, while it affords means of ascertaining new ones. The part in question is found in almost every fern, covering the fructification before the latter comes to maturity. It originates sometimes from the margin of the leaf, but more commonly from some nerve or vein, in which half it is either lateral and parallel, or terminal and vertical. The involucrum adheres firmly to the frond on one side, whereas its nourishment, while growing is derived, and on the other is more or less closely pressed to, or sunk into a cavity in, its surface, without being really united with its cuticle, at least as far as can be observed. Not but that even on this side also the air is altogether excluded, so that in whatever mode the impregnation of the generis is accomplished, that operation must go on in secret under this covering, without any external communication, except through the falks by which the capsules themselves are attached, as the theory of Berchtold supposes; while Hadwig's implies an occasional elevation of the margin of the young involucrum, which we can find no reason to believe. When indeed the seed, seeds, and spores are arrived at maturity, the neighbouring parts, and especially the involucrum, dry up, the latter separating at the edge, and becoming crinkled or reflexed, to allow of the discharge of the spores.

In the Essay in question the Linnaean genera of dorciferous ferns were thus distinguished by characters taken from the involucrum, in addition to those by which they were previously known.

Acrisichne. Involucrum none, except little scales, or hairs, intermixed among the capsules.
Polypondium. Invol. uniloculic, separating nearly all round. Such species as have no involucrum were still retained here for further examination, they being then supposed very few.

Asplenium. Invol. originating laterally from a vein, and separating inwards; that is, towards the nerve or rib.

Hemionitis. Invol. in pairs, originating from the vein (which runs between the lines of capsules) and each separating outwards.
Blechnum. Invol. originating from the surface, continuing separating towards the nerve.

Pteris. Invol. from the inflexed margin of the frond, uninterrupted, separating on the inner side.

Lonicera. Invol. from the inflexed margin of the frond at each fuscus, in pairs, cresecent-shaped.

Adiantum. Invol. like scales, from the inflexed margin of the frond, divided, separating inwards.

Trichomanes. Invol. marginal, un-shaped, undivided, opening outwards, shorter than the column bearing the capsules.

To these the following new genera were added:

Davallia, distinguished from Asplenium by the involucrum separating outwardly, or towards the margin of the leaf.

Scopendrium, distinguished from Hemionitis, by its double involucrum separating inwards, the valves folding over each other.

Woodwardia, differing from Blechnum in having separate, short, or interrupted, vaulted involucrums.

Lindlea, published by Mr. Dryander in Tr. of Linn. Soc. v. 3.; differing from Pteris in its continued nearly marginal involucrum separating outwards.

Vittaria, having a double involucrum covering its long line of capsules, one valve from the margin, turned in, the other from the surface, separating outwards; its character combining those of Pteris and Lindlea.

Davallia, having a small scale-like involucrum to each round mass of capsules, terminating a vein or nerve, near the margin, or separating outwards.

Dicksonia of L'Heritier, having a double involucrum to each round mass of capsules, one from the surface, separating outwards, the other from the inflexed margin of the frond, embracing the former, and separating inwards.

Cyathia, bearing its capsulae in scattered hemispherical cups opening at the top without any lid.

Hypomorphium, having an involucrum of two flatth flattish valves at the edge of the leaf, opening outwards, longer than the column to which the capsules are attached.

Schiarea, having a double uninterrupted involucrum, formed of the inflexed edges of each linear appendage to the fronds, which bears the fructification.

All these genera have, or at least were supposed to have, a ring embracing each capsule; but it has since been observed that in some, as Schiarea, there is only an appearance of such a ring, as will be mentioned hereafter. Another section was subjoined, consisting of three genera unknown to Linnæus, whose capsules are not only decidedly delinete of a ring, but remarkably different in appearance and structure from the former, being sessile, naked, opening by pores.

The author termed these, as the former are annulata.

Glechonite. Capsules with three cells and three valves; partitions originating from the middle of each valve.

Marattia of Swartz's Prodrorus. Fl. Ind. Occ. Capsules oval, buried longitudinally on their upper side, with several cells in each division.

Davillia. Capsules of one cell, opening by a pore at their summit, and accumulated together in two parallel rows.

See in their proper places Cyathia, Davilla, Darea, Davallia, and Dicksonia.

This essay being republished in Germany, called the attention of the learned cryptogetic botanists of that country to the subject. Hence various tracts on the genera and species of ferns have appeared in different periodical publications, from the pens of Berdah, Wildenow, Mohr, and others. It was also published in English in 1798, in a volume of Travels by the author.

Several new observations were made, and mistakes corrected, by the writers just named. Mohr observed that the capsule of some ferns is only corrugated, so as to resemble a ring, but not really furnished with one, as in Schiarea. The same discovery was long ago made, but never published, by Mr. R. Brown. Onoclea, hitherto thought delinete of a ring, was proved to have one, and to be a true dorciferous fern. Several new genera were defined, but not in every case justly. Thus, the Siphonopteris of Bernhardi is more precisely a Cyathia, he having conceived a wrong idea of the latter genus, from some of the European Sphagnum certain species. His Wicklia is a Davallia, and his Ripidium a Schiarea. The good genera established by this and other writers will be mentioned hereafter.

At length the whole that had been done was revised and improved by the able Dr. Swartz, professor of botany at Stockholm, who published, in Schréder's Journal at Gottingen in 1800, the Genera and Species of Ferns arranged in systematic order, which work appeared in a still more perfect form, with a preface, descripisions of new or rare species, and several figures at Kiel in 1816, under the title of Synopsis Filicis. The family of Lycopodium and its allies are subject to a
FILICES.

difficult natural order; a distinction to which we cannot assent.

We shall enumerate the genera of ferns according to Dr. Swartz's work.

Section 1. Ferns whose capsules are surrounded with an eliastic ring; called by him Filices Gyrita.

* Involucrum none.
1. Acrophyllum. Capsules forming an indeterminate spot or affembles, over the back of the leaf.
3. Hemionitis. Spots linear, forked and reticulated. Dr. Swartz separates from this genus such species as have an involucrum, by the name of Diplopygium.
4. Grammitis. Spots linear, direct, continued, foliary between the rib and margin on each side, parallel.
5. Polypodium. Spots roundish, scattered.

** Spots veiled with an involucrum.
7. Aspidium. Spots roundish, scattered, covered with an umbilicate, more or less circular, involucrum.

This consists of the whole tribe of Linnian species of Polypodium, which differ from the sulphur and a few others in having an involucrum, and of which we have already spoken. It is by far the largest and most troublesome genus of the whole order.
9. Dorea. (Called by Swartz Crecepis, after Berghius.) Spots linear, near the margin. Involucrum lateral, separating outwards.
10. Stenopteris. Spots linear, in pairs, scattered. Involucrum of two opposite superficial valves, folding over each other.
11. Diplopygium. (Hemionitis Smith.) Spots linear, scattered, in pairs, simple or branched, at each side of a vein. Involucrum of two valves, originating from the vein, separating outwards.
12. Lunulitis. Spots crescent-shaped, at the confines of the leaf. Involucrum from the inflexed margin of the leaf, separating inwards.
13. Petes. Spots linear, continued, marginal. Involucrum from the inflexed margin of the leaf, uninterrupted, separating inwards.
14. Pictaria. Spots linear, continued, longitudinal along the axis or near the edge of the leaf. Involucrum double, uninterrupted; one separating outwards, the other inwards.
15. Onoclea. Spots indeterminate, entirely covering the backs of some leaves. Involucrum from the membranous revolute margin of the leaf, either continued or interrupted, separating inwards.
16. Blechnum. Spots linear, longitudinal, continued, parallel, one on each side of the rib. Involucrum superficial, continued, separating inwards.
17. Woodwardia. Spots oblong, diminutive, lying near the rib. Involucrum superficial, vaulted, separating inwards.

The term superficial involucrum, involucrum superficial, expresses one that originates from the surface, not from the margin nor rib.
18. Lindsaea. Spots linear, continued, near the margin. Involucrum superficial, continued, separating outwards.
19. Adiantum. Spots roundish or linear, diminutive, marginal, growing upon the inner side of the membranous involucrum, which are formed out of the reflexed edge of the leaf, and separating inwards.
20. Cheilanthes. Spots roundish, diminutive, marginal, each covered with a distinct membranous involucrum, formed of the reflexed crenate edge of the leaf, and separating inwards.

This genus, established by Dr. Swartz, and named from Xanthes, the brim or margin, and a细心, a flower, comprehends 12 species in his work, some of which had previously been referred to Adiantum, others to Petes, and some even to Polypodium, which diversify of opinion among authors affords a strong presumption of their not agreeing well with any known genus, and consequently of the necessity of founding a new one to receive them. Accordingly the above character sufficiently distinguishes them from Adiantum, the only genus with which they could, in the present state of the science, be confused, by the fructification being seated on the leaf itself, and not on the scales which form the involucrum—Polypodium fragrans, Linn. Mant. 307; and a distinct species is called by Desfontaines, Fl. Adiant. t. 257; also Adiantum capense of Thunberg, according to Swartz, species of Cheilanthes.
22. Dicksonia. Spots roundish, separate, marginal. Involucrum double; one superficial, separating outwards, the other from the inflexed margin of the frond, separating inwards.

The proper character of this genus consists in the involucrum growing under the infection of the capsules, either in the form of a membranous undivided cup, as in C. arborea; (Polypodium arboreum; Linn.) and several others; or of a similar cup composed of numerous scales, as in C. borrida; (Polypodium borridum; Linn.) Whether some European species, as C. fragrans Fl. Brit., whose involucrum is a membrane enfolding the capsules while young, properly belong to the same botanists are not agreed, nor have those who have decided on this subject been furnished with proper materials for the purpose.

Section 2. Capsules of one cell, destitute of a distinct ring, opening by a longitudinal fissure on one side.—These are called by Swartz Filices spinar gyratae, because they have a wrinkled capsule, imitating the ring in the former section; or incurvata, alluding to the figure by which the said capsule discharges its seed.
26. Splecia. Capsules crowded, selloe, on the backs of several appendages to the leaf. Involucrum from the inflexed margin of each appendage, uninterrupted.
27. Lygodium. Capsules solitary, selloe, within the imbricated two-ranked scales, of terminal or lateral spiky appendages to the leaf.

The name, derived from lyglos, a twig or wand, alludes to the slender flexible habit. This elegant genus, which comprises the Ophioglossum fendant and flexuosum of Linnaeus, has been indicated by several writers. Wildenow has
FILICES.

has named it Hydroglysum; Cavanilles Ugena; and Mirbel Raymundi. None can be more distinct.

28. Mobria. Capsules separate, sessile, at the edge of the leaf. Involucrum from the inflexed crenate margin.

A genus founded by Swartz in honour of his able cryptogamic friend Mobr, upon the Polypodium cafiforum Linn. by some referred improperly to Osmunda.

This genus is separated by Swartz from the following, chiefly because its capsules are sessile on a branched receptacle, not stalked and flattened on the back of a leaf, neither are they so much divided into two valves. The difference is rather difficult to define, but may be founded in nature.

Both genera are quite distinct of all involucrum.—The present consists of 17 species, amongst which are Osmunda phyllitidis, birta, bifurca, adventispi, bipinnatifida, and fibulatifolia of Linnaeus, all fine West Indian ferns figured in Plumiier.

30. Osmunda. Capsules crowded, stalked, naked, on the metamorphosed leaflets of the frond.

31. Todea of Willdenow. Capsules nearly sessile, on the transform, almost parallel, veins of the leaf, naked. The only species is T. africana. (Acrolochiium barbarum Linn.)

Confirms of fern species, one of which, M. furcata, is Acrolochiium furcatum Linn. figured in Plumiier, t. 28. This genus is scarcely distinct from the following.

33. Gleichenia of Smith. Capsules three or four together, sessile in a little hemispherical depression of the leaf.

It appears from this character that Swartz considers as separate capsules, what the author took for cells of one capsule, and analogy confirms the opinion of the former.

34. Athamia of Hoffmann. Capsules sessile, naked, placed in a double series, in little parallel neighbouring spots, all together forming a longitudinal line near the margin.

The only species is A. excisa, a most elegant large fern, found in the South Sea and Philippine islands.

Section 3. Capsules deliquescent of all traces of a ring.

* Capsules of many cells.

35. Marattia of Swartz. Capsules oval, scattered, at first closed, then separating into two parts, and discharging two rows of cells, opening by the top.

36. Drynea of Smith. Capsules oblong-linear, transform, parallel, immersed in the frond, with two rows of cells, opening at the top.

* Capsules of one cell, with two valves.

37. Botrychium of Swartz. Capsules distinct, sessile, crowded into a cluster, bursting transformely. Separated by Swartz from Osmunda, and containing our O. lunaria, &c.

38. Ophiochyron. Capsules united into a two-ranked, somewhat jointed spike, bursting transformely.

The Lycomonoideae of Dr. Swartz we consider as no less genuine filices than the foregoing. They have an herbaceous, or bristly, leafy item, with axillary fructifications, and may be defined as follows.

Section 4. Capsules axillary, naked, of one, two, or three cells.

This is a large and beautiful genus, comprised amongst others by Dillettii and Linnaeus, from which its fruit totally differs. Nothing is known respecting the flower or impregnation.

40. Tmesipteris of Bernhardi. Capsules of two cells, with a transformely structure.

T. colonnes, a New Holland plant, is the only known species.

41. Pileatum of Swartz. Capsules of three lobes and three cells.

Confins of Lycepodium nudum of Linnaeus, and one more species. They have leaves, though small ones, analogous to those of Lycepodium, and the capsules are really axillary.

Cavanilles, in his Letters on Botany in Spanish, published in 2 ed. 8vo. at Madrid in 1803, has adopted the same principles of arrangement, carefully acknowledging whence he has derived them, and describing many new ferns from the East and West Indies. Swartz refers to this work, which is the more necessary, as their generic names often differ.

One of the latest writers on the subject is Professor Sprengel of Halle, who, in his Letters on the Study of Cryptogamous Plants, already mentioned, treats copiously of ferns, both physiologically and systematically. The author does not seem to be aware of the former to whom he is obliged for his leading principles and generic characters, having apparently never been above-mentioned Eifflay, though he properly mentions "the excellent Swartz," whole treatise, as it stands in Schrader, he might very well take to be original; neither has the translator corrected this omission, which we are well assured is an accidental, not designed, injustice.

Sprengel establishes the following genus upon the European Cyatheae.

Athyrium. Capsules in small, scattered, round spots, on the whole lower surface of the frond. Involucrum fixed on one, mostly the inner, ridge, and commonly opening towards the margin.

This definition is not sufficient to give a clear idea of the supposed genus, which, as far as concerns the species that we have all along referred to Cyatheae, ought to be characterized as having a lacertous involucrum, enclosing the masts of capsules, and infesting beneath them. The reformers of Cyatheae have not had access to the whole series of species which appear to us to connect these with the primary one.

But however this may be, we are persuaded several of Sprengel's Athyria belong rather to other genera, from whence he has removed them.

We cannot take leave of Professor Sprengel without which is far from excellent compiled matter, without grounding our readers against a position in his 6th letter, p. 74. "The only character," says he, "that can be derived from the fhape of the fruit, in the classification of ferns, is the presence or want of the annulated ring of the feed-veils. From this therefore they may be divided," the ought rather to have said they have been divided, into annulated, with a ring, and eomnulated, without a ring; but this is an artificial, not a natural character; for the genus Onches, whose feed-veils are annulated, approaches very near to Osmunda, whose capsules are without a ring; and Polypodium is closely related to Marattia, Paris to Athamia, and Digites to Digites. This is too extraordinary an assertion, as to shake our confidence in the author's judgment and observation to the very foundation. No ferns, no plants of one natural order, are more distinct, unlike, and effectively different from each other than these, inasmuch that we cannot account for, nor trace, the chain of ideas which caused them even to be compared. We must repeat that nothing is more natural or absolute than the distinction between annulated and eomnulated ferns, nor between either of these, and such as have a wrinkled, or partially annulated, capsule. The writer of the present article honestly confesses that the discovery of the latter tribe at first made him doubt the fidelity of the distinction as far as
FIL.

ferns with single capsules were concerned; nor had he
leisure to resume the subject, before Dr. Swartz's publi-
cation removed every scruple, and set the matter at rest.
About the _teccco_ (Marattia and Danae) there could never
be any uncertainty. Their fruit is so unlike the annulated
ferns, that to term them _annulata_ seems to imply a fort
of affinity or resemblance, (independent of the ring,) for
which there was no foundation; another term was there-
fore contrived, but it has not been adopted. The author
is the more ready to regret it, as he has ever found the
necessity of keeping a watchful eye upon the invention of
new terms, in this and other branches of natural history,
which are often but a substitute for a deficiency of new
ideas.

Thus the German writers are pleased to call, after Hed-
wig, the feed-veil _sporogium_, though _pericarpium_ is of
precisely the same meaning, and has long been established.
Professor Swartz rightly uses _capitula_, which moreover
expresses what sort of feed-veil is intended. Yet the latter
prefers _genesis_, a new botanical word, to _annulus_, because, it
ferns, _annulus_ is used in _fungi_, as if there could be any
ambiguity or confusion! Jullienow and Swartz call the
involution _indigium_, (a cover,) which we think needless,
because the part correctly answers to the Linnaean idea, as
well as to the true meaning of the word _involution_, and has
long been so called. Cavanilles names it _segmentum_, and
Hedwig _perisporegium_. So the latter calls the ring _fylpklakium_,
and Palhott Beauvais names it _annulus_. There is no end
to such futile and reprehensible changes. _Seri_ of Swartz
may be advantageously admitted for the spots of fructi-
fication, which cannot always be called _pamula_ or dots,
being sometimes linear, and sometimes broad and unlimited,
so that the terms _lineae_ and _maculae_ have been reserved to:
whereas the word _foris_ spots, comprehends every different
shape.

We have in another place, Introduction to Botany, p. 388,
put in a protest against a corruption of the generic nomen-
clature of ferns, on which subject we shall here be very
brief. Several of the new names are compounded of _Peltis_,
a fern, and some other word. Now if these are allowed to
remain, some such distinctive syllables might be prefixed to
the old genus _Peltis_ of Linnaeus, to get rid of the latter;
else a very found Linnaean law is needlessly infringed, which
forbids forming new generic names of already established
types, combined with another word to give them a new
meaning. All writers, before they publish, should study
and observe these matters, that science may remain uncor-
rupted and unobfeured.

In the above general synopsis of ferns we have laid
nothing of _Phylidaria, Liottia, Marjela, Selasia_, and _Equis-
feuam_, which have generally been considered as belonging to
this natural order, but they ought rather to compose a new
one. It is hinted in the Flora Britannica that the two first
might perhaps be removed to _Menocia_ in the artificial sys-
tem, and if the last should remain among the _Phylidae spinata_,
see _Equisetum_, it can only be on artificial principles.
_Marjela_ and _Selasia_ we have never critically examined,
but they seem near akin to _Phylidaria_, and are likewise per-
haps monocious.

Of the Books containing figures of ferns, Plumier's
splendid volume of Outlines is the most valuable. Pictet
has copied it on a diminished scale. There are many East
Indian species in Rheed and Rumphius; some from all quants
in Plukenet. The younger Hedwig, now alas no
longer surviving his father, has published several coloured
plates of this tribe; but no plants lefs require this additional
illustration, being all so much alike in colour. Many Euro-
pean ferns are delineated in the Flora Daukea, and English
Botany, and a few in Dutilh's Herbarie de la France.
Lamarex has given several of the new genera, with the old
on his general plates—Ferns are usually dried and pre-
furred in a herbarium; no other plants being so little attacked
by insects.

Propagation and Culture.—Of the propagation of ferns
by seed we have already spoken. Shade and moisture are
requisite for the success of the experiment; and the feed-
lings are of extremely slow growth. Ferns of cold countries
are in our gardens hardly perennial, generally requiring a
moist and shady situation, and slowly increasing by root.
Those of hot climates are many of them beautiful trees,
and when not too large, well worthy of culture in our flower.
The _Dicksonia arborea_ from Madeira is so preserved in a few
curious collections, but does not succeed very well. _Poly-
phodium aureum_, _Decaxia concinnum_, and _Woodwardia radi-
ante_, are easily kept in a greenhouse, and increase slowly by
means of their creeping roots. We have been growing in
the hove of Mr. Evans at Stepney in 1825, the _Toila
africana_, Wild. Rare Fern, t. 5, in full fructification.
It was said to have been brought from New South Wales, but
possibly that might be a mistake, as we have often detected
such in the reports of those who bring plants from remote
countries. It is not however impossible that this fern may
grow in New Holland as well as Africa, in which case it
will only afford a fresh instance of the improbity of names
of countries for specific appellations.

FILICULA, a little fern, was by Tournefort applied as a
generic name to some of the smaller kinds of ferns, which he
peremptorily from others merely on account of their size. They
belong to various genera, and have no good natural nor arti-
tificial characters.

FILIGRANE, FILIGREE, or FILIGRE-VOEK, a kind
of enrichment on gold or silver, wrought delicately, in
manner of little threads or grains, or both intermixed.

The word is compounded of _fil_ or _flum_, thread, and
granum, grain. In Latin it is called _filtrum elegantium opus_
_argentum_ aureum: but this is to be understood as alluding to
the latest Latin writers, for _filtrum_ occurs only once in
Lacerti, who applies it only to wooden thread. In this
kind of work fine gold and silver wire, often curled or
twisted in a serpentine form, and sometimes plated, were
wrought through each other, and folded together so as to
form fillons, flowers, and various ornaments; and they were
also sometimes melted together by the blowpipe into little
balls, by which means the threads became so entwined as to
have a very beautiful and agreeable effect. It was formerly
much more employed than at present, in the manufacture
of small articles, which served more for show than for use;
such as vases, needle-cases, vases to hold jewels, small
boxes, particularly shrines, decorations for the images of
saints, and other church furniture. This art, however, is of
great antiquity; and seems to have been brought into
Europe from the East. Among church furniture we meet
with filligree work of the middle ages. The Turks, Ar-
menians, and Indians make at present some matters-pieces of
this fort, and with tools that are exceedingly coarse and
imperfect. Articles of this nature, which are very pretty
and elegant, are manufactured in the Deccan, and also in
China, where the filligree work is mostly wrought of silver;
but this is much inferior in delicacy of workmanship to that
of the Malays, described by Marsden, in his "History of
Sumatra," p. 140, &c. In this island it is universally
used and worn; and the goldsmiths who are employed in it
are settled every where along the coast. The surprising
delicacy of the work is the more extraordinary, as the
tools employed in it are very rudely and inaccurately formed by the goldsmith, from any old iron which he can pick up. The gold is melted in an earthen rice pot, in a crucible of ordinary clay. In general they use no bellows, but blow the fire with their mouths, through a joint of bamboo. and when the quantity of metal to be melted is considerable, three or four persons sit round their furnaces, which is an old broken iron pot, and blow together. At Padang alone, where the manufacture is more extensive, they have adopted the Chinese bellows. When they have drawn the wire to a sufficient fineness, much in the European manner, they flatten it, by beating it on their anvil, and then give it a twist, like that in the whole bone handle of a punch ladle, by rubbing it on a block of wood with a flat file. After twisting they again beat it on the anvil; and thus form a leaf or element of a flower in their work, which is cut off. The end is again folded and cut off, till they have got a sufficient number of leaves, which are all laid on figly. Patterns of the flowers or foliage, in which there is not much variety, are prepared on paper, of the size of the gold plate on which the filagree is to be laid. They then begin to dispose on the plate the larger compartments of the foliage, for which they use plain wire of a little size, and fill them up with the leaves before mentioned. To fix their work they use a glutinous substance, made of a red berry called boa fago, ground to a pulp, on a rough stone. This pulp they place on a young cocoa-nut, about the size of a wall-nut: the top and bottom being cut off. The juice of the cocoa-nut serves probably to keep the pulp moist, which would otherwise speedily dry and become unfit for the work. After the leaves have been all placed in order, and stuck on, bit by bit, a folder is prepared of gold filings and borax, moistened with water, which they blow over the plate, and then putting it on the fire for a short time, the whole becomes united. In executing the open work the foliage is laid out on a card, or for kind of wood, and stuck on with the fago berry: and the work, when finished, being covered over with their folder, is put into the fire, when the card or soft wood burning away, the gold remains connected. If the piece be large, they folder it at several times. When the filagree is finished, they cleanse it by boiling it in water, with common salt and alum, or sometimes lime-juice; and in order to give it a fine purple colour, they boil it in water with brimstone. In making little balls, with which their works are sometimes ornamented, they take a piece of charcoal, and having cut it flat and smooth, they make a small hole in it, which they fill with gold dust, and this, melted in the fire, becomes a little ball. They are very expert at filing and polishing the plain parts, hinges, ferrules, and the like, being in this as much excelled by the European artists, as these fall short of them in the fineness and minuteness of the foliage. The price of the workmanship depends upon the difficulty or uncommonness of the pattern. In some articles of usual demand, it does not exceed one third of the value of the gold; but in matters of fancy it is generally equal to it. This art is now neglected and little esteemed in Europe. Augsburg, however, a few years ago, had a female artist, Maria Euphros. Reinhard, celebrated for works of this kind, who died in 1779. In 1769 she ornamented with this work some silver boxes, which were sent to Russia for the use of the church, and which gained her great honour.

The term has been lately applied to ornamented works, formed, as fancy directs, of strips of paper, differently coloured, rolled into various figures, and artistically combined.

FILING, in Mechanica, is the operation of using a file in cutting away and reducing various substances into any required form. The file is chiefly confined to the working of metal, though it is occasionally applied to wood, ivory, bone, &c. The art of filing is an essential to every workman in metal, and it requires great practice and skill to perform it well; the principal difficulty consists in filing a flat plane and even surface to any piece of metal. To do this the work must be held firmly in a vice, so that the surface to be filed be truly horizontal; the workman then files it over with a file, adapted in its cut, or size of its teeth, to the magnitude of his work: in doing this, if it is large, he takes one end of the file in each hand, holding it firmly, as he moves it backwards and forwards, in a horizontal plane, taking care not to lean heavier upon one end of the file than the other. The file only cuts in going forwards; he must therefore press harder upon it, that it may take hold of the metal: in drawing it back it is unnecessary to lean on the file, because it is not then adapted to act; it is usual, in filing a piece of flat work, to begin at one side, and every time the file is drawn back, to move it sideways at the same time about the breadth of the file: the next stroke proceeds slantly forwards, as before, but in a fresh place, unless some sudden incrustation is to be removed; then two or more strokes should be made in one place, or the pressure on the file increased till all is brought to a flat or even surface. When the whole of the work has been done over in one direction, it is then filed in the same manner at right angles thereto, and afterwards diagonally, till it is finished, trying it occasionally by a straight edged ruler. Some workmen, by long practice and experience, are able to make the work flat by filing in one direction only, and without any trial; so that if two surfaces of metal thus filed are placed one upon the other, they will adhere together for an instant if the upper one be suddenly lifted up. The height of the piece, in which the work is held, is a matter of some importance in filing: if the work is large, it should be about forty inches above the floor on which the workman stands; for small work it may be higher, because the workman does not need to bear so heavily on the work. In filing articles which are to be fitted together, the workman makes use of bevels, gauges, rulers, compasses, &c. to mark out and try the work. Round pins, &c. are held in a hand vice, and supported on a piece of wood while they are filed, and the workman turns them round while he files, in order that they may be truly round and have no angles.

The file-makers in Lancashire, for cutting the teeth of their small files, sometimes make use of a knife, fig. 5. Plate XII. Missett, which has a bevelled edge; the workman uses it in the same manner as the chisel, except that no hammer is employed. The finest files used by watch-makers have sometimes as many as 350 teeth per inch, which are frequently cut by the knife; other watch-makers' files are cut in the manner above described, by the chisel, fig. 6, which is struck on the head by a small hammer. The smallest chisels used are not a vast deal larger than the figure, and the hammer, fig. 7, is the full size, though the handle in reality is somewhat longer; some of very fine watchmakers' files are not larger than needles, and are called needle-files.

FILIPENDULA, in Botany, so called because the knobs of the roots are pendulous on threads from the main root. Town. Inf. 293. 1. 150. See SPIRA.

FILIPPOPOLE, or Filippope, or Filide, in Geography, a town of European Turkey, in Romania, on the Maritz, where it becomes navigable; founded by Philip, father of Alexander the Great. In the year 200 it was taken by the Goths, who are reported to have massacred 100,000 persons in the sack of this city; and in 1670 it was taken by Amurath I. emperor of the Turks; 50 miles W. N. W.
of Adrianople, and 124 W.N.W. of Constantinople. This
town is nearly built, without fortifications, or one good
street. Its situation is low and moist, and the mud is
two feet deep, and fomes, like pools, are set up
to facilitate the progress of foot-passengers. Nevertheless,
it is a place of considerable size. N. lat. 43° 22'. E. long.
24° 44'.

FILITZ, a town of Germany, in the principality of
Culmbach; six miles S. of Kirch Laimitz.

FILLUS ANTS PATREM, q. d. the fox before the
father; a denomination applied by botanists and florists to
plants whose flowers come out before their leaves. Such
are the several species of colchicum, or meadow-saffron, the
colt's foot, butterbur, &c.

FIL IX, in Botany. See Ficllces and Fern.

FILL, in the Sea Language, is to brace the sails in
such a manner, that the wind entering their cavities from
behind, dilates them, so as to advance the ship in her course,
after the sails had been for some time thrashing or braced
back.

FILLER, in Geography, a town of Hungary, taken by
the Turks in 1554, but soon after recovered. Its fortifi-
cations are destroyed; 40 miles S.E. of Cremona.

FILLER, a term often provisionally used to signify
the horse which supports, and is placed between the shafts
carts or other carriages. It is commonly written thiller.
See Thiller.

FILLET, in Anatomy. See Frenum.
The word is French, fillet, formed of fil, thread.

FILLET, or Fillet, in Architecture, denotes a little square
member or ornament used in divers places and on divers oc-
casions, but generally a corn of corn in a greater
moulding. The fillet is the same with what the French call
reglet, bande, and bandelette; the Italians, linta, or lyella.

FILLET, in Botany. See Thread.

FILLET, Tenisla, in Heraldry, a kind of orle or bordure,
containing only a third or fourth part of the breadth of the
common bordure. See Bordure.

It is supposed to be withdrawn inwards, and is of a
different colour from the field. It runs quite round near
the edge, as a lace over a cloak.

FILLET is also used for an ordinary drawn like the bar
from the fuller point of the chief across the shield, in
manner of a scarf; though it is sometimes also seen in the situ-
ation of a bend, fesse, fosse, &c.

According to Guillim, the fillet is a fourth part of the
chief, and is placed in the chief point of the escutcheon.

FILLET, in Midwinter, a contrivance for the purpose of
extracting the child, in difficult births, when the head is
too large to pass readily through the pelvis. The invention
is probably very ancient, as it is mentioned by Avicenna,
as well known in his time; that is, towards the end of the
tenth century. The frappled, and probably the full con-
trivance of the kind, was made by cutting, in a strong flip
of cloth, a flit, sufficiently large to embrace, and take into
it, the head of the child. This was carried up into the va-
gina, upon the hand of the accoucheur, and passed over the
face of the child, and lodged under the chin, or over the
hind-head, and pressed close to the nape of the neck; the
hand was then withdrawn, and the child extracted by pulling
down the other end of the cloth. But as it was difficult to
keep the noose open, so as to make it embrace the head of
the child; this defect was attempted to be remedied, by
making a fisell, with a flip of strong cloth, two feet or
more in length, through which a thin piece of whalebone
was paffed. The noose being carried over the head,
FILLY Fowl, a term implying a mare or female fowl. See FOAL.

FILM, a thick skin or pellicle. To place it is often in a used for that thin moist fkin which separates the foods in the pond, and keeps them apart.

FILM, White, on the eye of a horse, may be removed by lifting the eye-lid, after the eye has been washed with wine, and floaking it gently with the thumb with wheat-flour: common salt and salt of lead, beaten fine, and put into the eye, are proper to consume a film; or the horse’s eye may be washed with the spittle in the morning, failing, having first put a little salt into your mouth; but there is nothing so effectual as sal ammoniac, beaten and put into the eye, and repeated every day till the film is gone.

FILMER, Edward, gent. in Biography, in 1629, collected, translated, and published, “French Court Ayres, with their ditties, Englishd, of four and five parts, dedicated to the Queen,” vol. These all were chiefly composed by Pierre Guerdon, with two by Anthoine Doffret. There is very little musical merit discoverable in these songs, which are, however, highly extolled in several copies of verses prefixed to the book, and, among the rest, in one by Ben Jonson. The editor seems to have taken great pains in translating the words, “totidem syllabis,” in order to accommodate them to the original melodies.

FILOPONKAJA, in Geography, a town of European Turkey, in Dobrouzze Tartary; 18 miles S.S.E. of Fismal.

FILOQUIA, Filloquial, or Jerozol, a town of European Turkey, in Livadia, on a river which runs into the gulf of Arta. It was anciently called Amphioleia, or Argos Amphioleium, and, although once a celebrated town, it was ruined by the war between the Venetians and Turks; 44 miles N.N.W. of Lepanto.

FILTER, or Filtre, in Chemistry, &c. a piece of woven cloth, linen, paper, or other matter, some of which are in the form of hollow inverted cones, used to filter or strain liquors through. The filter has the same use and effect with regard to liquids that the fusee or scarce has in dry matters. Filters are of two sorts: the first are simple pieces of paper or cloth, through which the liquid is passed without further trouble. The second are twisted up like a thin or wick, and filter wetted, then squeezed, and one end put in the vessel that contains the liquor to be filtered; the other end is to be out, and hang down below the surface of the liquor; by means of this the purest part of the liquor diffils drop by drop out of the vessel, leaving the coarser part behind. The filter or philtre acts as a siphon.

FILTER is also an apparatus used to separate water or other fluids from any foreign matter it may contain; this is effect ed by causing the water to percolate through an infinite number of apertures of various size and shape, which are too minute to allow the passage of any substance mixed in the water; by this means, the moist foul water, after passing through such a filter becomes perfectly transparent and sweet, though at the same time it is not deprived of any of its qualities which depend upon matter entering into combination with it; only such as depend upon mechanical mixture being arrested in its progress through the filter.

The great utility of filters for domestic use must be evident, as a filter is for culinary purposes can be obtained from any patrid and muddy water; on this account the construction of apparatus, which will at the same time be cheap and efficacious, is a desirable object; and a vast variety have been contrived, many possessing great advantages.

The filter in most general use is a basin formed of some porous kind of stone, and supported over any convenient vessel to receive the filtered fluid. The foul water being poured into the basin, inimmates itself by flow degrees through the minute pores of the stone, and is collected, drop by drop, into the receptacle placed beneath. This apparatus answers its purpose perfectly well for a time, but has its defects: the constant accumulation of the impurities in the basin, in time choked up the aperture of the stone; this may be removed by washing many times, but the more minute particles of matter are, by insensible degrees, carried down into the stone, fill up the pores, and at length no water will pass through. A trilling error is also committted in the form of the vesell, which is in general a hemisphere; in this figure the preffure of the fluid is greatest in the lowest point, and gradually diminishes in every other part, so that unless the preffure is greater in the centre than it ought to be, scarcely any water will pass through the other parts. A more eligible form would be that of a cylinder, formed either of earthenware or metal, with a circular plate of the filtering stone cemented into it at the middle; by this means, the preffure on all parts will be equal, and it would have another advantage, that when the water began to pass slowly through the stone, by inserting the cylinder, the filtrate would be filtered in a contrary direction, and act to remove the more matter deposited in the pores of the stone by the preceding process.

The filter proper for contructing filters, is of no means scarce; in London is a very porous lime-stone containing innumerable fragments of broken shells is employed; it bears strong reliance to the ragstone found at Barnack near Stamford, Northampton; a grit-stone, procured at Bircher and Stanton Moor near Winster in Derbyshire, is found to be well adapted for filters, which are carried all over the country. The expense of stone filters, and their liability to be choked up by long use, have given rise to many others more simple; sand finely washed, pulverized glass, pottery or charcoal, are frequently employed, being placed in a proper situation for the water to percolate through them. The latter, from its well known antieptic quality, is peculiarly adapted to correct putrid water, at the same time that it separates its impurities. Mr. John Isaac Hawkins, Tithe eld street, has established a manufacture of charcoal filters for the supply of the metropolis where the water in general requires such purifying agents.

Figs. 8 and 9, Plate XIII. Mistislan, represents two constructions. The latter is on a large scale, and constructed in a cafl A B C D, divided into two compartments by a vertical partition, E F, which does not reach within two inches of the botton of the cafl; the space a b d c is filled with charcoal, at first a stratum of coaly powdered charcoal four inches deep, and this is covered with another stratum of four inches, in pieces about the size of walnuts; in each division of the cafl the charcoal is covered with a perforated cover, the foul water is poured in on the side, A B E F, and is forced by its preffure down on the side, and up on the other, through the charcoal, in which it devours its extraneous mixtures, and rives in the fide, E F, perfectly transparent and sweet; it is drawn off for use by the cock a; at e is a cover to prevent the foul water being accidentally thrown on the wrong fide; the cafl is of wood, and charred with fire, to still further sweeten the water.

The filter in Figs. 8, is on a smaller construction; here A is the vesell for the foul water, furnished with a cock a, delivering the water in the spout b, of a second vesell B, containing the filter; it is filled with charcoal as high as the cover c, which prevents the small charcoal being disturbed by the entrance of the foul water, which, after percolating through the filter, escapes at the tube d into the inferior reservoir, where it is retained until wanted, when it.
F I L

is drawn off at the cock $c$. The cask filter is two feet eight inches in height, twenty-two inches diameter at the bottom, and sixteen inches at top; if constantly supplied with foul water it will purify one hundred gallons per day; its inventor strongly recommends it for the use of ships; the other filter, which is made of earthenware, and a much smaller size, will do a proportionate quantity; when the charcoal becomes foul it may be taken out and replaced, at an inconsiderable expense; sand, pounded glass or pottery, and other substances, have at times been recommended. Professor Parrot constructed a filter with sand; its form is an inverted siphon, the curve of which is filled with sand washed exceedingly clean, a constant stream of the foul water enters at one side of the siphon, and passing down through the sand in one leg, rises through the other, escaping on a level rather lower than it entered. Great stress is laid by the inventor upon the filtration by ascent, as well as descent; as he supposes the more weighty particles will subside; though from their exceedingly small size, they might escape through the interstices of the sand. It will be easily seen that the slip filter by Hawkins is the same in effect, though on a better construction.

Mr. James Peacock took out a patent in 1791 for filtration by ascent through any of the above-mentioned substances; but he does not describe any thing material which we have not mentioned above.

The filter delineated in fig. 10, is a contrivance of Mr. Cullen, and described in the Philosophical Magazine; A B C D is an ordinary cask divided into three parts by three horizontal partitions; the upper division A B a b is to contain the reservoir of foul water; the partition a b is perforated, and allows the water to pass slowly down into the middle division filled with broken corkery ware, presenting innumerable surfaces upon which the water deposits any matters which will subside; the cask is perfurred all round to admit air at a b; the water then passes into the inferior compartment which contains the filters; these are three cylinders, one of which is seen at D; they are formed of argil and silex baked together in a potter’s kiln. The water percolates through this substance, and is received into a vessel E communicating with the filters, formed of metal, and furnished with a cock at r to draw off the clear water; F is a metal tube placed upon the top of the vessel E, with which it communicates, and in which the water rises as it accumulates in the reservoir; a cock at f will draw off the foul water, and the tube F, being full, or nearly, of the filtered water, the pressure will be reversed, and the impurities lodged in the pores of the cylinders removed by the contrary action.

To the inhabitants of a large city the filtration of the water they make use of is a matter of considerable importance, but the practice is at present confined to apparatus on a small scale for the use of one family only; filters on a large scale might be simply constructed, and the expense of land for their formation would be amply repaid by the improvement of the water. The construction of the slip filter leaves itself adapted for this purpose, a large tank lined with brick-work, and divided into two by a wall which must have every other brick of the lower course omitted, so as to leave apertures at the bottom of the wall; this tank being filled two feet deep with pulverized charcoal would form an excellent filter, and several of these being arranged round the steam engine for pumping the water would alterately supply it. The expense of charcoal might be obviated by using the refuse or charcoal as it is term, or sawdust might be charred in an iron retort at a small charge. See Filtration.

F I L

Filter, or Flitter, is also a charm, supposed to have a virtue of inspiring love.

The word is derived from φίλληρα, which signifies the same thing, of φίλος, amio, I love.

The Greeks, when their love was without success, had several arts to procure the affections of their beloved. The Thessalian women were famous for their skill in this, as well as other magical practices. The means whereby it was effected were of divers sorts; it was sometimes done by potions, called φίλληρα, which are frequently mentioned in authors of both languages. Juvenal speaks thus:

"Hic magicus effert cantus, hic Thessalae vendit

Philitra, quibus valetas mentem vacare marit."  

Their operations are violent and dangerous, and commonly deprived such as drank them of their reason. Plinarch and Cornelsus Nepos report, that Lucullus, the Roman general, first loft his reason, afterwards his life by one of them. Lucertus, the poet, ended his life by the same way; and Cassius Caligula, as Suetonius reports, was driven into a fit of madness by a filter given him by his wife Cleopatra, which flies was mentioned by the same poet. Ovid likewise affirms us, that this was the usual effect of such potions.

The ingredients they were made of were of divers sorts, few of which, applied by themselves, were thought effectual.

FILTRIA, in Geography, a town in Sweden, in the province of Sodermanland; 10 miles S.W. of Stockholm.

Filtration, the act of passing any liquid through a filter, called also siphonation, procuration, and transmutation. See Filter.

The end of filtration is of two kinds; the one to free fluids from any solid bodies of a feculent nature with which they are mixed; and the other to separate any precipitated powder or other solid body from superfusible fluid; and the means must be varied accordingly. Such liquors as are incorporated with particles that adhere to them are rendered capable of filtration by coagulating and collecting the heterogeneous parts. This is effectually either by boiling or by mixing whites of eggs and boiling them with the turbid liquors. See Clarification.

Filter is the most commodious way of filtering is by white-brown paper, or paper without size, fastened over the mouth or aperture of a funnel; the small hairs of the pores of this paper admits only the finer parts through, and keeps the rest behind. There are also filtrations through sand, pulverized glasses, &c. Spirits of vitriol, salt, and nitre, are filtrated through a quantity of beaten glafs in the bottom of a funnel.

Filtration is also performed by a woollen or linen bag, called Hippocrates’s sieve: the choice of these must be directed by the liquor to be filtered.

Dr. Papin contrived a method by which filtrations through cap-paper might be made suddenly, and with great quantities of liquor, by the help of the air-pump. For this purpose he made use of the following contrivance: A A (Plate XIII. Miscellany, fig. 11,) is a glass receiver; B D a cover fitted to it; C C E is a pipe forming the communication between the receiver A A and the air-pump; D D a hollow vessel full of little holes; F F a pipe that makes the communication between the vessel D D and the receiver A A; F F a vessel to contain the liquor to be filtrated, and G G the plate of the pump. When this instrument is used, the hollow vessel D D ought to be tied about first with linen cloth, and then with cap-paper, so that no liquor may get into the holes of the said vessel but through the cap-paper, and linen cloth; this must be wholly placed.
placed within the liquor to be filtrated: let the air be extracted by means of the air-pump out of the vessel A A. Then the liquor in the vessel F must be drawn through the cap-paper, and the linen cloth into the vessel D D, and from thence through the pipe E E into the vessel A A; and this operation must be quick, on account of the great pressure of the atmosphere that drives the liquor; besides, the sediment of the liquor filling at the bottom of the vessel F must be drawn up, to drop the grains of the cap-paper as in ordinary filtrations. Buch's Hill, of the Royal Society, vol. iv. p. 356, &c.

Filtering flasks and filtering basons, either natural or artificial, for the purpose of purifying water, are not unfrequently used in this and in other countries. Rocky mountains, beds of sand, gravel, &c. are natural filters. The composition for making filtering basons, in order to purify water, consists of equal parts of tobacco-pipe clay, and coarse sea, river, drift, or pebbled sand. The basons are formed and turned on a potter's wheel, and they should be about 2 of an inch thick. When the vesicles are of the usual degree of dryness, the whole outside and inside surface must be shaved or turned off on a potter's wheel and, when perfectly dry, these basons are burnt or baked in a potter's kiln after the usual manner. Many patents have been obtained by different persons for filtering machines of their own invention. See Filter.

The secretion of the divers juices in the body from the mass of the bawl seems to be little else but filtration. Pic- cairn, and other late authors, hold that the diversity of filtration does not depend on the different configurations of pores, but on their different sizes or diameters.

Springs also seem to be raised from the ocean by the same principle of filtration.

Filtration, in Pharmacy, is chiefly concerned in tinctures; as when some portion is drawn from the ingredients or suspended in the tincture which is not necessary to it, but disturbs and renders the rest unpalatable both to the palate and sight. Besides this, there is a filtration which has much tortured the philosophy of some ages to account for; this is that performed by the ascent of the finer parts of a liquor up a cord or slant of cotton, or such like matter, which is contrived to drop over another vessel and leave the groffer behind.

After the same manner it is, without doubt, that the humidity of the earth is drawn up into the substance of the roots of vegetables, which we know consists of long and very minute fibres, so disposed as to form a great number of tubular interstices; these act in the nature of this sort of filter, and attract the juice and moisture appointed for the nutrition and increase of the plant.

Some say, that the cause of this ascent is because the liquor swells those parts of the filter that touch it, by entering into the pores of the threads which compose it, whereby they rise up, touch, and wet those next above them; and these again the next threads; and so on to the brim of the vessel, when the liquor runs over, and descends in the other part of the filter which hangs down by its own natural gravity.

But this account is liable to many objections, especially as liquors rise after the like manner in glasses tubes much above the surface of the liquor they are immersed in, where the glasses cannot be imagined thus to swell.

Others account for it, by considering every filter as composed of a great number of long, small, solid bodies, which lie very close together; so that the air getting in between them loses much of its pressure, and cannot gravitate so strongly as it doth on the fluid without them; the con-
1763, and an elegant composer. His pleasing productions for various instruments were soon noticed and admired; but alas! death stopped his career in the prime of life, before his genius and talents were well developed. In 1768 the musical world was robbed of this young artist, of whom, from the specimen he had already given of his abilities, the highest expectations were formed. In Paris and Amsterdam the following compositions appeared before his decease, six symphonies, six violin trios for the harpsichord, violin, and bass. Two were printed four, the Paris copy, by Brevis, as were most of his symphonies. Nothing was ever so elegant, and at the same time so cast, as his harpsichord trios. He left behind him in MS. various concertos for the violoncello, the German flute, the hautbois, and the clarinet, which were sold singly in MS. at the music fairs in Leipzig and Hamburgh, all much admired when executed by great performers. Besides these, some MS. duets and solos for the violoncello were long purchased and performed with great applause.

**FILUM Aquos.** the thread or middle of the stem where a river parts two lordships. *Et habebant illas buttas, uque ad filum aquae predictum. Fili du mer, the high tide of the sea.* Rot. Parl. 11 Hen. IV.

**FILURIA.** in Geography, a town of European Turkey, in Macedonia; 28 miles N. of Edessa.

**FIMARELLA.** a river of Naples, which runs into the gulf of Tarento. N. lat. 39° 36'. E. long. 17° 12'.

**FIMBLE HEMP.** in Rural Economy, a term sometimes applied to early ripe hemp, or female hemp. See Female Hemp.

**FIMBRIA.** in Anatomy, the fringed border of the opening, by which the Fallopian tube communicates with the abdominal cavity. This part is named the frumented extremity of the tube. (See Generation.) There is also a part in the brain called corpus fimbriatum. See Brain.

**Fimbrria.** in Surgery, was a term anciently employed to signify the outer tape, or fillet, which was put on to secure the rest of some bandage, or apparatus.

**FIMBRITARIUM.** a term in Heraldry, signifying that an ordinary is edged round with another of a different colour.

Thus, he beareth, or, a cros-patte gules frumented fable.

Gen. Ch. Cal. a single scale to each flower, concave, keeled, gradually deciduous, making part of a spike imbricated every way. Cor. none. Stam. Filaments usually three, rarely only one or two; anthers linear. Pist. German very small, superior; style with a half-globular bulb at the base, which falls off along with it; compressed and gradually dilated upward, fringed or ciliated at each edge; stigmas two, capillary, spreading, downy. Peric. none. Seed one, oblong, convex at each side, pointed at the base, without any surrounding bristles. Receptacle gradually elongated and becoming naked from the base upward, very closely pitted, the pits or cells having each a membranous border.

This genus is separated from Scirpus by Vahl, in consideration of the great extent of the latter, which has long rendered some such division desirable. He defines its habit as follows.

Stems several, erect, without joints, leafy in the lower part. Leaves channelled, rough-edged upwards. Inflorescence like the leaves. Rays of the umbel bearing each one spike, and having a central fertile spike at their base; sometimes each ray bears two spikes, one of which is fertile, the other sterile; all the spikes are gradually elongated as the seeds ripen. Keel of the scales green.

**F. dactylosum.** Spikes ovato-oblong. Inflorescence of about three leaves, longer than the repeatedly compound umbel. (Scirpus dactylotum; Linn. Sp. Pl. 74. Wild. Sp. Pl. v. t. 303. Sm. Fl. Græc. Sibth. v. 1. t. 52. Rottb. Gram. 57. t. 13. f. 1) — Native of the East Indies and South of Europe, in moist sandy ground. Root annual, fibrous. Herbaceous, glaucous-green. Stems from six to twelve inches high. Spikes more ovate and acute, as well as larger, than in the former. Stammen from one to three. Rottboil describes the style as rough, but does not represent it so, neither is that character, which makes the plant a Filbrystylis, exhibited by Mr. Bauer in the Flora Graeca.

**F. ferrugineum.** Spikes ovato-oblong. Scales somewhat downy or hoary in the middle. Inflorescence of about two leaves, as long as the simple umbel. (Scirpus ferrugineus; Linn. Sp. Pl. 74. Gramen cyperoides majus, spicis ex oblongo rotundatis compactis ferrugineis; Sonne Jam. v. 1. t. 18. t. 77. f. 2.) — Native of falt marshes in Jamaica. Stems a foot and half high, glaucous, ribbed, compressed. Umbel simple or compound, of three to five rays. Spike half an inch long, brown and hoary. Vahl is much confused in his quotation of Sonne, as in many other similar cases, his book being carelessly executed in that respect. In this he differs from copying Linnæus without turning to the book quoted.

**F. lapidic.** Spikes oblong, cylindrical, acute. Inflorescence rigid, of two leaves, as long as the doubly compound umbel. (Scirpus lapidic; Linn. Sp. Pl. 74. Gramen cyperoides majus aquaticum, paniculit plurimis junceis fariis, spicis ex oblongo rotundatis fariis; Sonne Jam. 18. t. 76. f. 2) — Native of watery places in the West Indies. Stems two or three feet high, rigid and rough, Spikes numerous, acute, an inch long, dark shining brown. F. argentum. Spikes cylindrical, obtuse, fuscous, clustered, in round heads. — (Scirpus argentum; Rothb. Gram. 51. t. 17. f. 6. Mullen-pullu; Rheed. H. Mal. v. 12. t. 101. t. 54) — Native of moist places in the East Indies. Root apparently annual. Stems numerous, from three to fix inches high, glaucous as well as the leaves. Spikes of a silvery grey, numerous, in dense heads. Vahl thinks
FIN

**Scirpus menander** of Rottboll, 52 t. 14. f. 3, is not different from this. We believe this genus will receive augmentation from several species hitherto considered as **Scirpus**, but not yet described. As far as we have observed, the progressively caducous rachis of the spikes, from the deciduous glumes, is very characteristic of a *Finiferae*. **FIn**, in Geography, a small river of the county of Monaghan, Ireland, which rises in the west of the county, and runs into Lough Erne.

**Fin**, *Piana*, in *Natural History*, the name of that part of a fish which distinguishes it from other aquatic creatures, no animal but a fish having fins and wanting legs.

The fish is properly a part standing out or hanging from the body of the fish, and consisting of a membrane supported by several rays or oblong bones, which are in some hard and firm, and in others cartilaginous. This definition of a fin properly excludes all those other parts of a fish which may be prominent from the body, and may be of a membranaceous structure, and even bear the appearance of a fin, though they have none of the rays or little bones within them, and therefore cannot serve the creature in the office of fins in swimming; for the cartilages or bones which support the membranes of the fins are what give them their due and necessary strength and firmness to bear against the water for the motion of the body of the fish; those other membranaceous appendages to the bodies of fishes cannot do this; for wanting the support of these rays, the simple and soft membrane has no more power of moving the water than the water has of moving it. Hence appears the use of the bones or rays supporting the fins, and the truth of the definition, that nothing is properly a fin which wants them.

The fins, by their differences, make very obvious distinctions among the several species of fish; and these differences are in regard to number, situation, figure, and proportion.

The number of the fins, including the tail, is very different in different fish. 1. In some there is only one fin to the whole fish: this is the case in the opidium humbriciforme, and in the murex. 2. The fins are two in number in others, as in the petromyzze, and the like. 3. There are many which have three fins, as the conger, the cel, the common ophidium, the Greenland whale, the sea-cow, and the like. 4. Many have four fins; of the number of which are the dolphine, the phocaena, and the second kind of the acus Arilolitis. 5. Several have five fins, as the annodytes, or eaud-cul, the sword-fish, the lupus marinus, the mola or fandel-fish, and many others. 6. The lamp-fish gives us an instance of six fins; for the common lamp-fish on the back of that fish is not a real fin, but only a cutaneous prominence. 7. Many fish have seven fins, as the gudgeon, the pleuronectes, the cyprinids, the culvora, the coregonids, the ophidium, the salmon, the cobices, the eooches, the cernua fluviatiles, the garofolces, the pipri, the labri, the fihruses, the mugil alatus, the remora, the caphricus, the hippurus, the pomplius, and the accipenser. 8. Many fin also have eight fins each; of this number are some of the perches, the clarae, the costus, the mugil, the labius, the fideis, the milii, the ling, the trachurus, the brachyurus, the trachinius, the uricans, and that little fish called the anguella by the Venecians. 9. The sohrrna of Rondeletius gives us an instance of the fins being nine in number; and finally, the stovini and thymi give us instances of eleven fins in the same fish.

The differences in situation are less numerous than those as to number, but they are not less obvious and essential.
subject to the Ligurian republic. Its capital is a sea-port town of the same name, having a good harbour on the coast of the Mediterranean; 31 miles S.W. of Genoa. N. lat. 44° 10'. E. long. 5° 24'.

FINALE, Ital. in Music, the last chorus, or movement at the end of an act of an opera; and in symphonies, concertos, quartettes, or sonatas, the last movement is called the finale. The finales of the Italian comic operas are the most ingenuous, varied, pleasing, and malleable compositions which dramatic music can boast; particularly those of Paisiello, Pinelli, Cimarosa, and Mozart. Such a variety of mountains, such fires, grace, passion and pathos, by turns, that the hearer, at the end, is unable to tell what movement or passage he likes best. They are extremely difficult to perform, yet the Italians, by dint of study and reheasal, are no more embarrassed than if, instead of fingering, they were only talking and squabbling the whole time.

FINIS PAUSA, in old music, two Latin words. See CORONA.

FINANCES, in Political Economy, denote the revenues of the king and state; much the same with the scheme of the Romans. The word is derived from the German, finanzi, finanz, fusion, efpoping, usury; though Du-Cange chooses rather to deduce it from the barbarous Latin, finanzia, praefatio pecuniaria.

The French have a peculiar kind of figures or numeral characters, which they call chiffre de finance. See CHARACTER.

FINANCES, British. See Fund and Revenue.

FINBO, in Geography, a mountain of the Lower Engadine; 8 miles N. of Träup. FINBY, a town of Sweden, on an island in the government of Abo; 28 miles S.S.E. of Abo. N. lat. 60° 7'. E. long. 25° 41'.

FINCASTLE, a post-town of America, in Virginia, and capital of Botetourt county, situated on the E. side of Catawba creek, a small stream which falls into James river, on the W. side of the North mountain. It has about 35 houses, a court-house and gaol, and contains 426 free inhabitants, and 276 blacks. It lies on the post road from Richmond to Kentucky; 36 miles E. of Lexington.

FINCH, a township in the county of Stormont, in Upper Canada, W. of Osnabruck.

FINCH, in Ornithology. See FINCHILLA.

FINCH-backed, streaked on the back with white. It is molly used in respect to cattle.

FINCHED, in Rural Economy, a term which is often used to signify a streaked on the back or other parts with white spots or stripes.

FINCK, Herrman, published at Wittenberg, in 1556, "Practica Mathematica," in Latin, with examples of various characters, proportions, and canon, with opinions of the ecclesiastical modes or tones, and a more pleasing and artificial method of singing. This may have been a useful tract when published, but it is dry, and little is to be learnt in it now, of material use.

FINDE, in Optics, a short telescope, generally affixed to the tube of a large one, for the purpose of expeditiously finding out any object. This finder does not magnify the object more than four, six, or eight times; but it has a large field of view, so that a great part of the heavens may be seen through it at once. In the indusc of its tube, and exactly at the focus of the eyeglasses, there are two fnder wires, which cross each other in the axis of the telescope. The finder is adjusted by means of screws upon the tube of the large telescope, in such a manner, that, when an object, seen through the finder, appears to be near the crossing of the above-mentioned wires, it is at the same time visible through the large telescope; hence, when the observer wishes to view a small distant object, as a star, a planet, &c., he moves the instrument to one side or the other, until, by looking through the finder, he brings the object clearly to coincide with the crossing of the wires. And when that takes place, he immediately looks through the large telescope.

FINDE, in our Old Statutes, are supposed to be the fame with those we now call searthers, who are employed for the discovery of goods imported or exported without paying custom. Stat. 18 Edw. III. 14 Ric. II. 17 Ric. II. &c.

FINDE, among Sportsmen. See Water-Dog.

FINDBORN, in Geography, a fishing-town of Scotland, on the N. coast of the county of Murray, at the mouth of the river Findhorn, near the north of Murray, with a tolerable harbour, and a large convenient bay; 9 miles W. of Elgin. N. lat. 57° 11'. W. long. 3° 29'.

FINDEING OF a Bill of Indictment, in Law. See Indicement.

FINE, in Geometry, one of the most celebrated mathematician of his time, was a son of a physician at Brussels, where he was born in the year 1492. This father dying while he was very young, he went to Paris, and, through the intercession of Anthony Silvelier, obtained a place in the college of Navare, where he went through a course of classical learning and philosophy. His attention to polite literature did not prevent him from applying much of his attention to mathematics, which he found most congenial to his taste and inclination. In these sciences he had no infirnum, and the study of them had fallen into disrepute. Regardless of the prevailing fashion of the age, he determined to proceed, and by the force of his own genius, and a few demonstrations, he made considerable progress in them. In 1519, he published an edition of "John Martin Siliccius' Arithmetic;" and afterwards, in 1523, he gave to the public a revised and improved edition of the "Margauca Philosophica," containing the principles of rational and moral philosophy. After this, he was still a student at the college of Navare, he gave private lectures in the mathematics, and then became a public teacher of them in the college of Geriwb. In this capacity he obtained so high a reputation, that Francis I., who had founded a new college at Paris, and who was desirous of filling the profefforship with men of the fttll rate abilities, recommended Fine as the most proper person to teach the mathematics. This excellent mathematician, like many others who flourished at the same period, was devoted to the art of judicial astrology, and, on one occasion, he suffered a long and severe imprisonment, for presuming to announce predictions that seemed to affect the court of France. Fine was likewise a good mechanic, and invented and constructed different instruments and pieces of mechanism, which added very much to his celebrity as a man of science. Notwithstanding his genius, abidity, and extraordinary talents, and the skill in which he was held by an almost inextricable number of perfons, it was his hard lot never to receive an adequate reward for his great services. Through the whole of his life he had to struggle with the evils of poverty, to the disgrace of many who affected to value him very highly, and who could not but be well acquainted with his wants, but who nevertheless had not the spirit nor the virtue to afford him any assistance. He died in the utmost distress in 1555, leaving behind him a wife and six children, involved with debt, and destitute of all means of support. Provision was, however, made for their decent maintenance, by those who had pretended...
tended to patronize him while living. The works of Fine were published together in three volumes folio, which bear the dates 1532, 1545, and 1546. Bayle, Mass. 214.

Fines, that which is pure, and without mixture. The term is particularly used in speaking of gold or silver. See Gold and Silver.

Fine, finis, or finalis concordia, in Law, denotes a solemn amicable agreement or composition of a suit (whether that suit be real or fictitious) made between the demandant and tenant, with the consent of the judges; and enrolled among the records of the court where the suit was commenced; by which agreement freehold property may be transferred, settled, and limited. (Crane on Fines.) Sometimes, says Shepherd (Touchft. c. 3.) it is taken for "a final agreement or conveyance upon record for the settling and securing of lands and tenements;" and accordingly it is designated by some to be an acknowledgment, in the king's court, of the land or other things to be his right that heщин complain;" and by others a covenant made between parties, and recorded by the judges; and by others a friendly, real, and final agreement amongst parties, concerning any land, rent, or other thing; whereby any suit or wrong is hanging between the said parties, and whereof the more fully or less is the agreement of record of an agreement concerning lands, tenements, or hereditaments duly made by the king's licence, and acknowledged by the parts to the same, upon a writ of covenant, writ of right, or such like, before the judges of the Common Pleas, or others thereunto authorized, and enrolled of record in the same court: to end all controversies thereof, both between themselves, which be parties and privy to the same, and all strangers not suing or claiming in due time."

A fine is sometimes said to be a feoffment of record (Co. Litt. 50a); though it might be more accurately called an acknowledgment of a feoffment on record; by which is to be understood, that it has at least the same force and effect with a feoffment, in the conveying and affuring of lands; though it is one of those methods of transferring estates of freehold by the common law, in whichIVERY OF FEIN is not necessary to be actually given; the supposition and acknowledgment thereof in a court of record, however fictitious, indubitably serves the same purpose. But more particularly, a fine may be described to be a valuable consideration for the grant of a suit, either actual or fictitious, by leave of the king or his judges; whereby the lands in question become, or are acknowledged to be, the right of one of the parties. (Co. Litt. 120a.) In its original it was founded on an actual suit, commenced at law for recovery of the possession of land or other hereditaments; and the poiffession thus gained by such composition was to be so sure and so effectual, that fictitious actions were, and continue to be, every day commenced, for the sake of obtaining the same security. A fine is to be called because it puts an end, finis, not only to the suit thus commenced, but also to all other suits and controversies concerning the same matter. Accordingly it is so expressed in an ancient record of parliament, 18 Edw. I. Fines, indeed, are of equal antiquity with the first rudiments of the law itself: they are spoken of by Glaseid and Bracton in the reigns of Henry II. and Henry III., as things then well known and long established; and instances of them have been produced even prior to the Norman invasion. (Burn. on Convey.) So that the statute of 18 Edw. I. (2 Stat. 9 Eliz. c. 1., called "Modus lendani fines," did not give them original, but only declared and regulated the manner in which they should be levied, or carried on. This is as follows:

1. The party, to whom the land is to be conveyed or affurred, commission an act or suit at law, against the other, generally an act of covenant, by suing out a writ or "practise," called a writ of covenant; the foundation of which is a supposition agreement or covenant, that the one shall convey the lands to the other; and the breach of which agreement the action is brought. On this writ there is due to the king, by ancient prerogative, a "primer fine," or a noble fee for every five marks of land sued for; that is, one tenth of the annual value. (2 Inst. 511.) The fine being thus commenced, there follows

2. The "licentia concordandi," or leave to agree the suit. For, as soon as the action is brought, the defendant, knowing himself to be in the wrong, is supposed to make overtures of peace and accommodation to the plaintiff; who accepting them, but having, upon making out the writ, given pledges to prosecute his suit, which he endangers, if he now defects it without licence, he applies to the court for leave to make up the matter. This leave is readily granted; but for it there is also another fine due to the king, by his prerogative, which is an ancient revenue of the crown, and is called the "king's finis," or sometimes the "poll-tax," with respect to the "primer fine," before-mentioned. And that is, as much as the "primer fine," and half as much more, or 10 shillings, or exactly 5 marks for every mark of land; that is, three twentieths of the supposed annual value. (5 Rep. 39. 2 Inst. 511. Stat. 52 Geo. II. c. 14.)

3. Next comes the "concord," or agreement itself; after leave obtained from the court; which is usually an acknowledgment from the defendant (or those who keep the other out of possession,) that the lands in question are the right of the complainant. And from this acknowledgment, or recognition of right, the party leyving the fine is called the "cognizer," and he to whom it is levied the "cognizee." This acknowledgment must be made either openly in the court of Common Pleas, or before the chief judge of the court; as also before one of the judges of that court, or two or more commissioners in the county, empowered by a special authority called a writ of "decimus potestats," by which judges and commissioners are bound by statute 18 Edw. I. 4. to take care that the cognizer be of full age, found memory, and out of prison. If there be any feme-covert among the cognizors, he is privately examined whether he does it willingly and freely, or by compulsion of another husband or wife.

By these acts all the essential parts of a fine are complete; and if the cognizer dies the next moment after the fine is acknowledged, provided it be subsequent to the day on which the writ is made returnable (Comb. 71.) still the fine shall be carried on in all its remaining parts; of which the next is

4. The "note" of the fine; which is only an abridgment of the writ of covenant and the concord; naming the parties, the parcel of land, and the agreement. This must be enrolled of record in the proper office, by direction of the statute 5 Hen. IV. c. 14.

5. The fifth part is the "fact" of the fine, or conclusion of it; which includes the whole matter, treating the parties, day, year, and place, and before whom it was acknowledged or levied. Of this there are accessories made, or affected, at the chirurgist's office, and duly red to the cognizer and the cognizee; firstly beginning thus, "we acknowledgment concords," on this is the final agreement, and the reciting the whole proceeding at least. That the fine is completely levied at Common Pleas: By several statutes some additional solemnities are introduced, in order to render the fine more inviolably public, and less liable to be void by fraud or corvin. And lastly, by 27 Edw. I. c. 4, the amount of the fine shall be openly read in the court of Cogni.
Plea, at two several days in one week, and during such reading all pleas shall cease. By 5 Hen. IV. c. 14, and 23 Eliz. c. 7, all the proceedings on fines, either at the time of acknowledgment, or previous, or subsequent thereto, shall be enrolled in record in the court of Common Pleas. By 1 Ric. III. c. 7, confirmed and enforced by 4 Hen. VII. c. 24, the fine, after engrossment, shall be openly read and proclaimed in court (during which all pleas shall cease) sixteen times, viz. four times in the term in which it is made, and four times in each of the three succeeding terms, which is reduced to once in each term by 31 Eliz. c. 7, and the elocations are endorsed on the back of the record. It is also enacted by 23 Eliz. c. 3, that the choreographer of fines shall every term write out a table of the fines levied in each county in that term, and shall affix them in some open part of the court of Common Pleas all the next term, and shall also deliver the contents of such table to the sheriff of every county, who shall at the next adjourn fix the same in some open place in the court, for the more public reading of the fine.

Fines, thus levied, are of four kinds: 1. What is in our law French called a fine "fur cognizance de droit, come ceo quilad de fon done," or a time upon acknowledgment of the right of the cognizor, as that which he hath of the gift of the cognizor. This is the best and surest kind of fine; for thereby the defendant, in order to keep his covenant with the plaintiff, of conveying to him the lands in question, and at the same time to avoid the formality of an actual feoffment and livery, acknowledges in court a former feoffment, or gift in possession, to have been made by him to the plaintiff. This fine is therefore said to be a feoffment of record; the livery thus acknowledged in court being equivalent to an actual livery; so that this assurance is rather a confession of a former conveyance than a conveyance now originally made; for the defendant, or cognizor, acknowledges, "cognizor," the right to be in the plaintiff, or cognizor, as that which he hath "de fon done," of the proper gift of himself, the cognizor. 2. A fine "fur cognizance de droit tantum," or upon acknowledgment of the right merely, not with the circumstances of a preceding gift from the cognizor. This is commonly used to pass a reserfatory interregnum, which is in the cognizor. For of such reversions there can be no feoffment, or donation with livery, soppofed; as the possession during the particular estate belongs to a third person. (Moor. 629.) It is thus worded: "that the cognizor acknowledges the right to be in the cognizor; and grants for himself and his heirs, that the reversion, after the particular estate determines, shall go to the cognizor." (Well. Symb. p. 2. § 95.) 3. A fine "fur cognizor," is, where the cognizor, in order to make an end of disputes, though he acknowledges no precedent right, yet grants to the cognizor an estate "de novo," usually for life or years, by way of safeguarded composition. And this may be done referring a rent, or the like; for it operates as a new grant. (Well. p. 2. § 66.) 4. A fine "fur done, grant, et render," is a double fine, comprehending the fine "fur cognizance de droit come ceo, &c." and the fine "fur cognizor," and may be used to create particular limitations of estate; whereas the fine "fur cognizance de droit, &c." conveys nothing but an absolute estate, either by inheritance, or at least of freehold. (Salk. 342.) In this last species of fine, the cognizor, after the right is acknowledged to be in him, grants back again, or renders to the cognizor, or perhaps to a stranger, some other estate in the premises. But, in general, the first species of fine, "fur cognizance de droit, come, &c." is the most used, as it conveys a clear and absolute freehold, and gives the cognizor a

FINE.

The force and effect of a fine principally depend, at this day, on the common law; and the two statutes, 4 Hen. VII. c. 23, and 32 Hen. VIII. c. 56. The ancient common law, with respect to this point, is very forcibly declared by the statute 18 Edw. I.; which states that the fine is to be high a bar, and of such force, that it precludes not only those who are parties and privies to the fine, and their heirs, but all other persons in the world, who are of full age, out of privity, of found memory, and within the four years, the day of the fine levied; unless they put in their claim on the foot of the fine within a year and a day. But this statute, after the fine has been levied, becomes a bar to the parties, &c., and, in its nature, judge of their title. This doctrine of barring the right by "non-claim," was abolished for a time by the statute made in 34 Edw. III. c. 15, which admitted persons to claim, and lapse a fine, at any time until the death of the finee, and whereby, as Sir Edward Coke observes, (2 Inst. 518.) great contention arose, and few men were sure of their possessions, till the parliament, held 4 Hen. VII. reformed that mischief, and excellently moderated between the latitude given by the statute and the rigour of the common law. By that statute the right of all strangers whatsoever is bound, unless they make claim, by way of action or lawful entry, not within one year and a day, as by the common law, but within five years after proclamations made: except fine-covers, infants, prisoners, persons beyond the sea, and such as are not of able mind; who have five years allowed to them and their heirs, after the death of their husbands, their attaining full age, recovering their liberty, returning into England, or being restored to their right mind. Henry VII. seems by this statute to have covertly extended fines so as to have been a bar of estates-tail, in order to render them more open to alienations; but doubts having arisen whether they could, by mere implication, be adjudged a sufficient bar (which are expressly declared not to be by the statute "de donis"), the statute 32 Hen. VIII. c. 56, was the statute made, which declares that a fine levied by any person of full age, to whom or to whose ancestors lands have been entailed, shall be a perpetual bar to them and their heirs, claiming by force of such entail; unless the fine be levied by a woman after the death of her husband, or lands which were, by the gift of him or his ancestor, assigned in tail to her for her jointure (stat. 11 Hen. VII. c. 2); or unless it be of lands entailed by act of parliament or letters patent, and whereof the reversion belongs to the crown.

From the view now given of the common law, regulated by these statutes, it appears that a fine is a solemn conveyance on record from the cognizor to the cognizee; and that the persons bound by a fine are parties, privies, and strangers. The parties are either the cognizors of cognizees; and these are immediately concluded by the fine, and barred of any latent right they might have, though under the legal impediment of coverture. And, indeed, as this is almost the only act that a free-coveet or married woman is permitted by law to do, (and that because she is privately examined as to her voluntary consent, which removes the general infinque of coverture or coverture,) it is therefore the usual and almost the only safe method whereby the can join in the sale, settlement, or incumbrance of any estate. Privies to a fine are such as are any way related to the parties who levy the fine, and claim under them by any right of blood, or other right of representation. Such as are the heirs-general of the cognizor, the issue in tail since the statute of Henry VIII., the vender, the devisee, and all others who must make title by the persons who
who levied the fine. For the act of the ancestor shall bind the heir, and the act of the principal his substitute, or such as claim under any conveyance made by him subsequent to the fine so levied. (3 Rep. 87.) Strangers to a fine are all other persons, except parties and privies. These are also bound by a fine, unless, within five years after proclamation made, they interpose their claim, provided they are under no legal impediment, and have then a present interest in the estate. The impediments, as we have already mentioned, are coverture, infancy, imprisonment, insanity, and absence beyond sea; and persons, who are thus incapacitated to prosecute their rights, have five years allowed them to put in their claims after such impediments are removed.

Persons also that have not a present, but a future interest only, as those in remainder or reversion, have five years allowed them to claim in, from the time that such right accrues. (Co. Litt. 377.) And if within that time they neglect to claim, or (by the statute 4 Ann. c. 16) if they do not bring an action to try the right within one year after making such claim, and prosecute the same with effect, all persons whatsoever are barred of whatever right they may have, by force of the statute of non-claim. But, in order to make a fine of any avail at all, it is necessary that the parties should have some interest or estate in the lands to be affected by it. Else it were possible that two strangers, by a mere confederacy, might without any risk defraud the owners by levying fines of their lands; for if the attempt be discovered, they can be no sufferers, but might only remain in statu quo; whereas, if a tenant for life levies a fine, it is an absolute forfeiture of his estate to the remainder-man or reversioner. (Co. Litt. 521.) if claimed in proper time.

It is not therefore to be supposed that such tenants will frequently run to great a hazard; but if they do, and the claim is not duly made within five years after their respective terms expire (2 Lev. 52.), the estate is for ever barred by it. Yet where a stranger, whose presumption cannot be thus punished, officiously interferes in an estate in which no wife belongs to him, his fine is of no effect; and may at any time be set aside (unless by such as are parties or privies thereunto) (Hub. 334.) by pleading that "partes habuerunt." And even if a tenant for years, who hath only a chattel interest, and no freehold in the land, levies a fine, it operates nothing, but is liable to be defeated by the fame plea. (5 Rep. 123 Hardr. 401.) Wherefore, when a lease for years is diposed to levy a fine, it is usual for him to make a feoffment first, to displace the estate of the lessor (Hardr. 402. 2 Lev. 52.), and create a new freehold by dilisit. Blackl. Com. Bk ii. See Recovery.

In order to punish criminally such as thus put the estate of another to the hazard as far as in them lies, the statute 21 Jac. 1. c. 26 makes it felony without benefit of clergy to acknowledge, or procure to be acknowledged, any fine, recovery, or judgment, &c. in the name of any person not privy or confenting to the same.

Fines may be recovered for error, so as the writ of error be brought in 20 years, &c. and not afterwards by Stat. 12 & 13 W. III. c. 11, which 20 years are to be computed from the time of the fine levied, and not from the time the title accrued (2 Stra. 1257.) No person can bring a writ of error, to reverse a fine, or any judgment, that is not intituled to the land, of which the fine was levied. In order to avoid a fine there must be an actual entry, except where the time is levied without proclamation; for the statute 4 H. VII. c. 24. does not extend to such a fine, and it may be avoided at any time within 20 years. (2 Will. 45.) The entry, when necessary, must be made by the person who has a right to the lands, or by some one appointed by him. (1 Stat. 258 a.) Nothing can be agitated for error that contradicts the record. (1 Rol. Abr. 755.) Fines are not verifiable for fraud, intermission, misprision, or any want of form, but it is otherwise if of substance. (Stat. 23 Eliz. c. 3.) Fines may be avoided, where they are obtained by fraud, covin, or deceit, though there be no error in the process. (Cro. Eliz. 471.)

Fines are generally divided into those with, and those without proclamations; the former is termed a fine according to the statutes 1 R. III. c. 7. 4 H. VII. c. 24.; and the latter is called a fine of the common law, being levied in such manner as was used before the statute 4 H. VII. c. 24.; and is still of the like force by the common law, to discontinue the estate of the cognizor, if the fine be executed.

Fines are either single or double. Single fine is that by which nothing is granted or rendered back again by the cognizors to the cognizor, or any of them. Double fine contains a grant and render-back, either of some rent, common, or other thing out of the land, or of the land itself, to all or some of the recognizors for some estate, limiting thereby remainders to strangers not named in the writ of convenant.

In this kind of fine, called "fur done, grant and render," both the fines "fur cognizance, &c. and "fur consequit," are formed into one; and it is partly executed and partly executory. See Fine above.

Sometimes also a double fine is when the lands lie in several counties.

Fines, with regard to their effect, are divided into executed and executory. Fine executed, is such as of its own force gives a present possession (at least in law) to a cognizor; so that he needs no writ of "habere facias finis," for execution of the same: of which sort is a fine "fur cognizance de droit come eco, &c." that is, upon acknowledgment, that the thing mentioned in the concord is "jus ipius cognisati, ut illa quo idem habet de dono cognitirius." Well. § 51. K.

The reason is, because the fine paffeth by way of release of a thing which the cognizor hath already (at least by supposition) by virtue of a former gift to the cognizor, which is, in truth, the finest fine of all. See Fine, supra.

Fines executory, are such as of their own force do not execute or give the possession to the cognizor without entry or action, but require a writ of "habere facias finis," as a fine "fur cognizance de droit tantum," unless the party be in possession of the lands. This kind of fine is commonly made use of to pass a reversion. There is also another executory fine called "fur consequit." See Fine, supra.

Fines in England are now levied in the court of Common Pleas at Westminster, in regard to the solemnity thereof, ordained by the statute of 18 Ed. I. Stat. 4. before which time they were sometimes levied in the county-court, court-bartons, and in the exchequer, as may be seen in Origins Judiciales, &c.

Fines are also taken by commissioners in the country, empowered by decimus parliamentum, 15 Ed. II. Stat. 2 fine. Though by the common law all fines were levied in the court. Fines levied before the justices in Wales, or in the counties palatine of Chester, Durham, &c. have the same effect as those that are levied before the justices of C. B.

Fine adullando brevitu de tenemento quod fuit de ejbimo domino, a writ directed to the justices of C. B. for dissolving a fine levied of lands in ancient demesne to the prejudice of the leed. Reg. Orig. 15.
Fine for alienation, are fines formerly paid to the king by his tenants in chief, for licence to alienate their lands, according to the statute 1 Edw. III. c. 12, but taken away by statute 12 Car. II. cap. 25.

Fine capitules postumos, &c., a writ lying where a person upon conviction of any offence by jury hath his lands and goods taken into the king’s hands, and his body is committed to prison; to be remitted his imprisonment, and have his lands and goods restored to him on obtaining favour for a sum of money. Reg. Orig. 142.

Fine pro divisione effluxionis in fort. 33 H. VIII. cap. 12, denoting that a person is forced to do that which he can in no way avoid.

Fine levado de tementibus de reg. in capite, &c., a writ directed to the juries of the Common Pleas to admit of a fine for the title of land holden of the king in capite. Reg. Orig. 167.

Fine non capitulos pro falsiure placitandi, a writ to inhibit officers of courts to take fines for fair pleading. Reg. Orig. 170.

Fine pro rediffinse capitanda, &c., a writ laying for the release of one imprisoned for a reddifying, on payment of a reasonable fine. Reg. Orig. 222.

Fines are all fines to the king. Under this head are included fines for original writs. Thus, for every writ of plea of land, if it be not of right patent, which is for the yearly value of five marks, and for all original writs in debt and trespass, where the debt or damage is 40s., a fine is due to the king of 6s. 8d. and more proportionably when the writ is for greater value.

In fine, according to Coke, signifies a sum of money paid as an income for lands or tenements let by lease, usually called per ignem.

In fine is also used to denote an amends, pecuniary punishment, or recompense, for an offence committed against the king and his laws, or against the lord of a manor. In which case a man is said, jussere fines de transferre causam regni, &c.

In all the diversities of the use of the word fine, it hath but one signification; and that is, a final conclusion, or end of differences between parties. In the last sense, where it denotes the ending and remission of an offence, it is used by Bracton, who speaks of a common fine that the country pays to the king for false judgments or other trespasses, which is to be allowed by the justices in eyre before their departure, by the oaths of knights and other good men, upon such as ought to pay it. There is also a common fine in courts leet.

The discretionary fines (and discretionary length of imprisonment) which our courts are enabled to impose, may seem an exception to the general rule, that the punishment of every offence is ascertained by the law. But the general nature of the punishment, viz., by fine or imprisonment, is fixed and determinate; though the duration and quantity of each may frequently vary, from the aggravations, or alleviations, of the offence, the quality and condition of the parties, and innumerable other circumstances. The quantum, in particular, of pecuniary fines neither can, nor ought to be, ascertained by any invariable law. The value of money is fluctuating; and what would be ruin to one man’s fortune may be matter of indifference to another. Thus the law of the twelve tables at Rome fined every person, that struck another, twenty-five denarii; and this, in the more opulent days of the empire, became a punishment of so little consideration, that Aulus Gellius tells a story of one Lucius Neratus, who diverted himself by giving a blow to any person at pleasure, and then tendering the legal forfeiture. Our statute law has not therefore often ascertained the quantity of fines, nor the common law ever; merely directing such an offence to be punished by fine in general, without specifying the certain sum: and this will appear to be fully sufficient, when we consider that, however unlimited the power of the court may seem, it is far from being wholly arbitrary: but its discretion is regulated by law. For the bill of rights (lat. 1 W. and M. d. 2. c. 2) has particularly declared, that executive fines ought not to be imposed, nor cruel and unusual punishments inflicted (which had a retrospect to some unprecedented proceedings in the court of king’s bench, in the reign of king James II.), and the same statute further declares, that all grants and promises of fines and forfeitures of particular persons before conviction, are illegal and void. Now the bill of rights was only declaratory of the old constitutional law; and accordingly we find it expressly holden, long before (21 Hals. 48.) that all such previous grants are void; since thereby many times undue means, and mere violent proceedings, was used for public lucres, not the quiet and just proceeding of the law would permit.

The reasoonableness of fines in criminal cases has also been usually regulated by the determination of “Magna Charta” (c. 14.) concerning amercements for misbehaviour by the factors in matters of civil right. See AMERCEMENT.

Counts of record may fine for an offence committed in court in their view, or by confession of the party recorded in court. (1 Lill. Abr. 621.) A man shall be fined and imprisoned for all contempt done to any court of record, against the commandment of the king’s writ, &c. (9 Rep. 60.) See CONTEMPT. Some courts may impose, and not fine, as the constables at the petit feiions; some courts cannot fine, or imprison, but amerce, as the county, hundred, &c.; but some courts cannot fine, imprison, nor amerce, as ecclesiastical courts hold before the ordinary, archdeacon, &c., or their commissaries, and such who proceed according to the canon, or civil law. (11 Co. 43. 44.)

A fine may be mitigated the same term it was set, being under the power of the court during that time, but not afterwards. (T. Raym. 376.) And fines assessed in court by judgment upon an information, cannot be afterwards mitigated. (Cro. Car. 221.) If a fine certain is imposed by statute upon any conviction, the court cannot mitigate it; but if the party comes in before conviction, and submits to the court, they may assize a less fine; for he is not convicted, and perhaps never might. The court of exchequer may mitigate a fine certain, because it is a court of equity, and they have a privy-seal for it. (3 Salk. 33.) If an excessive fine is imposed at the feiions, it may be mitigated at the king’s bench. (1 Vent. 336.)

All fines belong to the king, because the courts of justice are supported at his charge: and wherever the law puts the king to any charge for the support and protection of his people, it provides money for that purpose. (Brach. 129.)

Fine-drawing, or rentering, a very nice way of sewing up or rejoining the parts of any cloth, stuff, or the like, torn or rent in the dressing, weaving, &c.

It is prohibited to fine-draw pieces of foreign manufacture upon those of our own, as has formerly been practised. See RENTERING.

Fine Loch, in Geography, is one of the extensive inland waters of Argyllshire, in Scotland, connecting with the sea by means of the cffuary of the Clyde rivers, and by Kylbrannan found on the west of the isle of Arran: it has also another communication with Clyde river by means of the Kyles of Bute on the west of Bute island. The principal branch of Fine Loch extends a few miles to the N.E. of the town of Inverary; from the top of Gilp Loch, which is a branch of this
this loch, the Crianan canal proceeds, for the passage of ships to the west into Crianan Loch, and the found of Jura. From Ealb Tarbeth Loch, another short branch of Fine Loch, the Tarbeth canal was, in 1773, proposed by Mr. Watt to form another communication with the found of Jura, by means of Well Tarbeth Loch. See Canal.

Fine-stilling, in the Diffillery; that branch of the art which is employed on the distilling the spirit from treacle or other preparations or remnants of sugar, is called fine-
stilling, by way of distinction from malt-stilling; and the person who exercises this part of the trade is called a fine-
diller.

The operation in procuring the spirit from sugar is the same with that used in making the malt spirit; a wash of the faccharine matter being made with water from treacle, &c. and fermented with yeast. It is usual to add in this case, however, a considerable portion of malt, and sometimes powdered jalap, to the fermenting backs. The malt accelerates the fermentation, and makes the spirit come out the cheaper, and the jalap prevents the rise of any muddy head on the surface of the fermenting liquor, so as to leave a greater opportunity for the free escape of the air, and thus to shorten the work, by turning the foamy into a hilling fermentation. Shaw's Lect. p. 122.

FINESSCHILARO, in Geography, a small island in the Mediterranean, near the N.E. coast of the island of Corfu; 7 miles N. of Bafia. N. lat. 42° 58'. E. long. 9° 39'.

FINEERING. See Veneering.

FINERS of Gold and Silver, are those who purify and part those metals from other coarser ones by fire and acids.

They are also called parters, in our old law-books, and sometimes departers.

FINEKY, in the Iron-works, is one of the two forges at which they hammer the low or pig iron. See Forge.

Into the finery they flirll put the pigs of iron, placing three or four of them together behind the fire, with a little of one end thrust into it; where, softening by degrees, they flir and work them with long bars of iron, and expulse at different times different parts to the blast of the bellows, in order to refine it as equally as possible, till the metal runs together with a round mafs or lump, which they call a cake or bloom. They then take this out, and give it a few strokes with their fedges; afterwards they carry it to a great heavy hammer, raised by the motion of a water-wheel; when, applying it dexterously to the blows, they presently bent it out into a thick short square. This they put into the finery again, and, heating it red-hot, they work it out under the fame hammer till it comes to be in the shape of a bar in the middle, but with two square nobs at the ends, which they call an anody. It is then carried into the other forge, called the chafery. Phil. Trans. No. 137, or Abr. vol. ii. p. 559. See Iron.

FINESS, a French term, of late current in English. Literally, it is of no farther import than our English fines or; but among us it is chiefly used to denote that peculiar delicacy or subtility, perceived in works of the mind, and the neatness and most secret and sublime parts of any science or art.

It is sometines used to express that kind of subtilty made use of for the purposes of deception.

FINAH In Ornithology. See LAMNIS Carulefons.

FINAGL, in Biography, the distinguished hero whose exploits and character are so charmingly portrayed in the fascinating poems of Oliffan, who, notwithstanding what has been advanced against their existence in the Gaelic language, from which they were professedly translated; was a real perfonage, a famous warrior, and renowned prince. The controversy respecting the genuineness of the originals was at one time as long and as ably defended by the partizans on each side the question, as that on the subject respecting the authenticity of the Idylls of Pindar by the critics of the day, under those able leaders in controversy, Barlow and Bentley. What was the family name of this supposed fictitious hero of romance, but really the gallant defender of his country from Roman subjugation, does not appear on the face of history; in that early period it not unfrequently happened, the real name was sunk in the official designation, or honolral title. He was the son of Comhail, the grandson of Truthail, and the great grandson of Trenmor, all Caledonian princes of great military reputation, during the severe struggles the Celtic tribes held with the invaders of Britain. He was king of Morven, a country to the north of the river Tay, supposed by some to have had for its southern boundary the Caledonian forest; and by others to have extended farther southward, into part of the Roman province of Valencia: it doubtful, from the bell authorities, comprised the whole of the northern and western Highlands, inclusive of the Hebrides or Western isles. His principal residence was at Selma, in the vicinity of Glenelg, county of Moray, supposed to be the Cona celebrated by Oliffan. According to the Irish annals, he was born A.D. 282; but the poems of Oliffan fix the date of his birth a few years later. The time of his death is uncertain.

After the Romans had overrun the country of the Picts, and given to that part of the soil to the north of their province, Valencia, the name of Caledonia, as the country next to be subdued, and penetrated part of the Highlands with an army under Lollius; they were repulsed and beaten back behind the frontier wall, erected at the command of Severus, by the Scottish provincials and the force of the troops under Com-
hal. On this occasion, the exploits performed by the son of that prince evidently he was equally qualified by talents, as deficient, to be the antagonist of a Roman emperor, and the hero of Oliffan; when Severus determined to conduct the war in person through North Britain, to wipe off the dis-
grace of his defeated legions under Lollius, and revenge the severities inflicted on his troops by the enraged natives; he called the two waits for those purposes, with the collected force of the empire in Britain; and entered with a spirit of vengeance, and reiterated messages of extirpation, the dist-
trict of Caledonia. At that period, the prince denominated Fingal was the head of the united British forces in the north, the Vind-gait of the combined army, a nation or office similar to that of the Pendragon among the western Britons; which has likewise been confounded with the family names, and considered a personal appellation. The haughty and enraged emperor was met by the undaunted Fingal, whose troops, well acquainted with the defiles and passes of the country, hung upon the invader's rear, har-
railed the imperial army in its march, selected advantageous ground, and made at every turn vigorous attacks, and frequent-
ly drew the enemy into invidious and fatal ambuscades. Thus wearied and reduced by the superior manoeuvring of their bold and vigilant opponents, the Romans experienced the greatest distress, so as to be obliged to destroy their sick and wounded, lest they should fall alive into the hands of whom they considered a barbarous enemy. In this expedition alone, according to Ammianus Marcellinus, they lost 15,000 men, and were constrained to cede to the victors that part of the country conquered by Lollius. And when the Romans, after being reinforced, again entered the country under the command
command of Caracalla, who was commissioned to exterminate the natives, Fingal met the Roman general in that part, now the county of Stirling, the latter was defeated on the banks of the Carron, the contested dominions given up, and the Romans again obliged to retire to the south of the wall. Exclusive of these contests, in which, through a protracted warfare, he displayed a superior prowess, and undaunted intrepidity, he appears to have conducted also naval wars. He is stated to have made frequent voyages to Scandinavia, the Orkneys, and Ireland, designated by Olfan, as Locklin, Ineffucre, and Ulfin.

"The character of Fingal," Dr. Blair observes, "is perhaps the most perfect that was ever drawn by a poet, for we boldly defy all the writers of antiquity to throw us any hero equal to Fingal. Throughout the whole of Olfan’s works, he is presented to us in all that variety of lights which give the full display of a character. In him concur almost all the qualities that can enoble human nature, that can make us admire the hero, or love the man. He is not only unconquerable in war, but he maketh his people happy by his wisdom in the days of peace. He is truly the father of his people. Wmtaker’s History of Manchethcir. Olfan’s Poems, with notes, &c.

FINGAMO, in Geography, a town of Japan, on the island of Nikhoon; 45 miles N. of Menczo.

FINGERS, in Anatomy, the last divisions of the upper extremity. For their names, see Digitus. The bones and joints of the fingers are described in the article Extremities. The structure of these organs, consisting of three bones moveable on each other, renders them particularly well suited for grasping, seizing, and holding external objects; for all those offices which come under the common name of prehension. By this arrangement any object of moderate size can be encircled by the fingers. The size of the bones, the firmness of the joints, and the strength of the muscles, below on them great powers in addition to their flexibility. The integuments at their extremities are highly organized, and receive a large supply of vessels and nerves, so as to constitute them the organs of touch, and the faculty with which they can be applied to any body, of which we are desirous to learn the properties, makes them a very convenient situation for that organ.

FINGERS, Amputation of. See Amputation.

Fingers, Carious. In these cases the surgeon is to endeavour to extract the exfoliating portions of bone immediately when they become loose. For this purpose, he is justified in making such incisions as may enable him to fulfil the object in view. Until the process of exfoliation is sufficiently advanced, he can do little more than apply simple dressings, and keep the part in a clean, quiet state.

When the separation of the dead pieces of bone will certainly destroy the utility of the finger, and convert the part into an inconvenient, stiff appendage to the hand; or, when the patient’s health is severely impaired by the irritation of the diseased, the termination of which cannot be expected within a moderate space of time; amputation is proper. It is a truth, however, that many fingers are amputated which might be preserved, and surgeons ought to consider well, before premeditating to remove parts which, when curable, may become of the greatest consequence, in regard to the perfection of the hand. The bread of many persons, it is well known, depends on the unmitigated state of certain fingers. These remarks are offered, because we have seen several surgeons, who are fond of seizing every opportunity of cutting their fellow-creatures, remove fingers, which might have been usefully saved, either by allotting a little more time to the exfoliation, or by making incisions, and cutting out the dead piece of bone.

Fingers, Dislocations of. See Luxation.

Fingers, Fractures of. See Fracture.

Fingers, Supernumerary. Children are sometimes born with more fingers than are natural, and since allowing the redundant number to remain would keep up deformity and create future inconvenience, the surgeon is called upon to amputate them. The redundant fingers are sometimes with, sometimes without, a nail. If added more numerous than one on each hand, are generally situated just on the outside of the little fingers, and, as far as our observation extends, are incapable of motion, in consequence of not being furnished, like the rest of the fingers, with muscles. The best plan is to cut off supernumerary fingers with a scalpel, at the place where they are united to the other part of the hand. The operation should be performed while the patient is in the infant state, that is to say, before the superfluous parts have acquired much size, and while the object can be accomplished with little pain. The incisions ought to be made so as to form a wound with edges, which can be brought into contact with strips of adhesive plaster. The hemorrhage will almost always cease, as soon as the dressings are applied, without any ligature.

Finger, Godfrey, in Biography, who resided many years in England during the latter end of the 17th century, and the beginning of the 18th, was a good performer on the violin, and a voluminous composer for that instrument, and when he quitted England and returned to Germany, was, according to Telemann in Mattheson’s Ehrenpforte, chamber musician to Sophia Charlotte, queen of Prussia, in 1702, and in 1717 chapel master to the court of Gotha. Finger was not a man of genius; but in science he was infinitely superior to the musicians with whom he had to contend.

Finger’s Breadth, a measure of two barley-corns in length, or four laid side by side.

Finger-keys, in Musik, or clavier of the Germans, signify the arrangement of short levers of different colours, on which the fingers act in performing on organs, piano-fortes, and some other instruments with fixed tones; the arrangement of these within one octave, from C to C, is shown in Musik, Plate I.; the learning and recollection of which will be much facilitated, by considering the same divided (between E and F) into two parts, which Dr. Callcott, in his "Plain Statement of Earl Stanhope’s Temperament," calls a ditone and a tritone, see those articles. It may be proper here just to add, that D is always the middle of the ditone in first division, and that G and A are the middle notes of the tritone or second division of the figaro, or whole octave. In Mr. Hawke’s patent piano-fortos and organs, with 17 flirings or pipes in each octave (fold by Mr. Bill, Rathbone Place, and Mr. Elliot, Tottenham Court), the whole clavier or range of finger-keys is shifted, by pedials, for occasioning either the five flat or the five sharp notes of each octave to be brought into play, as may be desired; without altering the pitch of the long keys or natural notes. See Temperament for an account of this, and various other systems of musical intervals.

Finger-key Intervals, is a term sometimes used for the half-notes, or semi-tones, between the 13 finger-keys of instruments; these, according to the common theory and notation used by all composers and copyists of music, are equal among themselves, and conform to the equal temperament of the scale, see that article, and Philosophical Magazine, vol. xxvii. p. 195; but, in Æthiopia, these finger-key intervals, both the simple ones between the next adjoining as well
FINGER.

well as between the more distant finger-keys, differ very sensibly from each other, in most of the other different syllables of temperament, and even in different parts of the scale of each of such syllables themselves. The number of these finger-key intervals, which any interval, larger than the enharmonic diesis contains, appears on inspection, when it is expressed in the new notation of Mr. Fary, by the number of $r^2$, or lesser fractions which it contains; thus, his expression for the fifth $353\Sigma + 7f + 31m$, (Phil. Mag. p. 35. vol. xxx.) shews that interval to contain seven half-notes or finger-key intervals, and by which the situation of its treble above any note on the clavier or range of keys on an instrument, or of its bass below any note, considered as the treble of a fifth, can with certainty be found. See Fifth.

FINGER-KEYED VIOL, a musical instrument, noticed under our article CLAVIOLE, which is another name for the same invention: at that time we had not had an opportunity of seeing this instrument, but have now the satisfaction of being able to present our readers with a drawing and description of it, having, for that purpose, obtained the permission of its inventor, Mr. John Isaac Hawkins, proprietor of the useful and mechanical museum, No. 79, Great Titchfield street, London, where are many curious mechanical contrivances, the most striking of which we shall occasionally notice. Plate XIV. Michelliany, is devoted to the elucidation of this curious piece of mechanism: a general idea will be given by inspecting the first figure, which is a perspective view of the whole instrument, laid open, while the remaining figures explain the construction of the more minute parts. The instrument contains 68 gut strings, stretched in a vertical position, and arranged in four series: the first, A, corresponding to the double bass, with 17 large strings, 13 of which are covered with wire; the longest string is 38 inches, and the shortest 28 inches; the second series of 17 strings, B, producing the tones of the violoncello, from 28 to 15 inches in length; the third, C, is the viola, from 15 inches to seven long, and the fourth, the violin, are from seven to three inches long. The frame containing the strings is of equal height in all parts, though the effective lengths of the strings are only to be reckoned from their respective bridges, a, b, c, and d, to the keys; each string is provided with a finger-key, which keys are arranged in the same order as in the organ, &c. and each finger is adjusted to sound the proper note for the key to which it belongs: the adjustment is made at the upper end of the string by a screw. To keep the instrument in tune, through all variations of the atmosphere, each string is stretched by a helical spring, attached to the lower part of the frame at one end, and to the string at the other; by this means the tension of the string is always equal, notwithstanding its variations of length from the state of moisture in the air, as the force of the spring will not be sensibly changed, by such minute alteration of length: these springs are seen beneath the keys of the instrument at b, i.e., and several of the tuning-fires are shewn separately in fig. 2. The end of the string, c, or of a wire to which it is tied, is hooked upon a pin projecting from the nut, a, of the screw, b, which is turned round by a small handle to produce the motion of the nut, and adjust the string.

The next parts to be spoken of are the refined horse-hair bows, which are the most ingenious parts of this invention; they are four in number, being situated at E, F, G, and H in fig. 1. one to each series of strings. The horse-hairs are arranged within a circular frame of brass, J, in fig. 3, A, where the method is shewn by which an approximation to a circle can be formed from a great number of similar and equal chords within a larger circle; it is in fact a polygon, but with so many sides as to render its difference from a circle insensible in its effects: the brass ring containing the hairs is fastened by three wheels g, d, and i, within which admit of its rotative motion, and at the same time allow the strings to pass down through the ring at m; and to be as near to the hairs as possible, without touching them: for this purpose each series of the strings is arranged in a circular form to correspond with the curvature of the bows at EFG and H in the principal figure. The circular bows are put in motion by a pulley on the axes of the wheel i, and a strap or band passing round this, communicates motion from a vertical axis, k, in fig. i, which is common to the whole, and is kept in motion by a wheel, on the axis of a crank, which is turned by the treadle 1, and provided with a fly-wheel, k, fig. 1, to regulate the motion, and continue it, while the treadle is ascending: the communication between the horizontal axis, l, of the crank and fly-wheel, and the vertical axis, k, giving motion to the bows, is made by two conical wheels, m and n, covered with soft leather, touching each other in their circumferences: this is an excellent substitute for toothed wheels, both with respect to the freedom and silence of the motion, as the toothed wheels, being necessarily constructed of metal, could not be devised of an unpleasing sound, not to be endured in a musical instrument.

The keys are constructed, as shewn in figs. 3 and 4, moving on a fulcrum at o, and by that means, when pressed down by the fingers, the opposite end elevates one arm of the bent lever p; at the same time the other arm is drawn back, and the wire, q, moves one arm of a second angular lever r; the other arm ends in a hook, which is engaged with the string corresponding to the key: from this arrangement, when the key is forced down, the string is drawn in contact with the hairs of the bow situated at j, just above the lever rer, and the friction causes the string to vibrate in the same manner as the violin.

It is scarcely necessary, after this, to say anything respecting the action of the instrument: the performer keeps the bows in continual motion by the treadle L, which moves with such ease as to be no impediment to the freedom of motion requisite for a performer on a keyed instrument; an increase of pressure on the keys causes that fulness of tone which is so much admired in the violin, and the delicate softness, produced by lightly touching the keys, is a principal advantage in this instrument; and it is a great recommendation, that by its assistance these excellencies of the violin are secured to every good performer on keyed instruments. The velocity of the bows is another circumstance to be attended to at the same time with the pressure: when moved slowly the tones will be soft and delicate; but when the velocity is increased the tones are full, and adapted for grandeur of effect; the alteration in velocity is easily made. Mr. Hawkins having adapted an ingenious balance weight to the treadle, which acts to turn the wheel while the treadle is ascending, so that by this assistance the wheel can be made to revolve exceedingly slow, without danger of pitching, or stopping at the highest or lowest points of the cranks: this ingenious contrivance is equally adapted to lathes, or other machines receiving motion from the foot, and will be explained under the article FOOT WHEEL.

In this manner the velocity of the bows is completely manageable by the greater or less pressure upon the treadle, and the performer may easily make a sudden transition from quick to slow, by retarding the motion of the treadle when he wishes to retard, or accelerating the treadle while it is depending to accelerate the motion of the wheel: it is worthy of notice that each bow moves with a different velocity, 

$\frac{2}{5} L$
been adapted to produce the vibration of the strings it is applied to; this is effected by the different diameters of the four pulleys on the vertical axis of the bow, which turns the bows; these are in such proportion, that when the double bass bow revolves at the rate of 35 times per minute, the others make 35, 50, and 75 revolutions in the same period.

The instrument is provided with pedals, one of which, when pressed down, brings a piece of metal in contact with the hairs of each bow, so as to cause no interruption for this necessary operation. Another pedal elevates the bows all together, and causes them to act nearer the bridge than when it is not in use, producing the effect well known to performers on the violin when they bow near the bridge; for this purpose the frame containing the three wheels, fig. 6, of the bow, terminates in a stem, which slides in a socket, and can be elevated or depressed by the pedal just mentioned. A third pedal brings a piece of leather lightly in contact with the middle of each string, which causes it to vibrate in two portions, and found the octave in a beautiful tone, similar to the musical glissades.

COUPERIN, tablature, a name given to the Sambe or Sal mund, which included also Brongniart and Salmon, which is the leaf of the trutre kind, and supped by several, without sufficient reason, as Pennant conceives, to be the fry of the salmon. It is frequent in the Wye, in the upper part of the Severn, and the rivers that run it in, in the north of England and in Wales. These fisheries are also common in the rivers of Scotland, where they are called Pans. Thole of the Wye are there known by the name of Skirlings, or Lappings. This fish resembles the trout, but the head is narrower, and the mouth less than that of the trout; the body deeper; length seldom exceeding six or seven inches; the pectoral fins have generally one large black spot, sometimes attended by a single small one; the purplous or fat fin on the back is never tipped with red, nor is the edge of the anal fin white; the spots on the body are fewer than those of the trout, and not so bright, and it is marked from the back to the sides with five or seven large blue bars, whereas it has been called fingerin or finery; the tail is much more forked than that of the trout. Some have erroneously supposed it the father of most of this species.

**FIN**

**FINGERING on Keyed Instruments.** This is a subject which, to treat amply, requires great knowledge, meditation, and experience; and so many examples and illustrations of the rules, as in entire volume could hardly contain, much less an article of a dictionary. We shall, however, give the principal elementary rules for the carriage of the hand, and economy of the fingers, in a few keys, which, by analogy, may be extended to the rest. Couperin (see Doughter) was the first who treated the subject with intelligence, in the minority of Louis XV. 1717; and though his compositions, for which the rules were given, have long since been thrown aside and forgotten, most of his rules are still good for music of a very different kind. He advises parents to place their children under an intelligent master, at six or seven years old, and prefers not only the manner of placing the hands on the keys, but the carriage of the person. The height of the feat, if allowed to sit at an early age, should be such as would place the wrists on a level with the keys; the fingers should be curved so as to be all of the same length, in as such each should cover a key. Something should be placed under the feet of very young students, to prevent them from hanging loose in the air, and to support their frames in just equililum; and this support should be diminished in proportion to their growth. The distance at which a person of mature age

should sit from the instrument should be about nine inches and less in proportion to the short arms of children. They should place themselves in the middle of the keys, in as natural and easy a posture as possible; the knees not too close, and the feet even. Great attention must be paid to the countenance of children, that no grimace or apperance of difficulty should be visible, and become habitual, which would be attended to by flanders-by more than the music that is performing, however good and well executed. M. Couperin even advises a glass to be placed on the desk of the young performers in danger of becoming ridiculous, that they may correct themselves. Particular care should be taken to place the hands even, and not let very young subjects attempt reaching octaves too soon, as it flattens the left hand, and makes it feel to belong to a different person from the other. The time or measure should never be marked by the head, feet, or the whole person, which is unbecoming and confirmed into affectation. Even in counting the time it should be done in a whisper, or else it tends to prevent the ear from having any share in the performance. The keys should be covered with fingers and thumbs there may be, and all the force should come from the upper joints, not from the weight of the hand, which would be heavy and thumping. Children in their early lessons should not be satisfied to practice alone; they are too giddily and playfully to remember the rules, till duly improved by care and habit. Couperin used to take away the key of the instrument during the first lessons, that they might not undo in his absence all that he had tried with great pains to inculcate. Shakes, beats, and trills, in all keys, must be early practiced with both hands extremely slow, and quickened by degrees; as must be the exercises for each hand, called evolutions of fingering; for which see music plate. The weak fingers of both hands, that is, the ring finger and the little finger, must be very much exercised, to make them, if possible, equally brilliant with the others. Chords, if the hands are well placed on the instrument, are perhaps the best rules for fingering; for if the notes can be well and easily struck together, there will be no difficulty in breaking them into passages. The rapidly running up and down the keys whatever number of flats and sharps there may be at the clef, depends on the thumb, which, in keys with flats, should be placed, in general, on C or F, and in most keys with many sharps upon B and E, that is, on a long key, which, if there are more than five sharps, will be E and B#. The thumb of each hand, as far as five flats, must be appropriated to F and C for the fame reason; but neither the thumb nor the little finger, in the rapid ascent or descent of the scale, should be used for a short key, unless in playing octaves or chords composed entirely of flats and sharps. In practising quick passages, the fingers should be lifted up with a spring, and not allowed to hang on the keys, till wanted again, unless in arpeggiosing chords, or in passages of expression. In the first practice of a flake, in order to keep the wrist quiet, place the thumb on the 5th, 4th, or 3d below, and keep the fingers that are unoccupied as tranquil as possible. Couperin was the first, we believe, who made it a rule for his scholars never to play two notes together with the same finger, unless in repeating chords. See examples of deviation, Plate N V.

No VIII. Shakes should be practiced with all the fingers. Transient shakes, double shakes, a chain of running shakes turned, a series of double notes in 3ds, 6ths, and octaves; in the two latter, the thumb and the little finger only can be used, and nothing but downright drudgery and perseverance can acquire these modern tricks, so unnatural to the genius of keyed instruments. Double shakes.
can only be gained, if at all, by long and patient practice. The experiment, however, should be made.

N. IX. In order to transfer the fingers to different parts of the instrument, upwards or downwards, without quitting a note which ought to be sustained, the young student should change the fingers upon the same note with both hands without letting the key rise. There is no harm in letting children play their first lessons by heart; it fortifies the memory; occupies the ear more than the eye; and, indeed, it is impossible for them to find the keys without looking at them, till the fingers fall mechanically upon certain places and cords, as the feet, in walking, move without the owner paying the least attention to them.

With respect to reading music readily, it must be acquired by playing first with one hand, and then with the other, several new pages of notes every day, without repeating anything; and when that can be done readily, at fight, with each hand separately, then let the pupil begin playing simple strains with both hands. This will be practice for the eye alone. But in learning to execute difficulties, it must be done by beginning slow, and repeating quicker and quicker a thousand and a thousand times; this is practice for the finger. Expression depends greatly upon the sustaining and cessation of sound; or, in technical language, on what the Italians term legato or solennata, and flaccato or fibrillo, as well as on accents, and the different shades of piano and forte.

In the evolutions of fingering, or short exercises to form the hands, it seems a paradox, but it may be truly said of Nos. III. and IV. that, by throwing a finger away, the fingers, in such passages, become inexhaustible.

In the course of these exercises, where the fingers are marked, the semicircle, or star, includes such notes as lie under the hand, without any contrivance or change; and in other places, where no fingers are marked, such are used as lie over the keys.

The detached passages, N. VII. are meant to be frequently quicker and quicker, till the hand is tired.

FINIGRIGO, in Botany. See PISONIA.

FINIA, in Geography, a town of Sweden, in the province of Schonen; 20 miles N. W. of Christiansfeld.

FINIA, in Ancient Architecture, the flower, fruit, or foliage terminating a pediment or pinnacle in the pointed style. This represented a lily, a trefoil, an acorn, a pomegranate, endive, &c. according to the taste of the architect or artist.

FINIANA, or FINANA, in Geography, a town of Spain, in the province of Grenada; seven miles S. of Baça.

FINICA, a town of Astatic Turkey, in Natolia, near the coast; 50 miles S. of Satalia. — Alfö, a river of Natolia, which runs into the Mediterranean, 14 miles W. N. W. of Cape Chelidoni.

FINIMARBOO, a town of Africa, in Bamburra; 96 miles W. N. W. of Sego.

FINING. See REFINING.

FINING OF WINE. The usual method of fining down wines, so as to render them expeditiously bright, clear, and fit for use, is this: take an ounce of tinctures, heat it into thin threads with a hammer, and diffuse it by boiling in a pint of water; this when cold becomes a stiff jelly. Whisk up some of this jelly into a froth with a little of the wine intended to be fined, then stir it well among the rest in the cauld, and bung it down tight; by this means the wine will become brighter in eight or ten days. This method, however, is found to be best suited to the white wines: for the red ones, the wine coopers commonly use the whites of eggs beat up to a froth, and mixed in the same manner with their wines. The method by which these vicious bodies act in the operation is this; they entangle themselves among the flying lee or light effluences that float in the wine, and thus forming a mass specifically heavier than the wine, they sink through the body thereof like a net, carrying down all the foulels they meet in the way to the bottom; but when the wine is extremely rich, so that its specific gravity is greater than that of the mass formed by the ingredients used in fining and the dregs or lee; this mass then rises upwards, and floats at the surface of the wine, which will in this case also draw off fine. See Clarification and Prunigie.

FINIRE, in Law, was used to fine, or pay a fine upon composition and making satisfaction. It is the same with flavum facere, mentioned in Leg. Hen. I. cap. 53.

FINISHING, in Architecture, &c. is frequently applied to the crowning or acroteria over a piece of building, placed there to terminate and finish it.

FINISTERRA, in Geography, a town of Spain, in the province of Galicia, near Cape Finisterre.

FINISTERRE, formerly a portion of Bretagne, in 48° 25' N. latitude, now the most westerly department of France, bounded on the N., W., and S. by the sea, and on the E. by the departments of the North coasts and Morbihan, estimated at about 50 miles from N. to S. and 40 to 45 from E. to W., and containing 543 square leagues, and 474,049 inhabitants. It is divided into five districts, viz., Presqu'ile, having 149,610 inhabitants; Morbihan, 169,943; Chateaulin, 82,131; Quimper, 84,074; and Quimperle, 48,620. Its capital is Quimper, and its other chief towns are Bred, Morlaix, Chateaulin, Leseune, Landerneau, Crozon, Bric, Quimperle, and Bannalec. Its chief rivers are the Aude and Odet. The number of its cantons is 257, and that of its communes, 257; its contributions amount to 2,458,757 francs, and the expenses charged upon it are 315,193 f. 66 c. This department is tolerably fertile, producing grain, flax, hemp, fruits, and good pastures, with mines of iron and lead.

FINISTERRE, Cape, Galactic Promontorium, called Arbrectum by the ancients, and by some Nereum, a cape on the N. W. coast of Spain, in the province of Galicia. It is nearly S. or a little westerly, about five leagues from cape Toriano, and ships may anchor on the E. of a large rock, in six or seven fathoms, where is a great bay that runs far inland. Forty-two leagues from Cape Finisterre, there is a large rock above water, dangerous to navigators. N. lat. 42° 53', W. long. 9° 16' 15".

FINITE, something bounded or limited, in contradistinc-
tion to infinite.

The schoolmen make two kinds of finite; viz. the one as to extent, which is applied to things that have not all possible or conceivable extension.

The other as to perfection, applied to things which have not the last perfection.

To get an idea of a thing finite in point of perfection, we first conceive the thing as having certain perfections; and then conceive some other perfection which it has not, or some perfection in a further degree. After the first instance I conceive a room to be finite, by having an idea of expansion beyond what is contained therein.

FINITO, Ital. in Music, a canon or figure is said to be finite, i.e. finished, when it is not perpetual, but when at some certain place all the several parts stop together on the end of the key note; after having followed each other for several sounds, on signal being given by the leading part holding up his finger. See Canon.

FINITOR,
FINLAND, in Geography, a country of Europe, bounded on the north by Lapland, on the east by Russia, on the south by a gulf to which it gives name, and on the west by the gulf of Bothnia. This country was formerly divided into Russian and Swedish Finland. The former, or Russian Finland, anciently belonged to the Swedes; but it was partly ceded to the Russians by the peace of Nyklaed in 1721, and partly at the treaty of Abo in 1732: its capital is Viborgan, and it now constitutes the government of Viborgan. (See Viborgan.) The limits of Russia and Sweden, settled by the peace of Abo, are formed by the river Kyman; which flows into the centre of the gulf of Finland; on the south bank of which are a wooden house, a rampart of earth, and a small battery. The frontiers are defended by Frederiksborg, which lies. This province retains most of its ancient privileges, with some modifications under the new government. The country produces, besides flax, wheat, rye, oats, and barley, but not sufficient for the inhabitants. Viborgan retains its own civil and criminal courts of justice; in penal cases, not capital, the punishments prescribed by the provincial judicature are inflicted; but whenever a criminal is condemned to death, the Russian laws interrupt, reprove him from the sentence of beheading or hanging, &c. enjoined by the Swedish order, and confine him to the knot and transportation to Siberia. In the governor's court business is transacted in the Swedish, German, and Russian tongues; the peasants use only the Finnish dialect, but the inhabitants of the towns understand also Swedish, and many of them German. The Lutheran is the established religion of the province, but the Greek worship has been lately introduced by the Russians. This part of Finland is not so extensive as Swedish Finland. It is remarkable, that in both countries the productions of nature are sooner ripe in the parts covered with forests, than on the sea-coast and islands. The interval between feed-time and harvest is from 10 to 12 weeks. The Finns apply principally to the culture of hemp, flax, and tobacco, which thrives well in their country. As to trees, those which bear fruit, such as cherry and plum-trees, are almost always destroyed by the rigour of winter; the mulberry is planted and thrives only on the islands; the oak is laid not to grow beyond 61°, and the ash beyond 62°. The forests of fir r furnish in Finland the principal articles of commerce in wood, charcoal, timber, and planks, which are sent to Viborgan, Stockholm, &c. for exportation. The country abounds with game, and in the lakes and rivers various kinds of fish are plentiful. At the bottom of the morasses they dig earth, from which iron is extracted, and they have some mines of lead. The peasants of Finland differ very much from the Russians in their aspect and dress; most of them have fair complexions, and many of them red hair, which they part at the top and allow to flow at considerable length over their shoulders; they also have their beards; whereas the Russians have generally dark complexions and hair, which they cut short, and they also suffer their beards to grow. The Finns, by their commerce with foreigners, are in general more civilized than the Russian Finns who do not reside in the capital or in their vicinity. The small-town villages of Finland afford much better accommodations than are usually met with in the largest towns of Russia. In the 12th century great pains were taken to convert the Finns to Christianity; and Henry, who was bishop of Uppsal, in 1157, fell a martyr to his zeal in the accomplishment of this benevolent design. That prelate founded the first cathedral in Finland at Randamoki; but the fee was afterwards transferred to Abo, not far from the former place. Martin Skye, and Peter Sekkila, were the first promoters of Lutheranism in this country. The provinces of Swedish Finland are Finland Proper, the Isle of Oeland or Aland, Orkobothnia, Tavakaland, Nyland, Savolax, and that part from Sif to of Kymene and Carelia, which Sweden retained to itself; but the whole of Finland has lately (1829) been ceded to Russia; in consequence of the unsuccessful struggles of the Swedes to maintain their independence; and by the treaty of peace concluded between Russia and Sweden, and signed at Fredericksborg, the incorporation of the grand duchy of Finland with the Russian empire was confirmed. The town of Torne, and the river of the same name, form the frontiers.

FINLAND Proper, a province, lately belonging to Sweden, situated on the southern part of Finland, considered in its utmost extent, bounded on the S. by the gulf of Finland, and on the west by that of Bothnia; about 160 miles in length and 15 in breadth. The soil is fertile, and the land, especially in the southern parts, produces good corn, hay, and hops. It has several fine lakes and rivers, which yield abundance of fish, and on part of the coast is a pearl fishery. The inhabitants subsist by agriculture, grazing, fishing, and the manufacture of woolen ware. The principal articles of their commerce are grain, meal, cattle, butter, tallow, linen, yarn, stockings, &c. Finland is divided into two and four; the capital of the former is Birnborg, and that of the latter Abo.

FINLAND, Gulf of, that part of the Baltic sea which washes the coasts of the governments of St. Petersburg, Revel and Viborgan; it is above 400 versts in length, and from 100 to 120 in breadth. The gulf of Finland is of difficult navigation, both on account of the heavy gales of wind that are to frequent here, and the multitude of rocks and shales with which it abounds.

FINMARK, called also Lapmark, a province of Norway, bounded on the N. by the northern ocean, on the E. by the northern ocean and the territories of Russia, on the S. by Swedish Lapland, and on the W. by the northern ocean. The coast of this country is well inhabited, but it has neither towns nor villages. The inhabitants subsist chiefly by fishing, and their country yields the best salmon in Norway. The sun, such is their latitude, continues above their horizon in summer for some weeks. Finmark has a particular governor, regiller, and judge. It is divided into Weft Finmark, which includes twelve churches and chapels, served by five preachers; and Eait Finmark, in which are nine churches and chapels, served by three preachers. See FINNS.

FINN, a river of the country of Donegal, Ireland, which flows from a lake of the same name, and, after a course of several miles in an easterly direction, joins the river Foyle, near Strabane.

FINNERYDIA, a town of Sweden, in Weft Gothland, 34 miles S.W. of Orebro.

FINNHAR, a small island on the west side of the gulf of Bothnia. N. lat. 60° 58'. E. long. 17°.

FINNIKIN, in Ornithology, the name of a particular species of pigeon, called by More the Columba in grun fletens. It is of the shape and size of the common pigeon. The crown of its head has something of the resemblance of a snail's head; and it is gravel-eyed, and has a tuft of feathers on the hinder part of its crown, which runs down its neck not unlike a horse's main. It is not feather-legged, and is in colour always either a black or blue pied. They have their name from their singular manner of courting the female, which is always by rising over her
FIN and making three or four turns, flapping the wings, and then turning many times round the other way.

FINNIS Bay, in Geography, a bay of Scotland, on the east coast of the island of Harris. N. lat. 57° 53'. W. long. 6° 55'.

FINNS, a race of perfons, who are said to be the aborigines of Russia, and who inhabited the regions of the Volga and the Duna. These people, though they form one main item of the inhabitants of Russia (the Slavonians being the other), have never, in any of their branches, risen into a ruling nation; yet as they are the common flock of most of the northern nations of Europe, they are distinguished by their antiquity, and by their wide extent from Scandinavia to a great distance among the Alpatic nations of the north, and thence again to the shores of the Volga and the Caspian. Although the Finns have been thus widely intermixed, yet they have preserved a general resemblance in bodily frame, in national character, in language, and in manners. It is also remarkable, that the greater number of those who belong to the Finnish race, still dwell only in the north, which has ever been their favourite abode, and on which account they are called inhabitants of morasses or fens; and the fishery and chase have been their chief occupation and trade. Which of these widely intermixed people has the best claim to be considered as the parent flock, it is not easy to decide. The aboriginal name of Finns, known to the Roman historian Tacitus, is not in use with any of these nations; but they call themselves by a different appellation. None of these people have ever exhibited a conspicuous figure on the theatre of the world, nor acquired a permanent independence; but they have all, as far back as history can trace them, been a prey to their more enterprising and powerful neighbours. Accordingly, they have no chronicles of their own; and their history is only to be found in the annals of their conquerors. Of their ancient history nothing certain is known, except that they polished the greater part of Scandinavia and Russia in the north, and separated into several tribes, which either lived entirely without any government, or, like the Permians and proper Finns, under their own kings. All these were gradually subjugated by three nations, under the dominion of which they still remain; viz., the Norwegians, the Russians, and the Swedes. The Norwegians were the first who subjected a part of the Finnish north. Finmark, which is a large province extending even to the eait of Cape Nord towards Russian Lapland, has ever been tributary to them. Yet it appears that, long before the commencement of the 10th century, the whole tract, from Wardhys to the White sea, was independent of them; and that only the remoter Finns, about the gulf of Bothnia and Finland, and on the Duna, obtained their national freedom.

The inhabitants of Finmark have been amply described by Levens (De Lapponibus Finmarcia, Copenhagen, 1767, 4to.) cited in Pinkerton's Geography. This race of men, he says, is of small size, generally about four feet, with short black hair, narrow dark eyes, large heads, and high cheek-bones, a wide mouth, and thick lips, and of a swarthy complexion. In the southern part of Finmark they are mingled with Norwegians; but the northern wilderness is wholly their own. They call themselves "Same," their speech "Same-giel," and their country "Same-edna," being probably of the same race as the Saimoens. The language has only an affinity with the Finnish, but not nearly so much as the Danith has with the German; and, it should seem, that they had ananciently a different speech, which they enriched with large additions from that of their more polished neighbours the Finns. Towards the shore they build huts; and on the mountains use tents of a flatly conic form, and divided into two parts by a kind of passage; each part having three rude subdivisions; the two outer for the manner, mistrels, and guests; the middle on each side of the fire for the children; and these near the door for the servants: behind these the cattle find a refuge, but the cattle are few, the rein deer constituting their chief wealth. The sun abhors himself for seven weeks, and yet from ten in the forenoon to one in the afternoon, the twilight will enable a person to read without a candle; nevertheless the stars are visible, and the moon, when apparent, shines all the day. The sun never sets for seven weeks in summer; but in the night his beams are dull, and he assumes a redder hue. Several rivers, particularly the Tana, in eastern Finmark, sometimes much swelled by the melted snow, supply salmon and other fish, the chief food of the Laplanders; though at a festival they have mutton or reindeer, and mead. The men wear conic red caps, lined with fur, and a kind of robe of cloth or skin; the poor sometimes use that of salmon, which appears like a white flagnen; the head and neck are protected with a sort of coat, and the veil is of undress-then-flin, with the wool towards. The head-dresses of the women is narrowed in the middle, widening like a bason at the top: the veil and robe referable those of the men. Their annuements are floothing with the bow at a mark, a kind of tennis, and a game resembling draughts. They are also fond of wrestling, and other exercises. They were formerly addicted to magic, and were fabled by ancient times to invoke a demon in the shape of a fly, which was called the "gan-fly," and commissioned to sting their enemies. Till recent times they were immersed in paganism, regarding particular mountains and rocks as gods. Their chief god was "Radem," who dwelt in the fiery heavens; in the lower aerial regions were "Berti," or the fun, a god, as Grotius has observed, very unjudiciously; with "Horangalis," or the thunderer, and other divinities. On earth were the gods of hunting and fishing; and the goddes of "Maderon." with her daughter "Sarakka," a kind of Venus, who prepared the body; after Radem had been the soul. The "Saivo Olmak," or gods of the mountains, were supposed to be oracular. The places of sacrifice were chiefly holy mountains, near the birth of Waranger, and along the Tana, and some on the bay of Porsanger. Their magical fongs and drums are very trivial. For the conversion of the Laplanders to Christianity, Eric Bredal, bishop of Drontheim, made some vain attempts about the year 1660; but the royal mission was not founded till 1714; and extended to the Laplanders of Finnmark, with those of Novland to the south, being a considerable portion of this dioce of Drotheim. Since that period, the missionaries have been reftoluate, and indulgent, and successful; there being commonly two for Finnmark, one for the east, who preaches over Waranger, Tana, and Laxeford; the other for the west, over Porsanger, Haivalund, and Alten.

The Russians were the people who, next to the Norwegians, intermixed themselves among the Northern Finns; and though at first, on their settling about the Volkhof, they lived on good terms with their neighbours the Tschudow or Finns, and soon elected a government conjointly with them, yet afterwards they, later than the Norwegians, and earlier than the Swedes, conquered and subdued them. At first the Russians had merely the region about the gulf of Finland, or on the Kyrababolon, and about the Ladoga lake, quite up to the White sea. They afterwards spread farther round in these defart countries, and subjected to themselves a part of Finland. In the sequel they took not only the whole
whole of Lapland round Kola, but proceeded to levy a tribute on the Finns in the present Finnmark, and on those who dwelt in Trondem as far as Malanger. The other Finnish nations in the East, on the Volha, and in Siberia, became subject to them with their gradual extension into the regions, by the conquest of the Tartar kingdoms and the discovery of Siberia. The Swedes were the last who founded a sovereignty in the Finnish parts of the North. It was not till the middle of the 12th century, about the year 1157, that king Erik, the faint, undertook the subjugation and conversion of the proper Finns: 150 years afterwards the Swedes entered Tavastland; towards the end of the 13th century they established themselves in Karelia; and about the same time the Laplanders were also reduced under their authority. Thus the whole of the Finnish North was partitioned among three sovereigns, and the nation itself was removed from the rank of an independent people. Of the 13 tribes into which the Finnish flock was divided, 12 belong either wholly or in part to the inhabitants of the Russian empire; viz. the Laplanders, the Livs, the Tchekoffi, the Tschachasches, the Mordvines, the Votaks, the Permians, the Szyranes, the Vaganes, and the Kondish Oltists. The Madihares alone, the great mass of the mixed multitudes whom we at present call Hungarians, are the only Finnish nation which belongs not to Russia, and also the only one that has preferred its national independence.

The country which is inhabited by the Finnish nation comprises the north-eastern corner of the Botnic and Finnish gulfs, interspersed throughout with mountains, rocks, moraines, and lakes, between the 63rd and 65th degrees of N. latitude; its circumference being computed at 30,000 versts. The greater part of it did belong to the kingdom of Sweden; the smaller southerly portion, till of late possessed by Russia, contained Ingernland, Kexholm, and Karelia, forming the government of Vyborg and Wibarg, and part of that of St. Petersburg. In the government of Vyborg, the Finns compose by far the greater part of the inhabitants, or more properly they are the people of the country. In most of the circles of the Peterburg government, they, with the Ingrians, are known by the doiemy of the population: and in the government of Viter and Novgorod, they form considerable colonies, which have long been settled in these regions. The number of all the Finns living in Russia cannot be correctly ascertained; but they probably exceed 400,000 persons. Tooke's Russ. Emp. vol. i.

FINNO, in Geography, a town of Germany, in the Upper Mark of Brandenburg; 32 miles N. E. of Berlin.

FINSCALE, in Ichtyology, an English name for the river fish, more usually called the rudd, the rutilus latior, or rubello fluviatiles of authors. See Cyprinus crypoophthalmus.

FINSPAAGE, in Geography, a town of Sweden, in East Gotland; 15 miles N. W. of Nordkioping.

FINSTER-AAR-HORN, a high mountain of Switzerland, in the canton of Bern; the elevation of which has been found by actual measurement to be 14,116 English feet.

FINSTER Muefler, a town of the Tyrolese; 12 miles N. E. of Trafp.

FINSTERBACH, a river of Franconia, which runs into the Rednitz, 2 miles N. of Roth.

FINSTERWALDA, a town of Saxony, in the marquessate of Meissen; 30 miles N. of Dresden. N. lat. 51° 37'. E. long. 13° 36'.

FINTO, Ital. in rustic, implies a feint in preparing for something that is not performed, as cedam e reinita implies the making a full close expected, when, instead of the base failing a 4th or raising a 5th, another unexpected base and its harmony are given, which at present is called a disappointed caden e, and may be brought about various ways.

FINTONA, in Geography, a small port of Ireland, in the county of Tyrone, on the road from Omagh to Enniskillen; 7 miles S. from Omagh, and 94 miles N. W. from Dublin.

FINITRAT, a town of Scotland, in the county of Stirling, containing about 1000 inhabitants; 8 miles S. W. of Stirling.

FINVARA POINT, a cape of Ireland, in the county of Clare, on the southern coast of Galway bay. W. long. 9° 4'. N. lat. 53° 7'.

FINDA, a town of Asiatic Turkey, in Natolia, in the gulf of Satalia; anciently called Phot_props, near a famous pass into Pamphilia; now the site of a Greek bishop, though much decayed; 28 miles S. of Satalia. N. lat. 36° 36'. E. long. 32° 26'.

FIORE, a river which rises in the Sienaese, and runs into the sea below Montalto, in the duchy of Calto.

FIOREAVANTI, Lfownard, in Biography, a physician of Bologna, in the sixteenth century, who possessed a considerable degree of reputation among his contemporaries, not only on account of his knowledge in medicine, but also of his chirurgical dexterity. Nevertheless he was an arrant empiric, in the modern sense of the word, and in the writings which he left behind him, he dwells at great length on the excellence of the secret remedies which he poiffed, and is violent in his condemnation of blood-letting. He died on the 4th of September 1588. The titles of his works, which are in Italian, are as follows: "Del Specchio di Scienti Universale," Venice, 1564. "Regimento della pelle," ibid. 1565. "Capricci Medicinali," ibid. 1568. "Il Teforo della vita humana," ibid. 1570. "Compendio dei Secreti Naturali," Turin, 1580, Venice, 1581, &c. "Della Ficica, divisa in Libri Quattro," Venice, 1582, "Cirurgia," ibid. 1588. All these works have undergone several editions. —Eloy.

FIORANTINO, in Geography, a town of Italy, in the Campagna di Roma; 25 miles N. of Tarentina. N. lat. 41° 42'. E. long. 13° 6'.—Alfo, a town of Naples, in Capitanata; 7 miles S. of Lecan.

FOIENZIOLA, a town of Etruria, in a valley of the Apenines, on the site of the ancient Fidentia; 22 miles N. of Florence.—Alfo, a town of the duchy of Parma. —Alfo,
FIR

—Allo, a town of Naples, in Capitanata, anciently called Florentium; now decayed; 10 miles S. of St. Savaro.

FIORI, MARIO DA, in Biography, a painter of flowers, whose real name was Mario Nuzzi. He was born at Perona in the kingdom of Naples in 1623, and studied with his uncle Tomafo Salini. He imitated the lighter productions of nature, as flowers, shells, &c. with great beauty. A fulness and richness of touch and colour are given by him with great elegance and lightness. It was so much the talk of the time to admire his productions, that he could not keep them all enough for the demand; and what was more to his credit, Domenichini and other artists of renown were not ashamed to paint in conjunction with him. One of his most capital works is in the church of St. Andrea della Valle at Rome. It is a wreath of flowers encircling the portrait of St. Gaetano, which was painted by Andrea Camaschi. At Wilton is a very beautiful painting of his; a wreath of flowers round a head of the virgin, by Carlo Dolci. He died in 1673, at 70 years of age.

FIORITO, Ital. is a musical term, implying flowery, ornamented; as canto fiorito, fluid long, contrapposto fiorito; to dilligush them from canto fermo, and contrapposto semplice.

FIORLITA, in Geography, a small island of the Mediterranean, at the entrance of the gulf of Taranto. N. lat. 40 deg. E. long. 18 deg.

FIORONI, GIANN ANDREA, in Biographia, maceto di cappella at the great church or Duomo in Milan, about the middle of the last century. He was an excellent contrapuntist alla Palestrina, that is to say, in the style of our best old masters in their services and full anthems, which consist of good harmony, ingenious points and contrivances, but no melody. Sig. Fioroni is a voluminous composer and publisher of masques and motets in eight parts, a due lori. So that though this style, and that of the church, are abandoned in Italy, on days of festival, when instruments and secular singers are employed, the ancient grave style of the 16th century is not wholly lost.

FIR-Tree, in Botany. See ADET and Pinsus.

Fir-Tree, the common name of a tree of the evergreen timber kind, frequently met with in the more elevated and mountainous situations of the colder climates of the north. It has, for the most part, single leaves, which are produced on every side of the branches. This is a tree, which is capable of being raised upon almost any part of soil which is not very retentive of moisture; and it is both rapid in its growth, and hardy in its nature, but not perhaps so ornamental as some others of the evergreen kind.

The usual method of raising these trees is by sowing the seeds taken from the well ripened cones which they produce. The mode of extracting the seeds from the cones is, either by expelling them to the gentle heat of a fire, or by foaking them for a short time in warm water, by which they readily open and emit the seeds. The former method is the belt, when due attention is paid not to expel them to too great a degree of heat. This should not however be done until the period of sowing or putting them into the ground. The belt way is to sow them in a nursery where the land has been well prepared, in order that they may be well protected from the ravages of birds at the time of their coming up; as they are very apt to destroy them at that period, by picking off the buds of the seeds which come up along with the plants.

The proper time of putting the seeds into the ground is about the end of March, or beginning of the following month. They should be sown on a bed of light earth, and covered to the depth of about half an inch by means of a garden rake. The plants should be continued in this bed until the following spring, being kept perfectly clean from weeds. At that time other beds should be put in a proper state of preparation for receiving the young plants; into which they should be carefully transplanted in rows, at the distance of fix or eight inches from each other, and three or four inches apart in the rows. When the season happens to be very dry afterwards, it may be proper to water the plants once or twice a week according to the heat of the weather: and in some cases it may be requisite to cover the beds with mats in order to screen them from the sun and drying winds, until they have taken good root; after which a further care is necessary, except that of keeping them free from weeds. The plants may continue in these beds two years; at the end of which time they may be removed into other spaces of open ground properly prepared for them, being placed out at such distances as may be most suitable for them. The most usual distances in these cases are four or five feet from row to row, and two or three feet apart in the rows.

After they have been planted out, when the weather happens to be dry, they should have a good watering to settle the mould to their roots; and which may be repeated three or four times, in case the season continues dryness, with great benefit in promoting their taking root, and securing them from the effects of drying winds.

The plants may remain in these situations for two or three years longer, or until they may be wanted; during which time the ground should be dug between the rows in every spring, and be afterwards kept perfectly clean from weeds by frequent hoeing, care being taken in the diggings not to cut or injure their roots. This is all that is requisite in their cultivation while they remain in such boxes.

When they are to be removed into the situations where they are to remain, great care is necessary in taking up the plants, not to cut off or hurt the roots, nor to suffer them to continue any length of time exposed out of the ground, before they are replanted. The most safe time for performing the Luminas of removing this fort of trees for finally planting out in mould is in the beginning of April; though in dry lands they may often be planted about Michaelmas, with success.

Fir trees are frequently grown at the height of fix or seven feet and sometimes more, but the height of two or three feet is much better, and plants of this height generally, in the course of a few years, surpass those that have greater heights when first set out.

The fir, or large sort of plant, must, at first planting out, be always well secured by stakes or other means, in order to prevent their being moved and made loose by winds, which, whenever they occur, are sure of destroying the trees. These small plants only stand in need of having the mould firmly trodden in about their roots during the time they are planting out.

The chief improvements that have been made by planting large masses of trees of the fir kind on the poor, bare, bleak, exposed, moary, and heathy situations in the northern parts of Scotland, sufficiently shew their importance, and plainly demonstrate the advantage of such undertakings in such places, where properly managed. And though it may be admitted that the Scotch fir is amongst the most pernicious and least valuable sorts of timber wood that can be raised, and consequently sells at a very low price; yet as the expense of rearing it is very large, the returns are in all cases so abundant as to fully satisfy those who have engaged in the forming of such plantations. This has even been the case when no other circumstance but the direct in-
conce which has arisen from such plantations themselves has been taken into the account. But when the collateral advantages are considered likewise, the benefit occasioned by them is evidently extremely great. It has been stated by the author of the "Essays on Rural Affairs" that in the vicinity of plantations of the fir kind, housetops can be raised at no little expense, and the roofs are so much straighter, and better than the ordinary ones, that settlers in such situations are induced to make their houses much neater and more commodious than in other places; and besides rails, and other kinds of materials for dead fences, can be easily procured, that the poor people are first enabled to have good walled gardens, and then commodious enclosures of larger extent; the branches likewise afford fuel to them, which adds greatly to the comforts of their situation. The cutting and manufacturing of the wood into various kinds of utensils furnish employment for a great many persons; population is thereby increased, and with an augmentation of population, its necessary consequence, the desire for land to produce the necessaries of life, and of course an increase of rent to the proprietor. These new settlers in the desert wastes of Scotland, like those in America, cultivate and improve the soil in proportion as the trees are removed from it. At this moment, it is added, Mr. G. Dempster, who will be long respeoted by his countrymen, fees fields on his estate rapidly converting, in this way, the plantations into a valuable growth, and yielding him ten or twelve shillings per acre in rent, not only without any expense to himself, but after having derived a considerable profit from the sale of woods of his own planting, which grew upon land that twenty-five years ago was not worth to him above two pence the acre, and which might have remained in that state, perhaps for ages to come, had it not been planted at all. It is contended by the same writer, that it is by a judicious management of this sort that men of large landed estates, by a little fore-fight, find themselves enabled to provide both employment and subsistence, with much profit, to a numerous people, who must otherwise have either remained in a destitute condition, or have abandoned a country, which did not properly provide for their accommodation.

It may be remarked likewise that a plantation of Scotch firs may be made at much less expense than of any other fort of trees in those northern parts of the kingdom, as the young plants can be afforded at a lower price than any others. In Aberdeenshire, where planting is so general as to have become a sort of occupation, for plants of two years growth, above which age no experienced planter will ever buy them, sometimes will be sold at the very low rate of fourpence the thousand, which consists of twelve hundred plants; and they formerly seldom exceeded eightpence; on the average about sixpence, or one halfpenny the hundred: but they have lately been considerably higher. There are men who make a business of forming plantations, who will undertake to complete the whole, enclosing and planting, at the distance of one yard each way, and uphold them for five years, that is, supply any deficiencies that may take place, at the rate of from ten to fifteen or thirty shillings the Scotch acre, which is nearly equal to one and a quarter English, according to the size of the inclosure, and the nature of the fence. In all cases of this kind, it is supposed that the plantations are of the extent of thirty or forty acres or upwards; for where the inclosures are smaller, the expense of inclosing is proportionally augmented. The charge is thus not only rendered moderate, but the whole of the expense that is to be incurred, ascertained before the plantation is begun, by which the being involved in unforeseen difficulties is fully obviated.

Experience has fully shown that there is scarcely any soil so bad, or any exposure so bleak, that the fir-tree will not live in, if the plantation be of sufficient extent, and not upon the very summits of high peaked hills. They do not indeed bear the sea air very well, where they are much exposed to the severity of its blasts; nor is the wood ever of so good a quality, or the tree long lived, upon soils of the clay kind. It has been found that in the southern parts of the kingdom, the pinecarr bears the sea blast much better than any other of the fir tribe. This is a discovery of great importance, and which deserves the attention of improvers in the way of planting. The spruce fir will however bear a still more exposed situation than the Scotch fir; and after a few years from the time of planting, it shoots up with still greater luxuriance. This is the case probably only in particular situations. But the cones are not to be had in equal abundance; and the plants being more difficult in the rearing, they are sold at a much higher price, usually about four shillings the thousand, fit for being planted out. In a good soil the silver fir also prospers well, and is a beautiful tree, on account of the depth of its shade; but the price of the plants is too great to admit of large plantations of it being made with advantage. But wherever the situation is bleak, and much exposed to strong blasts of wind, the plantation must not only be of considerable extent, if the trees be expected to thrive, but it must be formed in miles, where the lower plants may stand at the distance of two to three feet at most from each other. The more exposed the situation is, the closer they should be planted; as it may be observed that until the branches begin to intermix, and give a mutual support to each other, the trees never begin to advance with vigour. Where the plantations are thus thick, there is a necessity for beginning to thin them out at a pretty early period, so that after the tenth to the fourteenth year from the time of planting, persons must be constantly employed in thinning them: and there are very few situations, indeed, in which the thinnings cannot be disposed of to advantage, or in which such sorts of plantations cannot be made.

It has been remarked by an able writer, in the Transactions of the Bath Agricultural Society, that though he does not think that the Scotch fir can, in this country, ever equal the yellow deal from the Baltic, yet it may be worth propagating, as being useful in ordinary buildings. The drier the soil is on which this sort of timber grows, the flower is its progress; and the closer its pores, the more it adds to its beauty. Where plantations are formed, the fir will shoot three or four feet in a season, and equal, if not surpass, the oak in growth. In his plantations, though chiefly confined to chalky banks, in a north-west exposure, the trees eince, that when once rooted, few obstacles will prevent their profitable progress. From observing the mistakes of others in endeavouring to ornament their naked downs too suddenly, he has learnt the necessity of planting firs only when a foot in height, and by opening the ground some time before, inverting the turf at the bottoms of the holes, and throwing the mould upon it in hilly lots to meliorate, his plantations succeeded well: for though the soil is scarcely fix inches in depth, the first set in 1760 are now 30 feet in height, and from two feet six inches, to two feet, in circumference, at four feet from the ground; some few planted at the same time in a deeper soil, and warmer situation, are now about three feet round. And spruce firs, planted in 1766, likewise in a tolerably good soil, are now 40 feet in height, and from two feet ten inches and a half, to three feet, round. But he has seen plantations that far surpassed either of these in growth; they however occupied ground which was infinitely more valuable. See Pinus.
FIR

hard, scarce seasons the tops or shoots of the fir tree have been utilized as a food for cattle, sheep, &c.

Fir. Most upright. See Lycopodium.

Fir, Scotch, in Botany. See Pines.

Fir-cones, fossil, in Natural History, are extraneous fossils, resembling the cones of the fir-tree. Numbers of these have been described by different authors, who appear evidently to have confounded recent and peat fossils with those belonging to, or found lodged in the undisturbed strata, or to have had but slight evidence of the identity of the fossils with recent cones. We have been told that a very perfect fir-cone was, a few years ago, found at Aspley in Bedfordshire, not many inches beneath the foil, in a completely rigorous state. The many fossils that have been published respecting the petrifying springs of this place, would have induced the writer to have taken no notice of this, had it not been related to him by a gentleman of veracity, and a competent judge of these matters; but since he has had himself the opportunity of making enquiries on the top of concerning this fossil.

Fir-wood, fossil, has generally been that obtained from out of peat mofles, in which recent fir-trees have been preserved during the growth of the peat; and, as Mr. Parkinson thinks, have undergone a degree of the bituminous fermentation (which fee), by which their inflammability has not only been preserved, but in some instances heightened. The same gentleman (Organic Remains, i. 440.) figures a fossilious remain, (Plate II. fig. 4 and 5,) which he describes as a piece of fir, but we think without offering sufficient proof of its identity to any of the recent fir tribe.

FIRABUS, in Geography, a town of Peru, in the province of Mecan; 45 miles W. S. W. of Kidger.

FIRAN, a small island in the Red sea, about 18 miles from the coast of Arabia, celebrated for its fisheries of pearl. N. lat. 17° 13'. E. long. 45° 30'.

FIRANDO, an island and kingdom of Japan, with a good harbour, in the sea of Corea. N. lat. 33° 35'. E. long. 135° 40'.

FIRE. This word has been used to express things somewhat differing from each other; yet bearing analogy to its most usual and most common signification, which is that of an active natural process, attended with the emission of heat and light, and likewise with the decomposition of certain substances, which are said to be burning, or in a state of combustion, during the processes, and are said to be burnt after the termination of the processes.

The general use of fire, which comes continually under our observation, suggests to our minds the meaning of the word perhaps much more readily than the recollection of the above stated definition; the latter, however, is attended with this advantage, namely, that it defines the limits of the meaning, whereas it prevents its equivocal application.

The various spectacles which fire exhibits to our senses; its alluring effects, and the innumerable uses to which it may be applied, have, at all times, rendered it an object of the utmost consequence to the human species. The newborn infant generally fixes his eyes to the flame of a candle, or to a common culinary fire, in preference to any other object; and a more advanced age the various means of exciting and of employing fires occupy the thoughts of a very great portion of the human species; and the industry of philosophers has at all times endeavoured to investigate the nature, and to account for the effects of fire.

It is not every kind of bodies that are capable of combustion. Those which are capable of supplying a fire, or of being burnt, are called combustibles, and such are either simple, as hydrogen, sulphur, and phosphorus; or compound, viz. those which consist of various substances together with a notable proportion of one or more of the above-mentioned simple combustibles; such as wood, coal, oils, &c. Several other bodies are not combustibles; those, however, may, by the action of a fire, be rendered red-hot, so as to emit heat and light, but they do not undergo any decomposition; or if they do undergo any, it is not of that kind which a fire produces amongst bodies that are really combustibles. The incombustible bodies that are rendered red-hot, are said to be in a state of ignition, or of incandescence, and this incandescence, which emits heat and light, exists no longer than the cauè which produces it; for after that it begins to diminish, and gradually vanishes; whereas the real combustibles, when once set on fire, continue of themselves to burn until their whole substance is changed into something quite different from what it was before the combustion.

Sometimes a substance which is actually combustible, may, when placed in a common fire, be only ignited, and act like an incombustible body; that is, without undergoing any perceptible decomposition. The reason of this is, that the given combustible requires to be exposed to a very high temperature before it will suffer decomposition; therefore when placed in a lower temperature, yet sufficient to render it red-hot, it will then only acquire a state of incandescence. Thus a diamond, which is perfectly combustible in a very high temperature, may be made repeatedly red-hot and cooled, without the least alteration of its nature.

It may also happen that a combustible body may be placed in a degree of temperature much higher than that which is necessary for its combustion; yet the combustion will not take place for want of some of the circumstances upon which that process necessarily depends. Thus a piece of charcoal placed in a close vessel may be rendered red-hot, and may be kept in that state for any length of time, without undergoing the least decomposition. The reason of which is, that in a close vessel no oxygen gas can come in contact with the ignited charcoal; and without the presence of oxygen, or of substances which can yield oxygen, no combustion can take place. See the articles Combustion and Excitation, wherein whatever belongs to the theory of combustion will be found.

From the former of these articles it appears, that no fire can continue long without a constant supply of a combustible substance, and of oxygen; for the whole process consists in a decomposition in both these substances, and the formation of new compounds, at the same time that the latent heat, or caloric, and the light, are separated and are set at liberty. As fire is of great and constant use for economical purposes, no pains have been spared to determine how the greatest effect may be produced in the safest and most economical manner possible, relative to all species of fire, from the burning of the helmet lamp, to that of the most powerful furnace. The combustibles, which are used for all these kinds of fire, are collectively called fuel, and in all cases the difficulty is to determine which kind of fuel is (according to other concurring circumstances of place, expense, &c.) the fittest for any given purpose. The full consideration of these particulars will be found under a variety of articles.
FIRE.

such as FUEL, LAMP, LIGHT, FURNACE, &c.; we shall
nevertheless barely mention in this place some of the lead-
ing facts, which have been determined in consequence of re-
peated experiments, and which may, for the present, fur-
nish the reader with a sufficient idea of the limits within
which our powers of employing fires have as yet been con-
fined.

Half an ounce of spermaceti oil, of the best kind, in a
proper lamp, which is furnished with a wick of a single
thread of cotton, may be made to burn for about twenty
hours, and it seems that no smaller or cheaper quantity of
any other combustible substance is known, which will main-
tain a fire for nearly so long a time. The Chinese use
a very peculiar mode of continuing a small fire. A very light
flick, about a twentieth of an inch in diameter, and about
fourteen inches in length, is crufled over with a fine sort of
faw-duff, wherein perhaps a very small quantity of nitre
may be contained. The faw-duff is probably made to ad-
here to the flick by means of weak glue. If one of these
flicks be crufted and lighted at one extremity, it will con-
tinue to burn, not with a flame, but like tinder, and will
last about a quarter of an hour or twenty minutes. The
Chinese keep such flicks burning before their idols, or for
the purpose of lighting their pipes, even in their boats upon
water; and when one of them is nearly out, another is put
in its place. The flame of a lamp, furnished with spirit of
wine, is much more active than when furnished with oil;
and it is to be remarked that the flame of spirit of wine
gives much more heat, and at the same time much less
light, than the like flame of oil. The flame of burning hy-
grogen gas in common air is not very active, at least
not nearly so active as a similar sized flame from
oil; yet it is said that the flame of hydrogen gas,
urged by pure oxygen gas, produces the most active fire
known. For this experiment the two gases must not be
mixed in a common vessel, and then let out of a small
 aperture in order to be lighted, and to produce a stream of
fire; for in that case the whole quantity of mixed gases
would at once explode, and burn the vessel; but the two
gases should be kept in separate vessels, as, for instance,
in two bladders furnished with stop-cocks, and when the stream of
hydrogen is burning, then the stream of oxygen ought
to be directed towards it. The gas, which is extricated
from coal by means of heat, has been found useful for light-
 ing apartments in certain circumstances, but the particu-
lar precautions will be found detailed under the article EXIIX.

For a culinary, or common fire place, several species of coal fur-
nish, coeteris paribus, the most lasting, and, upon the whole,
the most useful fire. The same will do for large furnaces;
but for small furnaces, wherein a clear fire may be wanted,
or for drying malt, &c. coke or charred coal is preferred;
for the action of charring excels from the coal a good deal
of grofs vapour, which otherwise renders the fire smoky,
especially at first. The greatest heat of an air furnace, eight
inches in diameter, according to Wedgwood's estimation,
amounts to about 21,877° of Fahrenheit's thermometer, or to
160° of Wedgwood's.

From the above-mentioned statements one may be en-
ably led to conceive what degree of credit must be given to those
idle theories of perpetual fires, and of lamps having been
found actually burning in old tombs, and stone coffins.
The improbability, or rather the absurdity of the account,
is so very glaring as to render them only fit for novels and low
poems, and it seems as if we must confine our notice under so many other obvious arti-

bles, as to supersede the necessity of rendering the present
very prolix; there are, however, two particulars, which
may with more propriety be expected in the present;
and therefore we shall briefly join them. These are a short
history of the principal opinions that have been entertain-
ing respecting the nature of fire, and some remarks on the
various leades in which the word fire has been used.

The opinions of the ancient philosophers respecting fire
were various and fanciful. Ignorant of the leading facts
which a theory is required to account for, and unaided
by experiments or tools, they generally made use of words
which convey no definite ideas. They called it an active
fermentation, an inflame motion, a repulsive agent, and
so forth; but no real attempt towards a rational investiga-
tion is to be found in their works. And though some of
their assertions seem to coincide with the more rational mod-
ern theories; yet that a parent coincidence must be con-
sidered as being accidental; for it is not grounded upon my
regular reasoning. It must be acknowledged, however, that
almost all the opinions, either ancient or modern, respecting
fire, may be divided into two classes: for some of them at-
tracted that fire was nothing more than a violent agitation,
in some unknown manner, of the parts of burning bodies,
whilst others attributed it to something peculiar, and sui-
generis which either existed in all combustible bodies, or
was communicated to them. The former, which is called
the mechanical hypothesis, was believed and maintained by
the most able philosophers of much earlier, and much more
enlightened times. Bacon, Boyle, and Newton, were of
that opinion; and there seems to have existed a considera-
bly纠纷 between those differing persons, and some cele-
bated chemists of those times, who maintained that fire
was a fluid of a peculiar nature. The former asserted that
the phenomenon of fire could be accounted for on the suppo-
sition that fire consisted in nothing more than the violent
agitation of the parts of the bodies concerned; but as no
such motion could be produced without an adequate cau-
sed, they were considerably perplexed by it, and, in fact,
their attempts towards an explanation are very confounded.
Boyle says that when a piece of iron becomes hot by hammering,
"there is nothing to make it so, except the forcible motion
of the hammer impressing a vehement and variously deter-
mined agitation on the small parts of the iron." — It is to
be remarked, that the same Mr. Boyle, on observing the
phenomena of the metallic bodies acquiring additional
weight by their calcination, was induced to publish a treat
ise on the possibility of rendering fire and flame ponderable.
Bacon defines heat, (which he considers as meaning the
same thing as fire) to be " an expulsive undulatory motion
in the minute particles of a body, whereby they tend with
some rapidity from a centre towards a circumference, and
at the same time a little upwards." Newton did not at-
tempt to afford any thing positive concerning it; but he con-
jectured that gross bodies and light might be convertible
into one another; and that great bodies of the size of our
earth, when violently heated, might continue and increase
their heat by the mutual action and reaction of their
parts.

The first of the chemists who attempted to form chemis-
try into a regular system, was John Josephus Beccher, but
the famous George Ernest Stahl, (who was born in the
year 1660, and died in the year 1734,) by following
Beccher's plan, continued to raise the science, endeavouring
to collect the principal facts then known into a coherent
system, by connecting them by means of general principles.
This intelligent man, among other improvements, formed
the famous phlogistic theory of fire (see the article Com-

5 BUSTION)
FIRE.

Inflammation, which was almost universally adopted, notwith-standing its insufficiency to account for some of the most essential phenomena of combustion. This theory continued in vogue until towards the close of the last century, when a new theory of chemistry, and a new theory of fire, was announced to the world by the immortal Lavoisier, who unfortunately died in the year 1794. His hypothesis, which he called the combustion theory, was based upon the idea that all forms of matter could be converted into a gaseous state. This hypothesis was supported by experiments conducted in laboratories and in the field. His work was revolutionary, and it was a key moment in the development of chemistry and the understanding of fire.

Since the publication of Lavoisier's hypothesis, or rather established theory, an objection, apparently of importance, has been made to it by Count Rumford, in consequence of some experiments which he made upon friction. This gentleman found, that in boring a cannon during half an hour, the temperature was raised 78°; and that it suffered a loss of 837 grains by the dute and scales torn off, which amounted to 74 per cent of the cylinder. He then, calculating upon the supposition that all the heat so raised was given out by these scales and dute, concludes that they must have lost 663½° of temperature; when at the same time he found that their specific heat was not thereby sensibly diminished. This observation made him doubt the existence of the calorific propelled by Lavoisier, as a principle in the universe, &c. and prompted him to make certain unwarrantable queries respecting the nature of fire; but he omitted to notice a very material circumstance; namely, the compression which the whole piece of metal suffered in consequence of the boring; hence Mr. Dalton justly says, "the heat excited does not arise from the scales merely, else how should hammering make a body red-hot without any loss of scales?" The fact is, the whole mass of metal is more or less condensed by the violence used in boring, and a rise of temperature of 70°, or 100°, is too small to produce a sensible diminution in its capacity for heat. Does Count Rumford suppose, that if in this case the quantity of metal operated upon had been one pound, and the dute produced the same as above, that the whole quantity of heat evolved would have been the same? The word fire has also been used both figuratively and incorrectly. The allegorical expressions of the fire of the imagination, the fire of youth, the fire of contention, and so forth, do not fall under the cognizance of natural philosophy; but the scientific use of that word for expressing heat without light, or light without heat, or fire, things which have neither heat nor light, is in want of correction. Thus phlogisticaceous substances, like certain pieces of decayed wood, fat, etc. are frequently said to be on fire; whereas they are not attended with any degree of heat. Also the heat of fermenting substances, and of other kinds of chemical combinations, has often been called fire. But the most singular use of that word is its being often employed for expressing the electric fluid, which in its quietest state has neither heat nor light. It is true that in a vast number of electrical experiments fire is actually produced, and every electric spark is capable of setting fire to certain inflammable bodies. A very small spark of electricity, such as indeed may appear not bigger than a pin's head, is sufficient to inflame hydrogen gas. But it must be considered that the effects of fire take place only when the electric fluid is obliged to pass through certain substances which in some measure obstruct its free motion. A Leyden phial fully charged with electricity, and left unsealed, does not show the least perceptible mark of light or of heat, more than a similar phial not charged with electricity. Let the charged
of the goddess Vesta (or Vesta) and of fire was brought
into Italy by ~Neus and the other Trojans, who landed
there, but the Phrygians themselves had received it from
the eastern nations. Fire was held in religious veneration
among the Gauls; and similar sentiments and practice have
prevailed in several countries of America.

The Hebrews kept up the holy fire in the temple. This
holy fire descended from heaven, sittl upon the altar in the
tabernacle at the consecration of Aaron and his sons to
the priesthood, Lev. x. 24, and afterwards it descended
anew on the altar in the temple of Solomon, at the consecra-
tion of that temple, 2 Chron. v. 1. And there it was con-
stantly maintained by the priest day and night, without suf-
fcring it ever to go out; and with this all the sacrileges were
offered that required fire. This fire, according to some of
the Jewish writers, was extinguished in the days of Manasseh;
but the more general opinion among them, is, that it con-
tinued till the destruction of the temple by the Chaldeans;
after that it was never more restored; but instead of it they
had only common fire in the second temple.

The Vejials were appointed expressly to keep up the
sacred fire of the Romans. See VESTALS.

Vulcan was worshiped among the ancients, and partic-
ularly the Egyptians, as the inventor of fire; and Boerhaave
has made it highly probable, that the Viking of the he-
thens was the Tubal-Cain of the Hebrews, the first who ap-
ppears to have known the use of fire, and to have applied it
in the fusion of metals and other preparations of chemistry.
See PROMETHEUS.

FIRE, Divination by. See PYROMANCY.

FIRE, in the Manege. To give the fire to a horse is to
apply the firing-iron red-hot to some preternatural dwelling
in order to disfus it, which is oftentimes done by clapping
the firing-iron upon the skin without piercing through.
We give the fire to farcy knots, by running a pointed burn-
ing iron into the ules. We likewise give the fire for
wrenches of the patterns. See Firing-iron.

FIRE, in the Military Language, is sometimes applied to
the fires lighted in an army in the night-time.

But the term fire or firing is more frequently used for the
discharge of the fire-arms, or the shot made on the enemy
from the artillery, &c. And accordingly it is used as a word of command to soldiers of all denominations to
discharge their fire-arms, grenades, cannon, &c. The
fire of the infantry is by a regular discharge of their
fire-locks, by plateaus, divisions, &c. that of the ca-
vahry with their fueves and pistols; and that of the
place besieged from their artillery. See Exercise and
Firing.

In fortification, the fire of the place denotes the flank, or
that part of the curtain where the line of defence terminates
from whence they fire to defend the opposite face of the
battlements.

FIRE-ARMS, a term attaching to all weapons, principally
of an offensive nature, from which bullets, &c. may be im-
pelled by the force of gun-powder. There are generally
divided into two species, the one requiring much labour to
transport, and known by the names of artillery, ordnance,
cannon, great-guns, &c. and again subdivided into calibres,
such as the mortar, the howitzer, the culverin, the demi-
culverin, the royal, &c. &c.; the other species are made on
a portable principle, and comprise those implements com-
monly called muskets, carbines, match-locks, arque-
bulles, blunderbusses, fullets, together with pistols of var-
ious sizes and descriptions; forming in the whole an ample
catalogue of inventions limited to enabling the human race
not only to defend itself against beasts of prey, and to attain
provisions from among the several inhabitants of the earth,
the air, or the waters, but to destroy each other whole-
fale; as though we were afraid that our increasing population
should ultimately condemn us either to starvation, or to
revert to the most horrid means of supporting existence, viz.
Cannibalism.

In treating of ARTILLERY, we have already explained the
nature of ordinance in general, and shewn the proportions
severally of the different natures, as the various sizes are
technically called; therefore, in this place our attention
will be chiefly directed towards those matters relating to
fire arms in general; by which we mean to be understood
as applying to that term to those lighter weapons popularly called
"small-arms."

The several nations of Europe, among which the arts
have made such rapid progress, have long since banished the
more rude and uncertain mode of igniting the powder in
the priming pan by means of a match, which being formed of
some substance that retains fire, but burns very slowly,
could merely, by the motion of a small lever, acted upon by
a finger, he applied thereto. This method is, however,
very generally retained among the nations of the East; where
the bark of the prunus, an indigenous tree every where
abounding, supphes the palolet, or match, in very great
perfection; merely by causing the threads stripped off from
the leffer branches to be beaten with a heavy iron mall, or
hammer, in the course of its drying, which it does in a few
days; the fibres are then twisted to about the thickness of a
fawn's quill, and to any length that may be judged necessary;
the spare part being allowed to hang down at the side of the
lock, or lever. The use of matches is not only attended with
great delay, but, in consequence of the multiplicity which
exists before applying it to the pan, ball, and, in many instances, subject the operator to danger,
or eventually to accidental contact, between the sparks and
the firing.

Match-locks, such as are in Hindoostan, which, including
China and Tartary, may be considered their head-quarters,
are not applied to the shoulder when about to be discharged;
but having a long fock, of a batten-form, are placed under
the arm. This takes off the recoil; or rather causes it
not to be felt; an object of some importance when it is
known that these pieces are generally charged heavily; and,
that on account of the scarcity of lead, malleated iron balls
are in general use: these, being very rough, require to be
rammed down very hard, otherwise they would remain in
the upper part of the bore, and subject the barrel to be
burr'd, as very frequently happens in consequence of the im-
perfection of the balls makes in its course through a long
bore, every where presenting an unfinished surface. On
the other hand it is to be remarked, that match-locks
throw balls to great distances, and, owing to the deliberate
manner in which they may be discharged, without any tug
at a flint trigger, or the fear of a kick from the butt, are
found to do immense execution; most of those persons who
use them are, indeed, as expert as the generality of rifle-men.
Many of these pieces are so long and heavy, as to require
moveable reels: tho' mounted as wall pieces, and called jin-
jauls, often throwing a ball near a mile, and weighing from
fifty to sixty pounds.

The muskets in use among the armies in Europe are far
more compact, carrying a larger ball, and in every respect
better finnished. These are provided with spring-locks,
which impel the flint towards a steel plate, called the hammer,
by which the spars are directed into the pan. It is
to be regretted that the flint usually provided for our mili-
tary are not of a better quality; so as to infure their striking
fire
FIRE.

Fire with greater certainty. Our fire-locks are indeed far too heavy, for which it is assigned as a reason, that lighter pieces would not send the balls to a sufficient distance; but if we consider the well ascertained fact, that not one musket ball in an hundred strikes upon an opposing line of troops, we certainly should set our minds rather more at ease, on the score of impetus in a weapon so very little contributing to the success of the day. It may not be too much to assert, that the decrease of weight, whereby fatigue and labour would be greatly lessened, would enable our brave foikers to act with greater promptitude in general, and to use their bayonets, which are really efficient in their hands, with more activity and vigour.

English fire-arms of every kind are made to the greatest perfection; their bores being perfectly smooth, and the locks remarkably neat, strong, and active. The sizes of the balls are all regulated when for public service; being cast in moulds of particular diameters; so that no mistake can be made, malefactors through shameful neglect, in supplying ammunition to the several corps. The British standard is as follows:

<table>
<thead>
<tr>
<th>Nature of the Piece</th>
<th>Number of Balls to one Pound of Lead</th>
<th>Diameter of each Ball in Inches</th>
</tr>
</thead>
<tbody>
<tr>
<td>Wall Pieces</td>
<td>6 1/2</td>
<td>.89</td>
</tr>
<tr>
<td>Muskets</td>
<td>14 1/2</td>
<td>.68</td>
</tr>
<tr>
<td>Carabines</td>
<td>20</td>
<td>.60</td>
</tr>
<tr>
<td>Pitols</td>
<td>34</td>
<td>.51</td>
</tr>
<tr>
<td>7 Barrel Guns</td>
<td>46 1/2</td>
<td>.46</td>
</tr>
</tbody>
</table>

In order to preserve a regularity in the supply of balls for pieces not on any regular scale, or establishment, it is usual to ascertain what ball will fit the bore in a proper manner, so as to allow of four folds of paper, (i.e. two on each side,) necessary to wind around the ball when made into a cartridge. The ball is then tried in a gauge, that is, a bar pierced with holes, all declining in size, in regular order, and numbered from one, which fits a wall-piece, to buck-shot; which is ordinarily estimated at about No. 32 or 32. Whatever hole the ball may pass through, but in so close a manner, as to flop in the next smaller hole, gives the designation of the bore on the registrar. But it is more usual to cast balls in moulds, designated according to the number of balls of that size made from a pound of lead. Therefore musket balls would be called No. 14, and carabine balls No. 20.

The mention of seven-barrelled-guns leads us to contemplate, with no slight admiration, the perfection to which this branch of mechanism has been brought! This perfection has naturally been produced by successive stages, each of which has had numerous candidates, to whom public liberality has been the inducement, and proved the reward. When we consider that a man provided with a musket having seven barrels, yet but one lock, may discharge seven times in less than half a minute, without any intermediate operations of priming or loading, we must yield our tribute of applause to the ingenuity of the inventor, though we cannot refrain from reflecting on that purpose to which it is devoted.

As to pistols, &c. they are made upon various scales, and for the particular purposes of those who are to use them. Thus, what we call horse-pistols, are intended to occupy the holsters attached to saddles; duelling-pistols, which are usually provided with hair-trigger, that act upon the slightest touch, are defined to the decision of those knotty points at which honour so speedily takes umbrage; while the pocket-pistol, made upon a diminutive scale, may be intended either for the use of the robber, or to repel his presumption. Whatever may be the purpose of fire-arms, whether for the military, for sporting, or for general defence, nothing can be more improper than leaving them loaded in places accessible to servants, strangers, and especially to children. We should suppose that the immense number of accidents that happen, and are publicly notified in the daily prints, might operate as a stimulus towards the secularising of fire-arms, beyond those ordinary means of accessibility, which place them within the reach of every one whose ill-fated curiosity may induce to handle them. Strange to say! we shudder at the detail of one of those accidental murders which too often occur, yet neglect to benefit by the melancholy lesson, until some domestic calamity of the same nature may burthen the negligent proprietor with shame, affliction, and remorse.

Fire-arrow is a small iron dart furnished with springs and bars, together with a match impregnated in powder and sulphur, which is wound about its shaft. It is used by privateers and pirates to fire the tails of the enemy, and for this purpose is discharged from a musket or a swivel-gun. The match being kindled by the explosion, communicates the flame to the tail, against which it is directed, where the arrow is softened by means of its bars and springs. This is peculiar to hot climates, particularly the West Indies, the arrows being extremely dry, are instantly set on fire, and the fire is conveyed to the masts, rigging, and finally to the vehicle itself.

Fire-ball, a composition of meal-powder, sulphur, salt-petre, robin, pitch, &c. about the bigness of a hand-grenade, made of an iron fleet, filled and covered over with several coats of the above mixture, the last coat being of ground powder. Thick brown paper made into the form of a shell adapted to the size of the mortar, and filled with an equal quantity of sulphur, pitch, robin, and meal powder, well mixed and put in warm, will answer the purpose as well as any thing else. This is to be thrown into the enemy's works in the night-time, to discover where they are; or to fire houfes, galleries, or blinds of the besiegers. The balls used for this intention are prepared with meal powder, salt-petre, sulphur, robin, steel or iron filings, fir-tree sawdust boiled in salt-petre ley, and birchwood charcoal, well rammed into a shell, having various holes filled with small barrels, loaded with musket-balls, and immered in melted pitch, robin, and turpentine oil. They are sometimes armed with spikes or hooks of iron, that they may not roll off, but flick or hang where they are desired to have any effect. See Balls.

Fire-barc, in our Old Writers, is used for a beacon. "Quod fine dilatatione levari & reparari facigna & firebars, super montes altiores in quolibet hundreds, jam quod tota patria per illumigna, quondam unicum hunc aerifum prae- munire potest." Ordin. Observand. Temp. Edw. II.

Fire-barrels, See Barrels, and Fire-flips.

Fire-blight, a disease or accident to which the hop plant is much exposed. It chiefly occurs towards the latter periods of the growth of the crops. It is suppoft by most hop-planters to depend upon the particular state of the air or weather at the time; but it is more probable that it may be caused by lightning, as it takes place very suddenly at those seasons when it most prevails, and generally affects the most forward and luxuriant plants. See Hops.

Fire, bon. M. Mahudel has a dissertation on the origin of bon-tires, wherein he endeavours to make it appear that they were unknown to the ancients, and consequently must be a modern invention.
FIRE.

He does not deny that the ancients had rejoicings on occasion of the conclusion of a peace or alliance, or the news of a victory's being obtained against their enemies; on the birthday, proclamation, or marriage of their prince; as also when they recovered from a dangerous sickness; but, according to him, the fire on all these occasions served only to burn the victims or the sacrifices; and as these sacrifices were usually offered in the night-time, the illuminations were only intended to give light to perform the ceremonies.

Fire-works, a term signifying a quantity of wood bound up for fuel, which, by the common law, the tenants may, for necessity, take out of the lands that have been granted to them.

Fire-clay, is that particular kind of clay which is proper for making bricks or tiles intended to stand a high degree of heat. The third kind is made of argilaceous clay, between the third and fourth grit rock, reckoning from the mill-wood grit upwards, which travels Derbyshire and part of Yorkshire, and produces heart-fine and foidite in great abundance, contains a very excellent fire-clay, which is dug at Heazle-nether-end, Whicker, Dickin Lane, and other places. The fillings of the fourth or lower strata of this district sometimes produce admirably maffes of fire-clay, of good quality, as at Mill Hill gate, near Water-loo, Staffordshire, and near New-haven, Derbyshire.

It is found that clay, more or less fit for fire-bricks, is found immediately beneath almost every seam of coal, and where it is not felt in the form of clay, the chine and other indurated substances composing the immediate floor of coal, will generally fall by exposure to the weather, into a brick clay or earth. See Floor.

Fire-cocks. Churchwardens in London, and within the bills of mortality, are to fix fire-cocks at proper distances in streets, and written marks near them, and to keep in every house thus marked an instrument or key for opening the plug, and a large engine and hand-engine for extinguishing fire, under the penalty of $10. The turn-cock whole water shall come first into a main-pipe at a fire, shall have 102. the first engine that is brought shall entitle to 32d. the second to 20s. and the third to 10s. 6d. Ann. cap. 31. 12 Geo. III. cap. 73. To prevent fires, it is required that workmen in the city of London, &c. build all front and rear walls of brick or stone; and that the front walls be 18 inches above the gutter, and coped with stone, tile, or brick; and party-walls between house and houses, those belonging to houses, the expense of building which is more than 120. to be of the thickness of 1 foot nine inches, or 2½ bricks in the lowest story; and of 2 bricks, or 1 foot 6 inches from thence to the garret floor; and from the garret upwards 1 brick, or 13 inches, and to be carried up to the full height of 18 inches above the adjoining gutters; and it is also required, that no timbers, except the girders, binding and tying joints, and the tempels under the same, shall be laid into such party-walls; and that there shall be 5 inches of solid brick-work laid left at or between the ends of all lintels, wall-plates, and bond timbers. See Building, and lat. 7 Am. c. 17. 11 Geo. i. c. 28. 33 Geo. ii. cap. 50. and 4 Geo. iii. cap. 144. And on the breaking out of any fire, all the contained and liberties shall repair to the place with their lances, and be affilling in putting out the same, and causing people to work, &c. No action shall be had against any person in whose house or chamber a fire shall begin, 6 Am. 10 Am. c. 14. But if such fire happens through negligence of any servant, such servant shall forfeit 10s. to be distributed among the sufferers; or, in default of payment, shall be committed to some work-house, and there kept to hard labour for eighteen months. See Arson.

All the laws relating to the prevention, &c. of fire, are reduced into one statute, and former statutes repealed, by 12 Geo. III. cap. 73.

FIRE-damp, in Natural History. See DAMP.

Fire-breakers. We have a great number of mountebanks who have procured the attention and wonder of the public by eating of fire, walking on fire, washing their hands in melted lead, and the like tricks.

The most celebrated of these was one countryman Richardson, much talked of abroad. His secret, as related in the Journals des Sciences of the year 1780, consisted in a pure spirit of sulphur, wherewith he rubbed his hands and the parts that were to touch the fire, which burning and captivating the epidermis, hardened and enabled the skin to refill the fire.

Indeed this is no new thing; Am. Paré affirms he had tried on himself, that after washing the hands in urine, and with unicorn's urine, one may safely wash them with melted lead.

He adds also, that by washing his hands in the juice of onions, he could bear a hot shovel on them while it melted hard.

Fire, Electrical. See Electricity.

Fire-engine, is a machine for extinguishing accidental fires by means of a stream of jet of water. The common fire-engine consists of a lifting pump placed in a circular or cylindrical vessel of water, and brought by two levers that act always together. During the stroke, the quantity of water raised by the piston of the pump spouts with force through a pipe joined to the pump-barrel, and made capable of any degree of elevation by means of a yielding leather pipe, or by a ball and socket turning every way, screwed on the top of the pump. The vessel containing the water is covered with a strainer, which prevents the dirt and filth poured into it with the water from choking the pump-work. Between the strokes of this engine the stream is discontinued for want of an air-vessel. However, in some cases, engines of this confection have their use, because the stream, though interrupted, is much finer than when the engine is made to throw water in a constant stream. The ball engine of this latter kind is that of Mr. Newsham, formerly an engine-maker in London. A perspective view of the whole engine, ready for working, is represented in Plate III. Hydraulics, &c. fig. 4.

This engine consists of a cylinder A B, about three times as long as it is broad, made of thick oak planks, the joints of which are lined with sheet-copper, and easily moveable by means of a pole and cross bars C in the fore part of the engine, which is so contrived as to slide back under the cover of the cylinder, and on four fold wheels, two of which are seen at D and E. The hind axle-tree, to which the wheel D and its opposite are fixed, are fattened across under the bottom of the cylinder; but the fore axle-tree, bearing the wheel D, &c. is put on a strong pin or bolt, strongly fattened in a horizontal situation in the middle of the front of the bottom of the cylinder, by which contrivance the two fore wheels and the axle-tree have a circular motion round the bolt, so that the engine may stand as firm on rough or sloping ground as if it was level. Upon the ground next to the hind part of the engine may be seen a leather pipe F, one end of which may be screwed on and off upon occasion to a brass cock at the lower end of the cylinder: the other end is immered in the water, supplied by a poad, fire-plug, &c. and the pipe becomes a sucking pipe for furnishing
the pumps of the engine by its working, without pouring water into the cistern. To the hind part of the cistern is fastened a wooden trough G, with a copper grate for keeping out stones, sand, and dirt, through which the cistern is supplied with water when the sucking pipe cannot be used. The fore part of the cistern is also separated from the rest of its cavity by another copper grate, through which water may be poured into the cistern. Those that work the pumps of this engine move the handles visible at the long sides, up and down, and are assisted by others who stand on two suspended trestles, throwing their weight alternately on each of them, and keeping themselves steady by taking hold of two horizontal rails, H, I, framed into four vertical stanchions, which reach to the bottom of the cistern, and are well secured to its sides. The hind trough there is an iron handle or key K, serving to open or shut a cock placed under it on the bottom of the cistern, the use of which we shall explain in the sequel of this article.

L is an inverted pyramidal box or cafe which preserves the pumps and air-veils from damage, and also supports a wooden frame M, on which stands a man, who, by grading or depressing, and turning about the spout N, directs the stream of water as occasion requires. This spout is made of two pieces of brass pipe, each of which has an elbow; the lower is screwed over the upper end T (see fig. 5) of the pipe that goes through the air-veil, and the upper part forms a joint, which, after a screw of several threads, is so truly turned as to be water-tight in every situation. The narrow form of the spouting-pipe serves for wire-drawing the water in its passage through it, which occasions a friction that produces such a velocity of the jet as to render it capable of breaking windows, &c. whilst the valves and-leathern pipes of the engine have sufficient water-way to supply the jet in its greatest velocity. Leather pipes of considerable length may be screwed at one end of the nozzle of the engine, and furnished at the other end with a wooden or brass pipe for guiding the water into the inner apartments of houses, &c. Between the pyramidal box L, and the fore-end of the engine, there is a strong iron bar O, lying in a horizontal position over the middle of the cistern, and playing in braces supported by two wooden flanks; one of which, P, is placed between the two fore-flanks of the upper rails, and the other is hid in the enclosure over the hind part. Upon proper spigots of these bars are fitted, one near each end, two strong hose bars, which take hold of the long wooden cylindrical handles, by means of which the engine is worked; and the trestles by which they are affixed are suspended at each end by chains in the form of a watch chain, and receive their motion jointly with the handles that are on the same side, by means of two circular sectors of iron fastened together, and fixed upon proper spigots of the middle horizontal bar; the two fore ones may be seen at Q; the two hind ones represented on a large scale in fig. 6 differ from the former only in thickness; for the fore sectors are made to carry only one chain each, fastened by one end to their upper part, and by the lower end to the trestles; whereas the pole of the two hind sectors is wide enough to carry two chains each; one end fastened like those of the fore ones for the motion of the trestles; and the other two chains are fastened by their lower ends to the lower part of these sectors, and by their upper ends to the top of the pinion bars, in order to give them motion. See fig. 6, in which the hind sectors and their apparatus are represented as they would appear to a person standing between the two fore-wheels, and looking at the hind part of the engine. The square over the letter A is the section of the middle bar, on which, right over the two barrels, are placed the two sectors BCA and DEA, forged together. E G H K and J  6 are the two pinion rods; and the openings between the letters G, H, and J, &c., are the spaces through which the hind parts of the two trestles pass. L and M represent two strong, and rivetted on the other side of the bars on which they are placed; and to each of these is fastened a chain like a watch-chain, fixed by their upper ends to the upper extremities D and B of the iron sectors, by which they are drawn up and down alternately. These sectors give also an alternate motion up and down to the pinion-rods, by means of two other chains that rise below the figure, in order to distinguish them from the others; these are fastened by their lower ends to the lower extremities of the sectors E and C, and their upper ends terminating in a male screw, are made tight to the pinion-rods at I and J, by two nuts. The shape of the pinion-rods, and the use and situation of the chains that give them motion, are so contrived, that the vertical axis of the pinions is exactly in the middle of the breadth of the perpendicular part of the chains, and the upper part of the pinion-rod taken together P Q represents one of the two crofs bars through the ends of which pass the long handles to which the men apply their hands when they work the engine; these crofs bars are fitted on the middle bar at some distance from the sectors.

The other parts of this useful engine may be understood by the help of fig. 5, which represents a vertical section taken through the middle line of the hind part of the engine, as also the section of the air-veil, and that of one of the barrels, and likewise the profiles of the hind sectors, and of several other parts. A B is the section of the bottom of the cistern, and C that of the Lindsmith axle-tree. D E is the vertical section of a strong piece of cast brass or hard metal, so worked as to have a hollow in it, represented by the white part, and fixed to the bottom of the cistern; this reaches from the opening D through the cock W, and afterwards divides itself into two branches, so as to open under the two barrels; one of these branches is exhibited in the figure, and the other is exactly behind this. Through this channel, which may be called the sucking-piece, water is conveyed to the pumps by the pressure of the atmosphere, either from the cistern itself, or from any place at a distance, by means of a leathern pipe F, fig. 7, which screws on to the sucking-piece at D, fig. 5, under the hind trough Z, the grate of which is represented by the horizontal strokes. F G represents the vertical section of another piece of cast brass or hard metal that may be called the communicating-piece, having two hollows for conveying the water from under the two pinions to the two openings of the flanch of the air-veil; one of these hollows appears in the figure; the other lies exactly behind this, though not in a parallel direction. Between the section of the sucking-piece D E, and that of the communication-piece F G, may be observed the section of one of the plates of leather, which makes all tight, and forms one of the two sucking valves, of which there is another just behind this under the other barrel. R S T is the section of the copper air-veil, and T V that of the conduit-pipe; this veil is pierced on to the hind part of the communication-piece, and at top is fastened by a collar of iron to a crofs piece of timber. Between the flanch of the air-veil and the communication-piece may be observed the section of one of the plates of leather, making all tight, and forming one of the two forcing valves, of which there is another just behind this, exactly over the other opening of the communication from the air-veil. These valves are located.
with a lump of cast iron or lead, having a tail or teat let through the flap of the valve and cros-s-pinned under it; and it is to be observed, that though both the valves are represented open in the figure, they are never both open at the same time; for when the engine is at work, they are closed down by the weights on their upper surfaces; and when the engine works, two are shut, and the other two are open alternately by the motion of the pistons and the action of the atmosphere, together with the reaction of the air contained in the air-vessel. \( H \) is the section of one of the barrels of the two pumps, which are both fucking and forcing, as is evident from the position of the valves and the structure of the pistons, each of which is composed of two iron plates, of two wooden treceners, and of two flat pieces of leather turning one up and the other down. \( L K \) represents one of the piston-rods edge-wise, behind which is one of the chains, the top screw of which, \( K \), can only be seen. \( M \) is the end of the middle bar, and \( N \) a section of the hind-mold of the two middle-stands which support the middle bar. \( O \) represents the end of the profile of one of the treceners, passing through the rectangle-shaped holes of the piston-rods, as in fig. 8. The weights on these treceners bring them and the piston-rods down alternately, and they are raised up again by help of the other set of chains, one of which may be seen edge-wise in this figure, placed on the side of one of the factors, &c. See fig. 6.

\( P Q \) is part of the cross bars which carry the handles of the edge-wise, and \( X Y \) represents an iron handle, by the help of which the cock \( W \) may be placed in the several situations requisite for the use of the engine. The mechanism of the cock \( W \) may be understood by figs. 9, 10, and 11, which represent the horizontal section of it in three different situations. It has three holes that are left white in these figures. In fig. 9, the position of the cock is represented when the handle \( X Y \) or \( K \) is in a direction parallel to \( D E \), or to the middle bar, as in fig. 5, and fig. 4. In this position, the water supplied by the fucking-piece enters at \( D \), and proceeds directly through the cock \( W \) to the valve under the two pistons; and there is now no communication from the barrels with the cavity of the cistern. In fig. 10, we have the position of the cock when the handle \( X Y \) is turned one quarter of a revolution towards the eye from the last mentioned situation, in which case there is no communication from the barrels with the outer extremity of the fucking-piece, but the water poured into the fore and hind trough, and passing from thence into the cavity of the cistern, enters the cock edge-wise at \( W \), and, turning at right angles through the cock towards \( E \), proceeds to the barrels of the pumps. Fig. 11, represents the cock \( W \) when the handle is placed diametrically opposite to its last situation, in which case there is no communication from the under-side of the barrels with the cavity of the cistern or the outward end of the fucking-piece; but this situation affords a communication from the cavity of the cistern with the outside of the engine, and the water left in the cavity of the cistern may by this means be employed when the engine has done working. These engines are made of five or six different sizes. See Defaguer's Course of Expnr. Philos. vol. ii. p. 505—518.

The principles on which this engine acts, so as to produce a continued stream, are obvious; the water, being driven into the air-vessel, as in the operation of common fucking and forcing pumps, will comprize the air contained in it, and proportionably increase its spring, since the force of the air's spring will always be in inverse as the space which it possesses; therefore, when the air-vessel is half filled with water, the spring of the included air, which in its original state is counterbalanced by the pressure of the atmosphere, being now compressed into half the space, will be equal to twice the pressure of the atmosphere; and by its action on the subjacent water will cause it to rise through the conduit-pipe, and to play a jet of 32 or 33 feet high, abating the effect of friction. When the air-vessel is two-thirds full of water, the space which the air occupies is only one-third of its first space; therefore its spring being three times as great as that of the common air, will project the water with twice the force of the atmosphere, or to the height of 64 or 66 feet. In the same manner, when the air-vessel is three-fourths full of water, the air will be compressed into one-fourth of its original space, and cause the water to ascend in air with the force of three atmospheres, or to the height of 96 or 99 feet, &c. as in the following table:

<table>

</table>

The fire engine, by Rowntree, is a double-forece pump, of a peculiar construction, similar in its action to the beard-engine, but as it is on a much larger scale, its constructions are of course varied. In this engine, figs. 1, and 2.

Plate IV. Hydraulics, are two elevations at right angles to each other, of the external part of the engine mounted on four wheels. Figs. 3. and 4. are two sections perpendicular to each other, of the body of the engine or pump; figs. 5. and 6. are parts of the engine. The fame letters are used as far as they apply in all the figures, \( A, A, A \); \( A \); figs. 3. and 4. is a cast-iron cylinder truly bored, ten inches diameter and fifteen long, and having a flanch at each end whereby to screw two covers, with flushing boxes, \( a, a \), in their centres, through which the spindle, \( B, B \), of the engine palfes, and being tight packed with hemp round the collar, makes a tight joint; the piston, \( D \), is affixed to the spindle within the cylinder, and fits it tight all round by means of leathers; at \( E, A, B \); fig. 4, a partition, called a faddle, is fixed in the cylinder, and fits against the back of the spindle tight by a leather.

We have now a cylinder divided by the faddle, \( E \), and piston, into two parts, whose capacity can be increased and diminished by moving the piston, with proper passagies and valves to bring and convey away the water; this will form a pump. These passagies are caue in one piece with the cylinder; one, \( d \), for bringing the water is square, and extends about 34 round the cylinder; it connects at bottom with a pipe, \( e \); at its two upper ends it opens into two large chambers, \( f, g \), extending near the whole length of the cylinder, and closed by covers, \( h, k \); screwed on; \( i, k \), are square openings (shown by dotted squares in fig. 3.), in the cylinder communicating with the chambers; \( f, h, m \), are two valves, closing their ends of the curved passage, \( d \), and preventing any

water
water returning down the passage, \( d \), \( n, o \), are two passages from the top of the cylinder to convey away the water; they come out in the top of the cylinder, which, together with the top of the chambers, \( f, g \), form a large flat surface, and are covered by two valves, \( p, q \), to retain the water which has passed through them. A chamber, \( K \), is screwed over these valves, and has the air-vessel, \( k, \) fig. 1. and 2. screwed into its top; from each side of this chamber a pipe, \( r, r, \) proceeds, to which a hole is screwed, as shown in fig. 1. Levers, \( x, x, \) are fixed to the spindle of each end, as shown in fig. 1, and carry the handles, \( H, H, \) by which men work the engine. When the piston moves, as shown by the arrow in fig. 4, it produces a vacuum in chamber, \( f, \) and that part of the cylinder contiguous to it; the water in the pipe, \( e, \) then opens the valve, \( m, \) and fills the cylinder. The same motion forces the water contained in the other part of the cylinder through the valve, \( q, \) into chamber, \( K, \) and thence to the hole through the pipe, \( r, \) the piston being turned the other way, reverses the operation with respect to the valves, though it continues the same in itself. The pipe, \( e, \) is screwed by a flanich to an upright pipe, \( P, \) fig. 5, connected with another square iron pipe, fastened along the bottom of the chest of the engine; a curved brass tube, \( G, \) comes from this pipe through the end of the chest, and is cut into a screw to fit on the suction hole when it can be used; at other times a close cap is screwed on, and another brass cap at \( H, \) within the chest, is screwed upwards on its socket, to open several small holes made in it, and allow the water to enter the pipe; in this case the engine chest must be kept full of water by buckets. The valves are made of brass, and turn upon hinges. The principal advantage of the engine is the facility with which it is cleaned from any sand, gravel, or other obstructions, which a fire-engine will always gather when in use.

The chambers, \( f, g, \) being so large, allow sufficient room to lodge a greater quantity of dirt than is likely to be accumulated in the use of the engine at any one fire, and if any of it accidentally falls into the cylinder, it is gently lifted out again into the chambers by the piston, without being any obstruction to its motion; to clear the engine from the dirt, two circular plates, \( r, r, \) five inches diameter, are screwed from the lids, \( b, b, \) of the chambers, \( f, g, \), and when cleaned are screwed on again; these screw covers fit perfectly tight without leather, and can be taken out, the engine cleared, and enclosed again in a very short time, even when the engine is in use, if found necessary.

The two upper valves, \( p, q, \) and chamber, \( K, \) can also be cleared with equal ease, by screwing out the air-vessel, \( k, \) fig. 1, which opens an aperture of five inches, and fits airtight, without leather, when closed. The valves may be repaired through the flame aperture. The use of the air-vessel, \( k, \) fig. 1 and 2, is to equalize the jet from the engine during the short intermittence of motion at the return of the piston stroke; this it does by the efficacy of the compressed air within it, which forces the water out continually, though not supplied quite regularly from the engine.

The engine from which our drawing was taken was made for the Sun Fire Insurance Company, in London, and from some experiments made by their agent, Mr. Samuel Hubert, appears to answer every purpose.

Fire-engine is also a name frequently given to a machine for raising water by steam, more properly called steam-engine, which see.

Fire-escape, a machine for escaping from windows when houses are on fire. Various machines of this kind have been invented by different persons; the following seems to be well adapted to the purpose for which it was designed. It was originally invented by the late John Daniel Massey, esq., and B. M. Potter, esq., has communicated to the public a description of it, with some improvements by himself, in the Philosophical Magazine. The principal parts of this machine, which is called the "flying fire-escape," are as follows:

1. The suspension iron \( A, \) (Plate XII. Miscellany, fig. 12.), which is formed like a ram-head commonly used for slinging goods from warehouses, with this difference, the bottom hooks are turned up close to the upright part, to form two close rings or eyes; the length of this iron is about four inches and a half, thickness of the iron out of which it is hammered is about half an inch.

2. The rope \( B. \) This is made of flax, and plaited in a peculiar manner, for which there was a patent taken out. It is held by Armstrong, St. John's-square, Clerkenwell, and measures about three-eighths of an inch in diameter. The rope must be in length somewhat more than twice the height of the window from the ground.

3. The regulator \( C. \) This is an oblong piece of beech wood, six inches and a half in length, three inches and a quarter broad, and about seven-eighths of an inch thick; in this there are four holes pierced for the rope to pass through; one of these is open at the side; there is also a notch at the top of this piece of wood, and an oblong hole about seven-eighths of an inch from the bottom.

4. The upper belt \( D. \) is a stout leather strap, about four feet three inches long, and one and a half broad, with a buckle to it.

5. The lower belt \( E. \) is a strap of the same sort as the other; but the end, after being put through the buckle, is lowered down: this is for the purpose of security, in case the tongue of the buckle should by accident break.

6. The union strap \( F. \) is called from its connecting the regulator to the other parts of the machine. This is leather, and is about a foot and a half long, and an inch and a quarter broad; it has, like the others, a buckle to it. It is flaxen black, which distinguishes it from the other leather straps.

The method of putting together all these parts of the machine is, first to pass one end of the rope through the holes in the regulator, then through the two lower rings of the suspension iron; the upper belt is then to be passed through a doubling of the union strap; after which the rope is to be tied to that belt, and the knot secured by a string from flipping (which string is to pass through two small holes in the leather); and at about a foot below the rope is to be tied to the lower belt in like manner. Next, the union strap is to be put through the oblong hole in the regulator, and buckled; by which the upper belt and the regulator will be connected. The other end of the rope may be kept wound on a wooden roller, to prevent it from getting entangled.

Persons who purchase these machines should have a very strong iron hook, with a spring catch, fixed to some secure part of the window-frame, or elsewhere; on this hook the suspension iron is to be hung by the upper ring, when any one wishes to descend from the window. The next operation is to step into the lower belt with both feet, and draw it up sufficiently high, so as to form a kind of swing to fit in: the part of the strap which is through the buckle is to be held hold of with the left hand; and the buckle, with the right hand, is to be flint to its proper place, according to the size of the person; the tongue is then to be put into one of the holes, as in buckshag common straps. After this is done, the upper belt is to be somewhat loosely buckled round the chest, and then the rope which is on the roller is to be thrown out over the window on the ground.
Now all being ready for descending, the person is to get out of the window, grasping tight with one or both hands, the rope at some convenient part, taking especial care not to meddle with the suspension iron until quite out of the window; after which the rope below the regulator is to be laid hold of with the right hand, and to be let to run through the holes as fast as there may be occasion; for which purpose, if necessary, it may be easily flipped out of the open hole; it will then have the check of only three holes: if the motion is wanted to be retarded, the rope is to be put into the notch at the upper part of the regulator.

When one person has descended, and there is a necessity for a second immediately to follow, the union strap is to be unbuckled; when the regulator will be separated from the upper belt; the belts may then be very easily drawn up, having the friction of the suspension iron only, and the person above is to put on the belts as the other did, and is to let down gradually, partly by the one below, and partly by managing the rope as the first did: in this case great care must be taken, as the check occasioned by the regulator is gone.

Observations and Cautions.

It is not easy to lay down exact rules for what number of holes the rope must pass through, as this must vary according to the weight of the person, and other circumstances. It would be well, before the person gets out of the window, to examine, first, (absolutely necessary,) whether the suspension iron is on the hook; then, that the three buckles are fast, the two knots tied, and that the rope is in the hole of the regulator which has the opening. Great care must be taken that there is not any impediment to the free running of the rope; for which the wall of the house must be examined, and any nails or hooks which may chance to be there removed; also iron scrapers, and every thing wherein the rope may be likely to hitch.

Mr. B. M. Forster has, in some respects, simplified Mr. Mattei's machine, particularly in substituting the ram-head suspension iron in the place of a more complicated, and, in his opinion, less feeble piece of mechanism. (See fig. 13.) It consists of a solid metal (in the latter improved ones) grooved cylinder, round which the rope coils two or three times, by which a considerable degree of friction was produced, and the rapid descent prevented, which would otherwise happen. The metal cylinder is supported on an iron frame, and suspended by a ring, which ring is moveable in the socket. A is the moveable ring in the upper part of the frame; B is the frame, enclosing the grooved cylinder; and C is a metal bar to hold the checks together.

Fire, Everlasting, in Pagan Theology, is a kind of reputed sacred fire worshipped by the Gavers or Gabres in Persia. Dr. Meunley, formerly physician to the zarrin's army, has given the following account of it: this perpetual fire rises out of the ground in the peninsula of Absheron, about twenty miles from Baku, and three miles from the Caspian shore. The ground is rocky, over which is a shallow covering of earth. If a little of the surface be scraped off, and fire be applied to the hollow, it catches flame immediately, and burns without intermission, and almost without consumption; nor is it ever extinguished unless cold earth be thrown over it, by which it is easily put out. There is a spot of ground, about two English miles in extent, which has this property, where the earth continually burns; but the most remarkable part of it is a hole about four feet deep, and fourteen in diameter. This fire is worshipped, and is said to have burnt many thousand years. The cracks in the walls of the caravanera, inhabited by the religious, are covered with flame, if a candle be held to them; and when there is occasion for a small light, no more is necessary than to flick one end of a piece of reed in the ground, and apply a lighted candle to the other; a flame will kindle at the top of the reed, and burn till it is extinguished by covering it. They burn stones into lime, by filling a hole in the ground with a heap of them, and bringing a lighted candle to the hole, upon which the fire kindles, and in about three days burns the stones sufficiently. The flame yielded by this fire, has neither smoke nor smell. This sacred and adored phenomenon is nothing more than an inflammable vapour, which issues in great quantity out of the ground in this place, and is supplied by the names with which the adjacent country abounds. Phil. Trans. vol. xlv. for 1748, p. 296.

Fire, Extinguishing of. The world has long been of opinion, that a more ready way than that in general use, might be found for extinguishing fires in buildings, and it has generally been attempted upon the doctrine of explosion. Zachary Grevil was the first person who put this plan into execution with any tolerable degree of success. He contrived certain engines, easily manageable, which he proved before some persons of the first rank to be of sufficient efficacy, and offered to discovery the secret by which they were contrived, for a large premium given either from the crown, or raised by a subscription of private persons. But this scheme meeting with no better success than things of this nature usually do, he died without making this discovery. Two years after this, the people who had his papers found the method; and it was shown before the king of Poland and a great concourse of nobility at Dresden, and the secret purchased at a very considerable price. After this the same person carried the invention to Paris and many other places, and practised it everywhere with success. The secret was this: a wooden vessel was provided holding a very considerable quantity of water; in the centre of this there was fixed a case made of iron plates, and filled with gun-powder; from this vessel, to the head of the larger vessel containing the water, there proceeded a tube or pipe, which might convey the fire very readily through the water to the gun-powder contained in the inner vessel. This tube was filled with a preparation easily taking fire, and quickly burning away; and the manner of using the engine was to convey it into the room or building where the fire was, with the powder in the tube lighted. The consequence of this was, that the powder in the inner case soon took fire, and, with a great explosion, burst the vessel to pieces, and dispersed the water every way; thus was the fire put out in an instant, though the room was burning before in all parts at once. The advantage of this invention was, that at a small expense, and with the help of a few people, a fire in its beginning might be extinguished; but the thing was not so general as it was at first expected that it would prove; for though of certain efficacy in a chamber or close building where a fire had but newly begun; yet when the mischief had increased to far, that the house was fallen in, or the top open, the machine had no effect. This was the contrivance first discovered by Grevil, and from which our chemist Godfrey took the hint of the machine, which he called the water-bomb, and would fain have brought into use in England. Act. Eruditorum. anno 1711. p. 183. (See Water-Bomb.) Dr. Hales proposed to check the progress of fire by covering the floors of the adjoining houses with earth. This proposal is founded upon an experiment which he made with a tin basin, half an inch thick, part of which he covered with an inch depth of damp
FIRE.

damp garden mould, and then lighted a fire on the surface of the mould; though the fire was kept up by blowing, it was two hours before the board was burnt through, and the earth prevented it from flaming. The thicker the earth is laid on the floors, the better; however, Dr. Hales apprehends, that the depth of an inch will generally be sufficient; and he recommends to lay a deeper covering on the floors, because the fire commonly ascends by them with the greatest velocity. Phil. Trans., vol. xiv. for 1748, p. 277.

Mr. Hartley made several trials in the years 1775 and 1776, in order to evince the efficacy of a method which he had invented for restraining the spread of fire in buildings. For this purpose thin iron plates are well nailed to the tops of the joists, &c. the edges of the sides and ends being lapped over, folded together, and hammerred close. Partitions, floors, and floors, may be defended in the same manner; and plates applied to one side have been found sufficient. The plates are so thin as not to prevent the floor from being nailed in the joists in the same manner as if this preventative were not used; they are kept from rust by being painted or varnished with oil and turpentine. The expense of this addition, when extended through a whole building, is estimated at about five per cent. Mr. Hartley had a patent for this invention, and parliament voted a sum of money towards defaying the expense of his numerous experiments. (14 Geo. III. cap. 85.) The fame preservative may also be applied to ships, furniture, &c.

Lord Mahon (now earl Stanhope) has also discovered and published a very simple and effectual method of securing every kind of building against all danger of fire. This method he has divided into three parts, viz. under-flooring, extra-lathing, and inter-securiting. The method of under-flooring is either single or double; in single under-flooring, a common strong lath of oak or fir, about one-fourth of an inch thick, should be nailed against each side of every joist, and of every main timber, supporting the floor which is to be secured. Other similar laths are then to be nailed along the whole length of the joists, with their ends butting against each other. The top of each of these laths or fillets ought to be at 1½ inch below the top of the joists or timbers against which they are nailed; and they will thus form a sort of small ledge on each side of all the joists. These fillets are to be well bedded in a rough plaster hereafter mentioned, when they are nailed on, so that there may be no interval between them and the joists; and the same plaster ought to be spread with a trowel upon the top of all the fillets, and along the sides of that part of the joists which is between the top of the fillets and the upper edge of the joists. In order to fill up the intervals between the joists that support the floor, short pieces of common laths, whose length is equal to the width of these intervals, should be laid in the contrary direction to the joists, and cloe together in a row, so as to touch one another: their ends must rest upon the fillets, and they ought to be well bedded in the rough plaster, but are not to be fastened with nails. They must then be covered with a thick coat of the rough plaster, which is to be spread over them to the level of the tops of the joists; and in a day or two this plaster should be trooled over, close to the sides of the joists, without covering the tops of the joists with it.

In the method of double flooring, the fillets and short pieces of laths are applied in the manner already described, but the coat of rough plaster ought to be little more than half as thick as that in the former method. Whilst this rough plaster is laid on, some more of the short pieces of laths above-mentioned must be laid in the intervals between the joists upon the first coat, and be slipped deep in it. They should be laid as close as possible to each other, and in the same direction with the first layer of short laths. Over this second layer of short laths there must be let in another coat of rough plaster, which should be trooled level with the tops of the joists, without rising above them. The rough plaster may be made of coarse lime and hair; or, instead of hair, hay chopped to about three inches in length may be submitted with advantage. One measure of common rough sand, two measures of flacked lime, and three measures of chopped hay, will form in general a very good proportion, when sufficiently beat up together in the manner of common mortar. The hay should be put in after the two other ingredients are well beat up together with water. This plaster should be made stiff; and when the flooring boards are required to be laid down very soon, a fourth or fifth part of quick lime in powder, formed by dropping a small quantity of water on the lime-dine a little while before it is used, and well mixed with this rough plaster, will cause it to dry very fast. If any cracks appear in the rough plaster-work, near the joists, when it is thoroughly dry, they ought to be closed by washing them over with a brush wet with mortar wash: this wash may be prepared by putting two measures of quick lime, and one of common sand, in a pan, and stirring the mixture with water till the water becomes as the confidence of a thin jelly.

Before the flooring boards are laid, a small quantity of very dry common sand should be trooled over the plaster work, and struck smooth with an hollow rule, moved in the direction of the joists, so that it may lie rounding between each pair of joists. The plaster-work and sand should be perfectly dry before the boards are laid, for fear of the dry rot. The method of under-flooring may be successfully applied to a wooden floor-cake; but no band is to be laid upon the rough plaster-work. The method of extra-lathing may be applied to ceiling joists, to sloping roofs, and to wooden partitions.

The third method, which is that of inter-securiting, is very similar to that of under-flooring; but no band is afterwards to be laid upon it. Inter-securiting is applicable to the same parts of a building as the method of extra-lathing, but it is seldom necessary.

Lord Mahon has made several experiments in order to demonstrate the efficacy of these methods. In most houses, it is only necessary to secure the floors; and the extra-expanse of under-flooring, including all materials, is only about nine pence per square yard; and with the use of quick lime a little more. The extra-expanse of the method of inter-lathing is no more than five pence per square yard, for the timber, side walls, and partitions; but for the ceiling, about nine pence per square yard. But in most houses, no extra-lathing is necessary. Phil. Trans., vol. lxviii. for 1778, part ii. art. 4th. p. 884, &c.

Fire-flies, in Ichthyology. See Raja Pajina. Fire-flies, in the History of Insects. See Lampyris. Among the flies of Guiana, there are two species of fire-flies. The largest is more than one inch in length, having a very large head connected with a body by a joint of a particular structure, with which, at some times, it makes a loud knock, especially when laid on its back. This fly has two feelers, or horns, two wings, and six legs. Under its belly, is a circular patch, which, in the dark, shines like a candle; and on each side of the head, near the eyes, is a prominent, globular, luminous body, and a third larger than a mustard seed. Each of these bodies is like a rising star, emitting a bright, and not small light, since two or three of these animals, put into a glass vessel, appeared.
FIRE.

A good light sufficient to read without difficulty, when placed close to a book. When the fire is dead, the bed of fuel will still afford considerable light, though less vivid than before; and if brushed, and rubbed over the hand and face, they become luminous in the dark, like a board smeared with phosphorous. They have a reddish-brown colour, and live in rotten trees in the day, but are always abroad in the night. The other kind are not more than half as large as the former, and their light proceeds from under their wings, and is seen only when they are elevated, like sparks of fire, appearing and disappearing every second. Of these, the air is full in the night, though they are all over in the day.

They are common, not only in the southern, but northern parts of America, during the summer. In Siam, the trees on the banks of the river Main in summer are beautifully illuminated with swarms of fire-flies, which emit and conceal their light as uniformly as if it proceeded from a machine of the most exact contrivance.

Fire. Line of; the direction in which balls, &c. are impelled from cannon and musketry, is called "the line of fire," and this again is divided, when speaking of the discharge of shot from cannon, against any fortified place, as in sieges, into two distinct branches; namely, the flanking, or direct fire, which plunges into a wall, &c. at right angles therewith; and the grazing, or grazing fire, which strikes such wall at a greater or lesser angle, in proportion as the piece from which the shot proceeds, may be more or less oblique from a direct fire. It scarcely need be pointed out, that the direct fire is by far the most destructive to that object against which it is peremptorily pointed; it is therefore a delirium, that is, to be able to take up such a position with the breaching batteries as may admit of this forcible mode of attack, the effects of which soon become visible. Nor can it be less obvious that the force with which a shot obliquely directed against any work, will gradually diminish according as the line of fire may approach to a parallel with the face to be battered; therefore the grazing-fire is fitted only to particular purposes, such as where an entablature cannot be made direct, that is, in the exact line with the platforms on the battery to be enfiladed, but rather in reverse; that is towards its rear.

Now it is evident that grazing-shots will do little service when they make an angle of less than 60° with the wall to be battered, especially if reveted with masonry. They will have little, if any, effect in execution, provided they touch on the merlons above the cordon, and especially if they fall within the embrasure, which at such an angle would afford a front nearly at right angles with such otherwise oblique fire, and of course, owing to that obliquity, render it a direct one in such particular situations. This, however, will only happen in front of the merlon; in its rear the obliquity will be rather encroached, whereby the shot will have still less power. But, as shown under the head of Entilade, such shots as may be thrown just over the epaulement at the angle of a bastion, &c. at an angle not exceeding five or six degrees, (or perhaps a little more,) in reverse, will generally do full as much damage, as when the entilade proceeds from a direct line of fire; and this will be considerably aided by the parapet being reveted with masonry, from which, not only will splinters be knocked off, but the shot will be thrown in such direction as may suffice to render the battery untenable: unless, indeed, numerous buttresses, called traverses, be thrown up for the purpose of arresting the progress of all such enfilading visitors.

In viewing the exterior of a work, we generally consider each face or battery as having its line of fire directly at right angles with itself; that is, that the cannons should severally be brought as square to genouilles, against which they rest, when brought forward to the embrasures. It is true, that, for the sake both of allowing greater scope to the direction of each piece, as well as for avoiding the flank which would attend the formation of narrow embrasures with parallel sides, they are made to engage perhaps to the extent of 12° on each side, the line of fire may be inclined five or six degrees towards either side; but, in such case, the revetment would soon be destroyed; in fact, the revetment, not only would the perdition be felt, but flames from make their appearance.

The difficulties attendant upon embrasures would long since have caused them to be exploded, were it not that the merlons afford so excellent a shelter for the men at the guns; in every other respect, parapets on a low construction, over which the muzzles of the several pieces can be laid, at the same angle of depression as the superior slope, have the preference; as they allow the line of fire to be changed full sixteen degrees towards either side of the direct line of fire; whence, especially in a tide's way, where a ship may be palming, the most important advantages may be gained. This kind of battery is best suited to situations not liable to be attacked by musketry, particularly from the poops and tops of shipping, nor within the ordinary reach of grape or can-shot. Guns thus laid over parapets are said to be "on barbette."

Fire-locks, inthisinstance, applies to every species of fire-arms, which are dis-charged by means of locks containing springs, &c., that impel a flint in a species of vice, at the head of that part called the cock, against a curved steel plate, called the hammer, so as to produce from their collision sufficient fire, in the form of sparks, or conflagrations, which being by the action of the device directed into a hollow called the pan, before covered by the hammer, cause the gun-powder deposited in that hollow, and which is called the priming, (it being the first portion of that combustible to be ignited,) to take fire, and of course, by means of the touch-hole, which opens into the pan, to explode the charge that is rammed into the bottom of the barrel. The designation fire-lock was in consequence of this ingenious contrivance attached to all pieces acting upon the above principle, in contra-distinction to match locks, which derive their appellation from the circumstance of the powder in their pan being ignited by the application of a match. See Fire-arms, and Match-lock.

The fire-locks used by the British are rather flatter than those in general use on the continent; yet are the former somewhat the heavier; and that too, notwithstanding the French, in particular, brace their barrels to the flanks by means of brass collars, two, three, or even four in number, whereas we affix them merely by wire pins paffing through eye-loops attached under the barrel.

The fire-lock consists of the following parts. The barrel, which is commonly about 40 inches in length, and carries a ball of fourteen to the pound. The charge being fixed drachms of powder; so that including the ball, the paper, and the twine, the entire weight of the cartridge should be 102. 9dr. 11gr. This barrel is affixed to the lock, not only by the pins above described, but by a flat projection at its butt, about two inches long, through which a very substantial flat-headed screw paffes into the more substantial part of the lock; which is mostly made from the finest hard wood; observing that the grain follows the curve of the lock where it bends between the grips, that is where held by the right hand, and the straight part, which receives the butt and lock, and passes all the way under the barrel, to within about three inches of the muzzle. The lock
FIRE.

This page appears to be a corrupted or damaged version of a text discussing firelocks, firearms, and related topics. The readability of the text is significantly impaired, and it's challenging to extract coherent information from it. However, it seems to contain historical and technical details about firearms, particularly firelocks and their various components and uses.

The page continues to discuss the use of firelocks in the context of artillery and military strategy, mentioning the importance of proper handling and the effects of the heat and smoke generated during firing. It also touches on the broader implications of fire and its role in the advancement of military technology and economics.

For better understanding, a full and legible version of the text would be necessary, as this version contains numerous errors and is difficult to comprehend.
are frozen behind. These fire-places are of little use in warming a room; because the air round them, which is warmed by the direct rays of the fire, does not continue in the room, but is continually collected into the chimney, by the current of cold air coming behind it, and is presently carried off. Besides, the greater part of the fire is lost, being absorbed by the back jams and hearth, which are so dark and porous as to reflect very little, and the upright heat flies directly up the chimney. To remedy this inconvenience the Sieur Gauger, in his book entitled La Mécanique de Feu, published in 1709, and since translated by Dr. Desaguliers, (see Chimney) proposed seven different constructions of. A third sort of chimneys, in which there are hollow cavities made by iron plates in the back, jams, and hearth, through which plates the heat passing, warms the air; whose cavities, which is continually coming into the room fresh and warm. This construction had many obvious advantages; but the expense and difficulty attending it discouraged the propagation of the invention. However, the upright heat was almost wholly lost in these as in the common chimneys. 4. Another kind of fire-place is the Holland iron-place, with a flue proceeding from the top, and a small iron door opening into the room. These serve to warm a room, fume fuel, and produce a conflant change of air. But the fire is not seen, and little use can be made of it besides that of warming the room. It is therefore rarely used in England, except in some work-shops.

5. The German flue is composed of five iron plates screwed together, and fixed so as that the fuel may be put into it from another room, or from the outside of the house. It is a kind of oven reversed, its mouth being without, and body within the room that is to be warmed by it. This flue warms a room with little fuel, and is attended with no danger from the irruption of cold air; but the fire is not seen, and there is no change of air in the room heated by it.

For an account of the Chinese flue, see Kang. 6. Another kind of convenience for warming rooms is a charcoal fire kindled in pots and charging, fives. This is chiefly used in the shops of handicraftsmen. But the fulphurous fumes arising from the coals render this mode of giving heat disagreeable and dangerous, and in a close room sometimes fatal.

The ingenious Dr. Franklin, whole name we have had frequent occasion of recording in this work, having recounted the inconveniences and advantages of fire-places in common use, proposes a new contrivance for this purpose, called the Pennsylvania fire-place. 1 This machine consists of a bottom plate or hearth-piece (see Plate X. A plunged, fig. 6.) with rising windings before for a footer, two perforated ears F, G, for receiving two screw-rods; a long air-hole a, through which the outward air passes into an air-box; and three smoke-holes represented by dark squares in B C, through which the smoke descends and passes away; besides double ledges for receiving between them the lower edges of the other plates. 2 A back plate without holes, and furnished with a pair of ledges to receive 3. The two side-plates, each of which has a pair of ledges to receive the side-edges of the front plate, with a shoulder on which it rests; two pair of ledges to receive the side-edges of the middle plates which form the air-box, and an oblong air-hole near the top, through which the air warmed in the box is discharged into the room, and a wing or bracket, as H, and a small hole, as K, for the axis of the regiller to turn in. See fig. 3, which represents one of these plates. 4. An air-box, composed of the two middle plates D E and F G, figs. 4 and 5. The flue has five thin ledges or partitions call on it, the edges of which are received into so many pair of ledges cast in the other; the tops of all the cavities formed by these thin deep ledges are also covered by a ledge of the same form and depth cast with them; so that when the plates are put together, and the joints luted, there is no communication between the air-box and the smoke. In the winding passages of this box, fresh air is warmed as it paffes into the room. 5. A front plate, which is arched on the under side, and ornamented with foliages, &c. 6. A top plate, with a pair of ears M N, (fig. 6.) answerable to those in the bottom plate, and perforated for the same purpose. It has also a pair of ledges running round the under side to receive the top edges of the front, back, and side plates. The air-box does not reach up to the top plate by 2 ½ inches.

All these plates are of cast iron; and when they are all in their proper places, they are bound firmly together by a pair of slender rods of wrought iron with screws, and the machine appears as in fig. 6. There are also two thin plates of wrought iron, viz. 7. The shutter, which is of such a length and breadth as to close well the opening of the fire-place, and serve to blow up the fire, and to secure it in the night. It is nailed or depressed by means of two brafs rods, and slides in a groove left between the foremost ledge of the side plates and the face of the front plates. 8. The regiller, which is placed between the back plate and air-box, and furnished with a key; so that it may be turned on its axis and made to lie in any position between level and upright. The operation of this machine, and the method of fixing it, may be understood by observing the profile of the chimney and fire-places in fig. 7. M is the mantle-piece or breadth of the chimney; C the funnel; B the false back, made of brick-work in the chimney, four inches or more from the true back, from the top of which a cloing is to be made over to the breadth of the chimney, that no air may pass into the chimney except that which goes under the false back, and up behind it; E the true back of the chimney; T the top of the fire-place; F the front of it; A the place where the fire is made; D the air-box; K the hole in the side-plate, through which the warmed air is discharged out of the box into the room; H the hollow, formed by removing some bricks from the hearth under the bottom plate filled with fresh air, entering at the passage I, and ascending into the air-box through the air-hole in the bottom plate near G, the partition in the hollow, designed to keep the air and smoke apart; P the passage under the false back, and part of the hearth for the smoke; and the arrows in the figure flew the course of the smoke. The fire being made at A, the flame and smoke will ascend, strike the top T, and give it a considerable heat; the smoke will turn over the air-box, and descend between it and the back plate to the holes near G, in the bottom plate, heating in its passage all the plates of the machine; it will then proceed under and behind the false back, and rise into the chimney. The air of the room contigious to the several plates, and warmed by them, becomes specifically lighter than the other air in the room, and is obliged to rise; but, being prevented by the closure over the fire-place from going up the chimney, is forced out into the room, and rising by the mantle-piece to the eiling, is again driven down gradually by the beam of newly-warmed air that follows; and thus the whole room becomes in a little time equally warmed. The air, also, warmed under the bottom plate and in the air-box, rises and comes out of the holes in the side plates, and thus warming and continually changing the air of the room. In the closing of the chimney a square opening for a trap-door should be left open for the sweeper to go up; the door may be made of plate or
FIRE.

tis, and so placed, that by turning up against the back of the chimney when open, it cloths the vacancy behind the false back, and throws the foot that falls in sweeping out upon the hearth. It will also be convenient to have a small hole about five or six inches square, cut near the ceiling through into the funnel, and provided with a shutter, by occasionally opening which, the heated air of the room and smoke of tobacco, &c. may be carried off without incommoding the company. For a farther account of improved fire-places, see Chimney.

Fire-places, in the Military Art, are small earthen pots into which is put a grendle, filled with fine powder till the grenade be covered; and then the pot is covered with a piece of parchment, and two pieces of match laid across and lighted. This pot being thrown where it is designed to do execution, breaks and fires the powder, and thereby fires the powder in the grenade, which ought to have no fuse, that its operation may be the quicker.

Fire, Roman, or revolting, is a fire from the artillery and small arms directed in a line parallel to the horizon, or to those parts of the works of a place that are defended.

Fire, Running, is when a rank or ranks of men drawn up fire one after another; or when the lines of an army are drawn out to fire on account of a victory; in which case each squadron or battalion takes it from that on its right, from the right of the rih line to the left, and from the left to the right of the second line, &c.

Fire-fight, is a vessel fitted up with combusible apparatus, so arranged as to appear audibly in a blaze, at any given time, or without. It is observed by Anderson in his History of Commerce, vol. ii. p. 422, that some English vessels, filled with combustible matter, and being amongst the Spanish ships, containing the Invincible Armada in 1588, are said to have given rise to the terrible invention of fire-ships. However, Livy informs us, that the Rhodians had invented a kind of fire-ships which were used in conjunction with the Roman fleet in their engagement with the Syrians, in the year before Christ 190; cauldrons of combustible and burning materials were hung out at their prow, so that none of the enemy's ships durst approach them; these fell on the enemy's galleys, lurch their beaks into them, and at the same time let them on fire. Liv. lib. xxxvii. cap. 30. tom. iii. p. 522. Ed. Crevier.

There is nothing peculiar in the construction of a modern fire-ship, except the apparatus by which the fire is instantly conveyed from one point to another, and from thence to the enemy, for this purpose the fire-room, in which the combustibles are included, is built between deck, and extends from the bulk-head at the foremost to a bulk-head railed behind the main-mast. The train included in this apartment is contained in a number of wooden troughs which intersect each other in different parts of the ship's length, being supported at proper distances by cross pieces and timbers. On each side of the ship are cut out six or seven port-holes, in size about sixteen by eighteen inches, with their lids opening downward, and close caulked up. Against each port is fixed an iron-chamber, which, when the ship is fired, blows out the port-hd and lets out the flame. Under the main and fore throns is fixed a wooden funnel, one end of which communicates with a fire-barrel, and designed to convey the flames to the throns. Between the funnels, called also fire-trunks, are two scuttle or small holes in the upper deck, serving also to let out the flames. Both funnels and scuttle must be flopped with plugs, and have sail-cloth or canvas nailed over them, to prevent any accident happening from above to the combustibles below. The port-holes, funnels, and scuttles, serve not only to communicate the flames to theoutside and upper works of the ship and her rigging, but likewise to open a passage for the inward air confined in the fire-room, so that it may expand itself without blowing up the decks. On each side of the bulk-head behind is cut a hole big enough to receive a trough of the fame size as the others; leading troughs whole foremost ends communicate with other troughs within the fire-room, extend obliquely from these openings to Saly-holes cut through the ship's side: the decks and troughs are well covered with melted rosin. When either of the leading-troughs is fired, the flame is immediately conveyed to the opposite side of the ship, and both sides burn together.

The cabins of the lieutenant and master are behind the fire-room, one on the larboard and the other on the larboard side. The captain's cabin is separated from these by a piece of the bulk-head.

Of these fire-ships we have two forts, viz. the conflagrating and the exploding. The former have been long in use, but the latter appears to be of rather later adoption. The vehicles employed may be from 60 to 200 tons, or more; their size being usually adapted to the service they are to perform. The following detailed account of the preparations and proportions of the requisite materials will give our readers a perfect idea of this horrible contrivance.

Proportion of combustible Stores for a Fire-Ship of 150 Tons.

The fire-barrels are about 2 feet 4 inches high, and 1 foot 6 inches in diameter. Each barrel must have 4 holes of about 6 inches square cut in its sides; and these holes must have a square piece of canvas nailed over them quite close. They are then filled with the same composition as for carecas; and 4 pieces of about 1 inch in diameter and 3 long, and well greased, are thrust into the top, and then left to dry. When dry, the plugs are taken out, and the holes filled with fire composition, with quick-match at the top. After this, the whole is smeared over with mealed powder, mixed with spirits of wine. When dry again, a sheet or two of brown paper is laid over the top, and then one of the canvas covers, which is made secure by the upper hoop of the barrel.

The composition for dipping reeds, bavins, and curtils, consist of:

</table>

This will dip about 100 reeds and 25 bavins.

Each curtain contains 1 square yard of bavins; and a cover for fire-barrels, 1 square yard of backing, immediately that the curtains, covers, &c. are dipped, they are to be threwed over with fire brimstone, before the composition grows cold. The new chambers for blowing open the
ports, hold from 9 to 11 ounces of powder. They are fixed in such manner as to prevent their recoil, and to ensure the ports being blown open. The vents are usually corked up, and covered with a piece of hessian, till required to be primed, for which the following composition is prepared:

- Saltpetre pulverized - 22½ lb.
- Ruminum ditto - 2
- Sulphur ditto - 20
- Meal clarified - 4½
- Linseed oil - 1 pint.

The ship should not be primed when fitted out, but only when intended to be fired. The mode of fitting out is this: The whole breadth of the fire-room is to be divided into nine parts; and troughs, about 4 inches wide and as many deep, are laid both along the whole length of that room, and across; so as to form a general communication, and to insure that the whole of the combustibles may be ignited nearly at the same moment. The eight fire-barrels are ranged along the two sides; and over them are two fire-fretals, or openings with fire-trunks, by which the flames are directed upwards towards the vent of the apparatus. The reeds and baius are tied down to the troughs, to prevent their rolling out of their places, as the ship may roll or pitch; and the curtains are nailed up to the beams, equally throughout the fire-room.

When the vessel is about to be fired, all the reeds and baius are to be taken up, and a little of the priming composition sprinkled in the bottoms of the troughs: the reeds, &c. are then to be lightly tied down as before. Quick match, of six or eight threads, doubled, must be laid along on the tops of all the reeds, &c. and abundance of priming composition fired over it, as well as over all the fire-room. The covers of all the fire-barrels must be cut open, and made to hang down on the sides of the apertures. Leaders, of strong quick-match, must be laid from the reeds to the barrels, and to the iron chambers; tying them to the several vents, to insure their not falling off. Strong leaders of quick-match, four or five times doubled, must be laid from the reeds to the fire-bars; and these last must be connected by quick-match, that the whole may fire at once.

The following mode is now in use for producing an external fire, in addition to that kindled within. Fire-boxes, filled with carcasse-composition, are distributed in the following manner in a ship with three masts:

- 1 box is suspended from each of the cat-heads and davits, on each side of the bow, in all 6
- 3 flung across the bowsprit - 8
- 4 across each of the out-riggers abaft - 8
- 2 from the grappins of each of the lower yard-arms - 12
- 1 from the dead-eyes on each side of the tops - 6
- 1 from the middle of the inside of the fore, main, & mizen forearms - 6

Total boxes of composition 44

These boxes are suspended by chains and hooks; but those thrown across the bowsprits and out-riggers are fixed by lappets. The two inner ones are laid with leaders of quick-match, which fire instantly; or else with port-fires, cut to burn a given time; they communicate with the outer ones by reeds tied down on the bowsprit and out-riggers. The boxes that hang from the dead-eyes and forearms are fixed by curtains suspended from the forearms; the lower ones hanging immediately over the large fire-barrels. The two boxes on each yard-arm are hung the one over the other; the upper one having a leader of quick-match carried along the yard from the forearms; this in burning will double-fire the lower one. Besides the boxes, there are fire-barrels arranged as follows: Two half-barrels on the fore-castle; two abaft the main-deck, and four on the main-deck; two in each top, placed against the masts; and four large fire-barrels, under fire-trunks, to convey fire to the curtains on the forearms.

All these fire-barrels and boxes are to be fired by separate leaders of quick-match or port-fire, so that every part of the ship may be fired, and envelope her in smoke during her approach to the enemy; while the residue need not be ignited until the crew may be quitting to escape in their boats. This is certainly a very hazardous duty; the attention of the enemy being always attracted by such fire-ships as appear likely to take effect; hence the boats are manned, and every endeavour is made by long poles, like boat-hooks, to get hold of so as to tow away into a contrary direction; or long-boats, &c. are moored with chains extending upon the forearms of the vessel, for the purpose of arresting the progress of the flaming visitor. Whether it be from a refined idea, or from the most determined resentment towards those who act in fire-ships, may be difficult to judge; but there is rarely any quarter given to such as fall into the enemy's power. However, under ordinary circumstances, the evacuation is not attended with much difficulty, unless there be much swell, by which the boat's return may be greatly impeded, thereby subjecting the crew to a heavy fire from every quarter. When we understand that two men, furnished with lighted port-fires, can set fire to the whole of the leaders on the deck, &c. in less than a minute, we may collect that after once the vessel has got into a proper direction, within a few minutes, fire will be the occasion for remaining in her, so as to rack the crew, never ever exist. In general, the fire becomes universal in the course of five minutes; the ports being blown open by the chambers, and allowing the flames to rush out in the most awful manner:—in such a manner as to preclude the possibility of approach in boats, which cannot act when the fire has become general.

Explosive fire-ships are constructed on a similar principle; adapting it to the explosion, at a given time, of an immense trough of powder running the whole length of the vessel, for the purpose of hurling her to pieces, and of destroying whatever vessels may be within reach of the shock.

Firing-fore is a coarse, harsh, daily fire-fore, of a moderately compact texture, of a pale greyish colour, nearly white, with a very light greenish tinge. This fore is moderately hard and heavy, and slightly colours the hands; it is composed of a small fine angular grit, cemented by an earthly sprarry matter, intermixed with numerous small spangles of a silvery hue; it will not strike fire with steel, and in the fire changes to a slight reddish hue. It is called also Rygetate-fore, from the place whence it is chiefly brought; it bears the fire and a high degree of heat, without melting or exfoliating; and is much used for chimneys, hearths ovens, stoves, &c.

It does not bear the weather, and is therefore unfit for building.

The best fire-fore that England affords, is perhaps that obtained from the mill-fore grit (lara), from a bed with globular ochry stains in it, and which is used for lining the iron furnaces of Derbyshire and other districts; it is dug at the Rooks quarry, in Ashover, on Stanton Moor, and other places. Of late years a good fire-fore has been used at Batterly furnace, by Mr. JeffJa, junior, from the fine micaceous
The defect whereof is now lost. They threw it out of a kind of mortar; and sometimes shot it with an odd fort of crosb bow, which was strongly bent by means of a handle, or winch, of much greater force than the bare arm.

That thrown with the mortar sometimes appeared in the air of the size of a tun, with a long tail, and a noise like that of thunder. It came flying through the air, says Joinville in his "Histoire de St. Louis," like a winged, long-tailed dragon, about the thickness of an hoghead, with the report of thunder and velocity of lightning; and the darkness of the night was dispelled by this deadly illumination. The use of the Greek, or, as it might now be called, the Saracen fire, was continued to the middle of the 14th century, when the scientific or casual compound of nitre, sulphur, and charcoal effected a new revolution in the art of war and the history of mankind. Leonardo da Vinci, in his MSS, published by Venturi, describes the composition of the Greek fire as formed by mixing over the fire, the charcoal of willow, nitre, brandy, rosin, sulphur, pitch, and camphor. A wooden cord is then plunged in the mixture, and made into balls, which may afterwards be provided with spikes. These balls, being set on fire, are thrown into the enemy's vessels. A similar composition has been given by Bapitla Porta, in his "Mag. Natur. l. xii. c. 2." The modern discoveries respecting combustion have disproved the whole secret of compositions which burn without access to the atmosphere, but by means of oxygen afforded from nitre. The balls described by Tuzier, (Des Faux d'artifices) which float on the surface of water are nothing else but the Greek fire.

The invention of fire-works is by M. Mahudel attributed to the Florentines and people of Sienna; who found out likewise the method of adding decorations to them of figures, with fire issuing from their eyes and mouths. The art of preparing and managing fire-works is called Pyrotechny.

The making or felling of fire-works, or fquilis, or throwing them about in any field, is, on account of the danger that may ensue to any thatched or timber buildings, declared to be a common nuisance, by 9 and 10 W. III. cap. 7, and punished by a fine of 20s.

Fire-workers, were formerly subordinate officers to the fire-masters, who commanded the bombardiers, but they are now second lieutenants to the royal regiment of artillery.

Fire receive the orders from the fire-masters, and see that the bombardiers execute them.

Fire, island, in Geography, a small island in the Indian sea, near the coast of Africa; S. lat. 17° 30'.

FIRENZUOLA, AGNOLO, in Biographia, an Italian poet, born at Florence in 1493, was son of Battiano de' Giovannini, a person of considerable note in his own country. He studied at Sienna and Perugia; and in the latter place he contracted an intimacy with the famous Peter Arcin, whom he accompanied to Rome. He was intended for the profession of the law, and executed the duties of an advocate, which he at length quitted to enter the congregation of monks of Vallombrosa, with the expectation of attaining some preferment in the church. He died at Rome about the year 1545, having passed much of his life in ill health.
writings rank among the lighter productions of Italian literature. They have been frequently printed; and were collected in three volumes at Florence in the year 1673. These consist of works in verse and in prose; of novels; amorous discourses; a piece against the new letters introduced into the Italian by Trionfo; discourses in natural history; two comedies; a translation of the Golden Age of Apuleius, adapted to himself and the circumstances of his own time. In almost all his pieces he exhibits a cultivated and elegant taste, but is often more free in his manners than became the clerical character. Morelli.

FIRGOS, in Geography, a town of the island of Samos; 3 miles W.S.W. of Cora.

FIRING, in the Manoeuvres, denotes a kind of correction or discipline of the whip, used by horse-dealers; and which they expressly prepare in order to terrify a horse, and thus to make his mettle, that he may appear to the best advantage. Wherein this object is most honestly and most effectually attained by a moderate use of the whip.

Firing, in the Military Arts, denotes the discharge of the firearms; and its object is to do the utmost execution to the enemy.

The prent, method of firing by platoons is said to have been invented by Gualtieri Adolphes, and first used about the year 1618; the reason commonly given for this method is, that a constant fire may be always kept up. There are three different ways of platoon firing; viz. flanking, advancing, and retreating. But previous to every kind of firing, each regiment or battalion must be told off in grand divisions, subdivisions, and platoons, exclusively of the grenadiers, which form two subdivisions, or four platoons, of themselves. In firing flanking, either by divisions or platoons, the first fire is from the division or platoon on the right; the second fire, from the left; the third, from the right again; and so on alternately till the firing comes to the centre platoon, which is generally called the colour platoon, and does not fire, remaining as a reserve for the colours. Firing advancing is performed in the same manner, with this addition, that before either division or platoon fires, it advances three paces forward. Firing retreating varies from either of the former methods; for, before either division or platoon fires, if they are marching from the enemy, it must go to the right about, and after firing, to the left about again, and continue the retreat as slow and orderly as possible.

In hedge-firing the men are drawn up two deep, and in that order both ranks are to fire flanking, Oblique firing is either to the right and left, or from the right and left to the centre, according to the situation of the object. The Prussians have a particular contrivance for this purpose; if they are to level to the right, the rear ranks of every platoon make two quick but small paces to the left, and the body of each feldrach turns one-eighth of a circle, and the next. Parapet firing depends on the nature of the parapet over which the men are to fire, and also upon that of the attack made to possess it. This method of firing is sometimes performed by single ranks stepping on the banquette and firing; each man instantly hands his arms to the centre rank of the same file, and taking back in the room of it; and the centre rank giving it to the rear to load, and forwarding the arms of the rear to the front rank; by which means the front rank man can fire by or seven rounds in a minute, with exactness. Parapet firing may also be executed two deep, when the banquette is three feet broad, or in field works, where no banquette are made. Square firing is performed by a regiment or body of men drawn up in a hollow square, in which each front is generally divided into four divisions or firings, and the flanks of the square, being the weakest part, are covered by four platoons of grenadiers. The first fire is from the right division of each face; the second from the left division of each face, &c. and the grenadiers make the left fire. Street firing is practiced in two ways; either by making the division or platoon that has fired to wheel by half-rank to the right and left outwards from the centre, and to march in that order by half divisions down the flanks on each side of the column, and to draw up in the rear, and go on with their priming and loading; or, to make the division or platoon, after firing, to face to the right and left outwards from the centre, and one half rank to follow the other; and in that order to march in one centre file down on each side of the column into the rear, and there draw up as before.

Firing iron, in the Manoeuvres, is a piece of copper or iron, about a foot long, one end of which is made flat, and forged like a knife; the back of it being half an inch thick, and the fore-edge about the fifth or sixth part of this. When the firer has made his firing-iron red hot in his forge, he applies the thinnest part to the horse's skin, and gives the fire to the hands, or such places as stand in need of it.

The utility of firing, or of applying the actual cautery to the skin, is doubtful. Mr. Lawrence tried it without success. Its use is said to be to diffuse swellings by promoting absorption, and by contracting the skin to form a constant bandage round the inflamed, both during the cure, and even afterwards: when the pattern-points are exceedingly full and fresh, the legs gorged, the tendons enlarged, and, indeed, the parts indurated, blistering and burning seem to be absolutely necessary; when no other measures will be sufficiently useful. In the Veterinary college, it is the practice, in this operation, to draw the lines vertically round the affected limb; the contraction of the skin in that direction, forming the most efficient and uniform bandage on the part. See SAWIN, RINGHOLD, &c.

FIRKIN, an English measure of capacity, for things liquid, containing the fourth part of the barrel.

The firkin of ale contains eight gallons; and that of beer, nine; two firkins of beer make the kilderkin; two keilders the barrel; and two barrels the hoghead. In this country a firkin of ale and beer is 8½ Wincheller gallons.

The firkins of herring, foap, and butter are on the foatling of the firkin of ale; 9½, a gallon per firkin less than that of beer.

FIRLAVENKA, in Geography, a town of Poland; in the palatinate of Lemberg; 34 miles E. N. E. of Lemberg.

FIRLOT, in Agriculture, is a term which is generally applied to a dry measure of grain in the northern parts of the kingdom; but which differs in size, according to Mr. Sommeville, in the proportion of 21, 27 to 31. There is therefore a small, and a large firlot. Wheats, rye, barley, and peas are usually full by the small firlot, but not, barley, and oats by the large firlot. Four small firlots are, according to the same writer, 1,057,276 Wincheller bushels; four large ones 5,065,653 Wincheller bushels. Four firlots make a ball. See Weights and Measures. The firlot is likewise distinguished into the oat and the wheat kinds. The oat firlot, which contains twenty-one and a quarter Scotch pints, is twelve and a half inches in diameter, both at the top and bottom, being of a perfectly cylindrical form, and seven and a half inches in depth. The wheat firlot contains about 1711 cubical inches, and that for barley thirty-one standard pints; it seems therefore that the Scotch wheat
FIRMAMENT, (from the Latin firmamentum.) This word has been used with great latitude by sacred writers, by astronomers, by poets, and other writers. When Ptolemy of Egypt endeavoured to reconcile the phenomena of the celestial bodies with the prevailing philosophy of the times, he supposed that the earth was immovably fixed in the centre of the universe, and that the moon, mercury, venus, the sun, mars, jupiter, and saturn, were carried round the earth by different spheres of solid but transparent matter. Beyond them he supposed the existence of an eighth sphere whereon the fixed stars were situated, and this he called the firmament of the fixed stars; and beyond this firmament he placed the primum mobile, and the columna ethereum. In process of time the absurdity of this astronomical hypothesis was clearly demonstrated, in consequence of which the Ptolemaic spheres were utterly disregarded; yet the word firmament still remained in use; its meaning, however, became less limited; so that sometimes it was used to express the region of the fixed stars; at other times it denoted a peculiar region, or some peculiar regions of the heavens, as may be deduced from the expressions, the middle firmament; the various firmaments. It has also been used to signify the sky, or the whole expanse of the heavens. Derham says (in his Astr. Theol.) "what an immense space is the firmament, wherein a great number of stars are seen with our naked eye?" Dr. Keill, in his Astronomical Lectures, says, "a spectator therefore living in the farthest part of the earth, who has a telescope, will observe its surface to be spherical-concave, and concentric to his eye, in which surface he will observe an innumerable multitude of stars, which we call fixed, every where dispersed throughout the whole heavens, which like so many gilded fluids, with a bright luster, adorn the firmament."

In various parts of the scripture, the middle region of the air is called the firmament.

It is curious to observe that whilst most writers, ancient or modern, seem to consider the firmament as something aerial, or fluid; others, with Ptolemy, have considered it as solid and transparent like crystal. Indeed, upon the least reflection, this last idea seems to be more consonant with the nature of the word, which signifies the idea of something firm and substantial, a sort of foundation fit to support great, heavy, and magnifying objects. In fact, some writers of note have used it in this sense, and entirely independent on astronomy. Thus Bacon (in his Advancement of Learning) speaking of the principles of every subject, which human industry always endeavours to find out, says, "the mind of man doth wonderfully endeavour, and extremely covet this, that it may not be possible; but that it may light upon something first and immovable, on which, as on a firmament, it may support itself in its swift motions and oscillations."

Considering that striking circumstance of the fixed stars constantly preferring their relative situations; it must be allowed, that Ptolemy was, not without apparent reason, induced to consider the firmament of the stars, as something solid and permanent. Previous to the very recent most accurate observations, which have shewn that very flight alterations of distances do actually take place among the stars, it was not even supposed that any such thing existed; and the daily movement which they were observed to have, was considered as the common movement of them all, or rather of their ornament, which appeared to revolve round the earth once in each 24 hours.

Besides this apparent daily motion, it is to be remarked that the sun returns to the equinox every year before it returns to the same point in the heavens, hence the equinoctial points have a retrograde motion, which, though very small, in process of time amounts to something considerable, and it will complete a whole revolution, so as to return to the same point, after a great number of years. (This is called the 'PRECESSION OF THE EQUINOXES,' which fee; and the whole revolution round the flary firmament is called the great year, or annus magnus.) This circumstance did not escape the notice of ancient astronomers, and their calculations respecting the quantity of the annual precession, or of the whole revolution, were not much less accurate than that of latter times. Ptolemy reckoned the annus magnus, or the great revolution of his flary firmament, equal to 36,000 ordinary years. Hipparchus came to the same conclusion, Tycho Brahe reckoned it equal to 25,412 years. And the more modern astronomers, though not quite agreeing among themselves, generally reckon it equal to about 26,000 years.

FIRMAN, in the East Indies, and particularly in the territories of the Great Mogul, is the passport, or permit, granted to foreign vessels, to trade within their jurisdiction.

FIRMINUS, MATERNEUS, JULIUS, in Biography, an ecclesiastical writer, flourished about the middle of the fourth century. He is said to be a Sicilian by birth; to have practised for some time as an advocate in the Forum at Rome; and, in his old age, to have become a convert from heathenism to Christianity. He was author of a treatise, "De Errore profanarum Religiosis," which was addressed to the emperors Constantius and Constan.tin. It is a learned and well-written performance, and sets forth, by way of contrast, the reasonableness and excellence of the Christian system, in comparison with the absurd and immoral tenets of the Gentile creed. It had been well had he been satisfied with demonstrating by argument the superior excellence of his religion; but unfortunately he called upon the civil power to propagate it by force, and by severe edicts to crush and overawe the abettors of error. This work has often been reprinted; and in the year 1656 it was published at Paris, at the end of Cyprian's works; and it is inserted in the fifth volume of the "Bibliotheca Patrum." A mathematical or, perhaps, more properly, an astronomical treatise, entitled, "Astronomicon, de De Morte, lib. viii.," is ascribed to Firmian, though not without dispute. It was first published at Venice, in 1527, in folio, from a copy brought by Pecenini Niger from Constantinople; and has been frequently reprinted since, together with the works of Minias, and the astronomical pieces of Ptolemy. It treats of the power and influence of the stars, according to the doctrine of the Egyptians and Babylonians; and contains a curious mixture of mathematical science with the revires of judicial astrology. Morei.

FIRMINIAN, an eminent Christian bishop, who flourished in the third century, was descended from an honourable family in Cappadocia. He was ordained bishop of Caesarea about the year 253, and was held in the highest estimation for learning and for the excellence of his moral character by his contemporaries. In all the important ecclesiastical matters that were agitated in his time, the opinion of Firmian was looked up to with profound respect and reverence. He was present at the council of Iconium, held in 254; at the council of Antioch, in 257, convened on the subject of Novatian's schism; he was also president of the council held, some years after, at the same place, to examine into the opinions of Paul of Samosata. He was again invited to the
the council held at Antioch, in the year 276, by which Paul was condemned and deposed; but died at Tarsus, on his journey, about the end of the year 269. This was an unhappy event for Paul, who had already been faved by his influence, and who would probably have again experienced his kindness in this new attack on his principles and character, had he lived to argue the matter in council. Firmian was not much distinguished as an author; yet his merits, moderation, and candour, entitle his memory to the respect of posterity. Theodoret characterized him as "an illustrious perfou, equally master of human and divine knowledge." He was united in strict friendship with Origen, whom he invited into his own country, and to whom he paid several visits, for the sake of improving by his inlucutions in divine knowledge. He took the part of St. Cyprian, in the dispute about baptizing heretics that returned to the catholic church; and wrote a long letter to St. Cyprian on the subject, in which he expounded the inhumanity, pride, and insolence of Stephen, bishop of Rome. St. Basili mentions with respect the works of Firmian, but without expressly naming them. He was a man zealously attached to the truth, but candid and liberal to those who differed from him, and anxiously desirous that they should never be molested on account of their opinions. Moreni. Lardner.

FIRMIN, THOMAS, was born at Ipswich, in Suffolk, in the year 1632, where he was educated under the eye of his parents, who were strictly religious; and with regard to this world's goods, they were respectable but not rich. "God gave them," says the friend and biographer of Firmin, the wife of Solomon, "neither poverty nor riches, but that middle estate and rank, which contains all that is valuable and definable in wealth, without the parade, vanity, and temptations that generally adhere to riches." When Thomas was of a proper age, he was bound apprentice to a tradesman in London. In this situation he was remarkable for his diligence and activity, as well as for his amiable and obliging manners. With his master he usually attended the sermons of the celebrated Armenian preacher, Mr. John Goodwin; by this he became an early convert from Calvinism, in which he had been brought up, to the principles of Arminius. At the expiration of his apprenticeship he entered into business on his own account, with a capital of 100l. only, which in 1663 was increased by an addition of 500l. that he received with a citizen's daughter whom he married. By skill and industry he soon acquired property; but, what was of infinitely more importance, he became eminently known for the excellence of his dispositions; the integrity of his dealings, his solicitude to promote the happiness of others, and his kind and constant exertions for alleviating the miseries of the poor and unfortunate. He was, from his first commencement in business, desirous of obtaining the friendship of persons eminent for moral worth, foreigners as well as his own countrymen, and particularly of the clergy of different denominations. From these connections he, in future life, was enabled to derive essential assistance in promoting the benevolent and useful designs for which he afterwards became so eminently distinguished. Among other persons, he was intimately acquainted with Mr. John Biddle, who confirmed him in his Armenian sentiments, and made him a profyte to Unitarianism, for the fake of which Biddle himself was persecuted and banished. (See Biddle.) Firmin was not to be diverted from his kind intentions, because the tyranny of Cromwell fell heavily upon him: he shewed him every attention while here; and when he was sent, by the protector, a prisoner to the Scilly isles, he procured for him a pension, which Cromwell had virtue enough to allow him to receive during his banishment. Mr. Firmin enrolled among his intimate friends Dr. Whitchoe, Dr. Worthington, Dr. Tilloton, and Dr. Wilkins. By the intercourse which he thus maintained with the clergy, and the great confidence placed in his judgment to recommend men of worth and abilities to offices for which they were adapted, he was enabled to serve the interests of many promising young preachers and scholars, who were candidates for lectureships, schools, &c. In the year 1664, Mr. Firmin, being a widower, married again; and with his wife he had a very considerable fortune. In 1666, his house was destroyed by the great fire of London; but his character as a tradesman was now so well known, that by the increase of business he soon repaired the loss which he sustained by that event, and might have amassed much property, had not his heart prompted him to devote a great proportion of his profits to benevolent and humane purposes. In the year 1676, he erected large premises, and established a linen manufacture, for the sake of affording employment to a number of poor children, who were useless to and a burden on, the community. Here he found constant work for many hundreds, who were either acquainted with the different branches of the business, or were willing to be instructed in them. The returns proved, as he expected, very inadequate to the expenses incurred; yet, from his own funds, and from the allusion which he obtained from well-disposed persons, he was enabled to bear the loss, and to give away occasional sums of money, more than their earnings, and to distribute fuel and clothing among the poor manufacturers in severe feasts. In the year 1678, he published "Proposals for employing the Poor, especially in and about the City of London, and for the Prevention of Begging, &c. in a Letter to a Friend." In this tract he describes the progress and good effects of his institution, and makes a number of valuable observations relative to the most proper means of providing for the necessities of the poor. After this he attempted to set up a woollen manufacture; but the losses which he sustained, through the ignorance of the persons employed, obliged him to relinquish his project. He erected a large warehouse on the banks of the Thames, in which he deposited corn and coals, purchased in the cheapest feasons, to be sold at prime cost, in times of scarcity, to the poor. Mr. Firmin wassignalized by the zeal and activity which he displayed in liberating poor debtors from prison, and in providing for the more comfortable subsistence of others whom he was unable to redeem. He was, however, the means of opening the prison doors to many, whole families were ready to perils for want; and his recommendation and influence are said to have had great weight with some leading members of parliament, in the passing of certain acts of grace in behalf of poor debtors. Mr. Firmin was one of the governors of St. Thomas's hospital, and extremely active to render it as useful as possible: he was also a governor of Christ's hospital, of which he proved himself a great benefactor and benefactant. When the French protestants fled into England, to escape the perfecutions of Louis XIV., Mr. Firmin was active in providing for their relief; and several thousand pounds were entrusted to his care and management, for the benefit of the refugees. He was equally zealous in behalf of those who fled from Ireland to England, to escape the perfecutions of James II. He was, in short, a most affable and religious man; and in no instance did he stand by to witness oppression, without endeavouring to avert the rights of the oppressed. By the distribution of publications written in defence
defence of public freedom, he endeavoured to move his countrymen to a vindication of their rights, in opposition to the king (James II.); and he may be regarded as a zealous promoter of the revolution in 1688. After that event, he gave evidence that his benevolence was attached to no party, but was active in relieving those who were suffering for conscience sake. The high character which this excellent man sustained attracted the notice of the queen, who expressed a deep concern that so good a man was not orthodox in his religious sentiments; and intreated archbishop Tillotson to endeavour to convince him of his error. The prelate replied, that he had already made the attempt; but that Mr. Firmin had been too early and too deeply impressed with Unitarian principles, to admit now of contrary impressions. After this, Dr. Tillotson published some sermons on the points in dispute, and sent one of the first copies to Mr. Firmin, who immediately drew up an answer to them, which he presented to the archbishop: still, however, their friendship for one another did not abate. With Dr. Compton, bishop of London, Mr. Firmin was equally in favour; and it must not be forgotten, that the annual collections for the poor, which are made in and about London at Christmas, under the authority of the king's letter, were set on foot by Mr. Firmin, who had the direction of the business several years. This excellent man died, December 20th, 1697, in the 66th year of his age. He was interred, according to his own desire, in the cloisters belonging to Christ's hospital, where the following inscription was erected to his memory.

"Under that stone, near this place, lyeth the body of Thomas Firmin, late citizen of London, a governor of this and Saint Thomas's hospital; who, by the grace of God, was created in Christ Jesus to good works, wherein he was indefatigably industrious, and successfully provoked many others thereto; becoming also their almoner, visiting and relieving the poor at their houses, and in prisons, whence also he redeemed many. He set hundreds of them at work, to the expending of great stocks. He rebuilt, repaired, and added conveniences to hospitals, weekly over-seeing the orphans. The refugees from France and from Ireland have partaken largely of his charity, pains, and earnest solicitation for them. He was wonderfully zealous in every good work, beyond the example of any of our age. Thus showed he his faith by his works, and cannot reasonably be reproached for that which brought forth such plenty of good fruits." Life of Firmin in Unitarian Tracts, vol. v. 1866.

FIRM, in Geography, a town of France, in the department of the Rhône and Loire; 5 miles W. of St. Etienne.

FIRM, St., a town of France, in the department of the Higher Alps, and chief place of a canton, in the district of Gap: the place contains 831, and the canton 4477 inhabitants, on a territory of 2224 kilometres, and in 9 communes: 13 miles N. of Gap.

FIRM, Z, a town of Bohemia, in the circle of Leitmeritz; 8 miles N.W. of Leitmeritz.

FIRMNESS, FIRMITAS, in Philosophy, denotes the confidence of a body; or that state, wherein its sensible parts cohere, or are united together, so that the motion of one part induces a motion of the rest. In which sense, firmness stands opposed to fluidity.

Some authors confound firmness with density; as thinking the same state or property of body implied by both; or at least, that firmness follows density: but this is a mistake. For mercury, the densest body in nature excepting gold, is yet one of the most fluid; and even gold itself, with all its density, when fused, wants firmness, or cohesion.

Many of the Cartesians, and others, hold firmness to consist in the mere quiet of the particles of the body, and their mutual immediate contacts; urging, that a separation of parts can only arise from some matter interposed between them, which is excluded by the motion of contiguity.

But the insufficiency of this hypothesis is evident: for mere simple rett has no force, either to act or resist; and consequently two particles only joined by rett and contiguity, would never cohere so as that a motion of the one should induce a motion of the other. This is obvious in the case of two grains of sand, which, however contiguous, and at rest, will never constitute a firm coherent body.

The firmness of bodies, then, depends on the connexion or cohesion of their particles. Now, the cause of cohesion, sir I. Newton, and his followers, hold to be an attractive force, inherent in bodies, which binds the small particles thereof together; exerting itself only at, or extremely near, the points of contact, and vanishing at greater distances.

The firmness of bodies, therefore, follows the laws of the cohesion of bodies. See Cohesion.

Hence, firmness in all bodies must be as the surfaces and contacts of the component parts: thus a body, whose parts are by their peculiar shapes capable of the greatest contacts, is most firm; and that, whose parts are capable of the least contact, will be most soft.

In the former, the greatest requisite is to be as near to cubes as possible, and in the latter to spheres. And in the same manner are to be accounted for, not only all the intermediate degrees between the most firm and the most soft bodies, but those different consistencies, which are distinguished by other names, as friable, tenacious, glutinous, and the like; for the greater are the solidities of the component parts of any body, in proportion to their surfaces, though that body, by the aptitude of the contacts, may be what we call very hard; yet it will be most friable or brittle. And where the surfaces of the component particles are much extended upon a small quantity of matter, the bodies they compose, though they may be light and soft, yet they will be tenacious or glutinous; for although the flexibility of their compounding parts admits of their easy changing of figure by any external force, yet by their touching one another in so many points, they are very difficultly separated.

The former is the case in crystallized salts, refins, and the like; the latter in turpentine, gums, and all of that sort.

FIRMORE, a kind of lead-ore.

FIRMUM, in Ancient Geography, Ferma, a town of Italy, in Picenum, nearly S. of Potentia; situated at some distance from the sea. In the course of the Punic war, it sent succours to the Romans against Hannibal. It was taken by Totila, in the year 544.

FIROSAPOUR, in Geography, a town of Hindoostan, in Mewat; 13 miles W. of Cuttibah. See also Rousapour.

FIROUSABAD, a town of Peria, in the province of Mecran; 60 miles N.W. of Ernomal.

FIROUZABADI, Ibrahim Aboi Ishak, in Biography, a Persian doctor of high reputation for knowledge of the principles of the Mahometan law, who flourished in the eleventh century of the Christian era, and was born at Firouzabad, a town near Shiraz. Here and at Baflora he received the fundamental principles of his education. From Baflora
Bagdat, 38 ilill if or remembrancer, fmall and in Geography, Geography is the Ann. the 65 See lie fuch but ufually the his two (liarp fine but fhall term the term of firft-fruits and tenth, Queen Anne granted her royal charter, confirmed by flat. 2 Ann. cap. 11 whereby the the whole revenue of firft-fruits and tenth is vested in truftees for ever, to fhort a perpetual fund for the augmentation of poor livings, ufually called queen Anne's bounty. Blackf. Comm. vol. i. p. 284. &c. See Augmentation.

First-Fruits, Office of, is kept in the Temple, under the direction of a remembrancer, receiver, and comptroller, and their deputies and clerks.

FIRUZABAD, Firoozabad, or Giaur, in Geography, a town of Persia, in the province of Farifian; 65 miles S.S.W. of Shirms. N. lat. 28° 49'. L. long. 51° 58'. Also, a town of Persia, in the province of Trak; 12 miles W.N.W. of Ncvehvand.

FIRUZINUS Color, a term that frequently occurs in some of the old writers on gems, and has been mistaken by many to mean a ruddy brown; and by others, black; but these are not colours to be fought after among the gems, and yet it is to thefe that this epithet is ufually applied. We find it used for a blue kind of Jasper by fome authors, the fame with the Jasper known by Pliny and Dioscorides, and by others for the Laphire, which some of the ancients, particularly Theophratus, having called it μορφας, that is, black its deep colour, authors have been led to fuppofe that this word stood for black; but as there are not, nor ever were, any black sapphires, it is certain from this, as well as many other inftances, that the ancients ufed this word, μορφας, for a deep blue, and in that fene, furuzinus color does signify the fame thing; it being the aequinus color of the ancients, or what we call sky colour, or a true blue; such as the colour of the meft sapphires.

FIRUZKOH, in Geography, a fortress of Greater Buccharia, on the mountains that separate Balk from Segedian, taken in 1404, by Timur Tce; 30 miles S. of Gaur.

FIS, German, a sharp needle.

FISA, in Geography, a town of South America, in the province of Tucuman; 25 miles N.W. of St. Fernand.

FISANELLE, in Ornithology, a name given by the Venetians to a water-fowl of the columbus kind, called by authors the columbus major, or great diver. Very common in the markets of Italy. See COLUMBUS.

FISC, Fiscus, in the Civil Law, the treasury of a prince, or state; or that to which all things due to the public do fall.

The word is derived from the Greek αὐτός, a great bafket, ufed when they went to market.

By the civil law, none but a sovereign prince has a right to have a fice, or public treasury. See ΑΥΤΟΙΟΣ.

FISCAL, something relating to the pecuniary interest of the king, the public, or a private person.

The emperor Adrian ereded the office of fiscal advocate in the Roman empire.

FISCARD, or Fishcard, in Geography, a small market and nihing town in the hundred of Comlaws, Pembrokehire, South Wales, distant from London 15½ miles.
miles, and by the returns made under the population act, contained, in 1801, 344 houses, and 1505 inhabitants. The town is situated on the declivity of a high cliff, near where the river Gwayne, which separates the hundred of Cemmars from the hundred of Pebidrig, falls into the sea, forming a convenient road with good anchorage, vessels lying safely in five and six fathom water. The church is remarkable for little, but being definitee of a flepee. In the town are two other places of worship, one for baptists, and another for methodist dissenters. There are very few good houses, and the narrow, unpaved, filthy streets are strongly controlled, by the cottages being wholly white-washed, both walls and roofs. The town is however in an improving state, and lately it has received the advantages of a post office, and a weekly market held on Fridays, which is well supplied with corn and other provisions, cloth, flannels, &c.

Yet still its public accommodations are so few and indifferent, that Mr. Malkin's advice to travellers, "that they should aim to avoid pausing a night here," is still eligible. A road cut through a rock, forming a communication between the upper and lower parts of the town, opens a fine view to the bay. The harbour, having been recently filled by the erection of a pier, is of great advantage to the Irish trade, as Fieshord is the only port on this part of the Welsh coast, unaccommodated with those dangerous sands, denominated bars; and its situation to the north of Milford renders it a safe retreat for ships in blowing weather, unable to get round St. David's head. The port has a small coal trade, which employs about fifty vessels, from 20 to 100 tons burthen in the conveyance of butter and corn. A manufacture of coarse cloth is carried on in the town, but the principal part of the inhabitants is occupied in the herring-fisheries, quantities of which in the season are caught and dried here, particularly what are termed red herrings, by the process of smoking. Several smoking-houses are in the vicinity, and from being used for the purpose of drying, the fish are esteemed for their superior flavour. From the north-east wall of the church is a remarkable echo, which repeats sentences distinctly three times. In a dingle below the church is a strong chalybeate spring, celebrated for its sanative virtues; and between the church and the river is a vast stone, calculated to weigh more than nine tons, flat at top, measuring nine feet in diameter, and reposing upon three others placed in the ground, evidently one of those British Druidical monuments, denominated cromleches.

This place was brought into general notice a few years since, by the circumstance of two holliies frigates appearing off the port, and afterwards landing at Llaneno, in the neighbourhood, 1403 French invaders, who, after alarming the whole kingdom, and keeping possession of this part of the country a few days, were opposed by the sea-fencibles, and a troop of yeoman cavalry, amounting to 600 effective men, under the command of lord Cowdroy, to which inferior force, after a small resistance, they surrendered, and were marched prisoners to Haverfordwell. A curious incident on that occasion deserves notice. To the speedy and favourable termination of this, at first, formidable aggression, it appears the females contributed. Numbers assembled upon the surrounding heights, clad in their scarlet abitoles, (long mantles), and drawn up in ranks, the enemy took them for additional forces.

FISCSEL, a town of Spais, in Arragon; 15 miles N.W. of Ainfa.

FISCCELLUS MONS, Mount Fiscella, a mountain of Italy, between the country of the Sabines and Picenum.

FISCHAMUND, a town of Austria, situated at the junction of the river Fischa with the Danube; 12 miles E.S.E. of Vienna.

FISCHAUEN, a town of Pruffia, in the Frisch-hoff, anciently the residence of the bishop of Samland; 3 miles W. of Konigberg. N. lat. 55° 45'. E. long. 20° 2'.

FISCHBACH, the name given to several towns of Germany, in the bishopric of Bamberg, in the territory of Nuremberg, and in the principality of Bayreuth.—Also, a town of Swabia, in the county of Limburg.

FISCHBACH, or Fisf, a town of Switzerland, in the valley; 27 miles E. of Sion.

FISCHBRUN, a town of Germany, in the territory of Nuremberg; 4 miles N.E. of Herbruck.

FISCHER, JOHN CHRISTIAN, in Biographical, the most pleasing and perfect performer on the hautbois, and the most ingenious composer for that instrument that has ever delighted our country during full sixty years, that is to say, since Bastilla San Martini ceased to be heard. Fischer was born at Friiburg, and brought up at one of the common reading schools in a village in Bohemia, where all the children learn music, with reading and writing, as a thing of course. The first instrument put into his hands was the violin, but after he had made some progress in it, taking up the hautbois in sport, he fancied he could express his feelings better with the reed than the bow; he therefore attached himself to that instrument, and became, early in life, so excellent a performer on it, that he was appointed one of the king of Poland's celebrated band at Drefden. Here he remained till its dissolution, when he went to Berlin, without any intention of continuing there; however, arriving at a critical time, he was retained, and had the honour, during a month, to accompany his majesty, Frederic the late king of Prussia, alone, four hours every day. This circumstance was occasioned by an offence having been given by C. Ph. Em. Bach, who, in a letter with the rest of the band from Potzdam to Sans Souci in winter, had been so frightened by the badness of the road, as to exclaim to one of the household on his arrival, in rather strong terms: "tell our matter, sir, that no honour or profit will be a sufficient compensation to us for such dangerous service; and unless the roads are rendered safer, we (speaking in the name of the whole band), can come hither no more." It is true that the roads were very bad, and it is as true that Bach was extremely frightened in passing them. But cowardice sometimes is expedient; situations give a courage in remuneration, of which the greatest heroes are not in possession; for Bach's boldness in this particular not only surprised that of all his brethren, but of the most intrepid generals, and great captains in the Prussian army; none of whom, however they might have wished it, had the audacity to complain of this dangerous pass ere they could arrive at Sans Souci. But a court is at all times, and in all countries, of difficult access! The consequence of the transport that had escaped Bach was temporary disgrace and banishment from court; and this accounts for Fischer being the only musician allowed to accompany his Prussian majesty in his retirement and musical recreations. From Berlin he went to Mainz, to hear and be heard, and thence to Paris, where he performed at the "Concert Spirituel," and of the sensation which his performance produced there, an enthusiastic account is given in the Mercure de France. As Fischer, like Abel, was obliged to work his way hither by concerts, as soon as he had a little repaid his purde, he came over to England, where it was always his intention to settle, and where, as soon as he had been once heard in public, at a benefit concert, no other concert, public or private, was thought complete without his performance; and being engaged to play a concerto every night at Vauxhall, he drew together all layers of
music, but particularly professors, among whom the elder Park, who played the hautbois at Drury Lane theatre, used to quit his post, and for it half his night's salary in order to run to Vauxhall to hear him; which he did not profitably, for no tonic approaches bear near to that of Fischer, his richets and powers, that of the elder Park.

When the queen's band was formed, Fischer was appointed one of her majesty's chamber musicians; and when Bach and Abel, writing, established a weekly subscription concert at Hanover-square, where, for a long time, no music was heard but that of these excellent masters. Fischer was allowed to compose for himself, and in a style so new and fancifal, that in point of invention, as well as tone, taste, expression, and niceness of execution, his piece was always regarded as one of the highest treats of the night, and heard with proportionate rapture. Here Cramer, Caffelli, Corvetto, and other eminent professors, established their reputation, and by every new performance mounted still higher in the favour of the public.

In all musical performances at the universities, the triennial meetings at Wouccler, Henford, and Gloucester, at Salisbury, Winchester, and other provincial towns, Fischer's concertos were eagerly expected and heard with rapture. Fischer's tone was not only uncommonly sweet, but so powerful, that Giraldi, who never could praise a German but through the medium of shafts, used to say that he had such an influence of tone as no other instrument could contend with. Then his execution was quite as much as the instrument would bear to produce an agreeable effect. His taste and chiro-teno were exquisite, and he had his reed under such command, as more seldom to canarder or cackle like a duck, than any player we ever heard. And as to his composition, though it was inimitated by Bach and Abel that he had not studied regularly, and was no very profound theorist, he was always to original, interesting and pleasing, that he may be pronounced one of the few intuitive musicians who had powers which he knew not how he acquired, and talents at which study alone can never arrive.

A certain musical traveller has drawn a parallel between the performance of Fischer and Berozzi of Dröfden, nephew to the two celebrated Berozzi of Turin, on hearing him play a very difficult concerto on the hautbois in a very pleasing and matterly manner: owning, at the same time, that the less he thought of Fischer, the more he was delighted with Berozzi. However, he tried to discriminate, and to discover in what each differed from the other; and first, Fischer seemed the most natural, pleasing, and original writer of the two for the hautbois, and was the more certain of his reed; whether from being in less constant practice, or from the greater difficulty of the passage, he knew not; failed Berozzi in rapid divisions, more frequently than Fischer; however, Berozzi's swell, or mezza di voce, was prodigious; indeed he continued to augment the force of a tone to much, and so long, that it was hardly possible not to fear for his lungs.

His taste and cor were exceeding delicate and refined; and he seemed to possess a happy and peculiar faculty of tempering a continued tone to different dates, according to their several relations: upon the whole, his performance was so capitol, that a hearer must be extremely faditious not to receive from it a great degree of pleasure.

Fischer left England in 1756, and in the beginning of the next year had not been heard of. His majesty enquired several times, with some solicitude, whether he had written to any of his friends in England, and was answered in the negative; one of them understood, by report, that he was at Stralsburg. He returned, however, at the end of 1777, and continued in England during the rest of his life. About the year 1777, he had married a daughter of the admirable painter, Gaspariform, an enthuasist lover of good music and performance, and of some to such as Fischer's; indeed he enounced the whole family with his friends, and were beyond measure captivating, and it stood so well at his instrument, that his figure had all the grace of a Titan at the altar of Apollo. But, alas! something else besides a fine figure and fine music are necessary to constitute domestic happiness. The marriage was not auspicious; the minds were not in tune together, the temperaments were different, and the coincidence too infrequent to produce harmony. But we wish not to "draw their frailties from their dear abode;" she had external beauty, grace, and accomplishments; but he, with a good person, and superior genius for his art, was extremely deficient in colloquial eloquence, and in all those undebatable charms of conversation which engage the attention, and educe the speaker. He had not a grain of sense but what he breathed through his reed; he never spoke more than three words at a time, and those were negatives or affirmatives. But peace to his ashes. Though he had few charms for a friend or companion, he delighted the public at large in a higher degree than is allowed to any but gifted mortals. This admirable musician was feized with an apoplectic fit during the performance of a solo at the queen's house, at his majesty's concert. Prince William of Gloucester, observing his situation, supported himself out of the apartment, whence he was conveyed to his residence in Compton-street, Sobb, where he expired about an hour afterwards.

FISCHER, John Andrew, a physician of Erfurt, was born on the 28th of November, 1657; his father was a celebrated apothecary of that place. He graduated in the university of his native city, in April, 1691. He was appointed professor extraordinary in the faculty of Erfurt in 1695, and professor of logic in the Evangelical College in 1699; but he relinquished both these appointments in 1718, in order to assume the duties of the professorship of pathology and of the practice of medicine, to which he had been nominated three years before. Fischer acquired considerable reputation at Erfurt, and in the courts in the vicinity of that city. He had been ten years physician to the court of Mayence, when he died on the 13th of February 1729.

He left several essays in the form of inaugural theses; which were published between the year 1718, and that of his death; but he was also author of some more important works: viz. 1. "Consilia Medica, quæ in ulam præceptum et forensem, pro fepe curandi et renunciandi adorea in fine". Three volumes of this work were published successively at Frankfort, in the years 1704, 1706, and 1712. 2. "His in acu, sed Medicina Synoptica," Erfurt, 1716—17. 3. "Responsa Præstæ," Leipzie, 1719. —Eloe. Fischer, in Geography, a town of the duchy of Carniola; 17 miles S.E. of Steine.

FISCHERLIN, in Ornithology, a name given by many of the northern nations to a small species of the larus or gull, called by Mr. Ray larus pigitus, by Linnaeus larus minutus, and in the English, the solitary sea-swalower. See Larus.

FISCHGEYER, a name given to the false rufus; which see.

FISCHIARE, Ital. to bits. Fischità, bitful. FISCHIETTO, Ital. a whistle, a bits, a cat-cull. FISCHOTTER, in Zoology, a name given by Ridinger to the minutus; which see.

FISGARD. See Fisgard.

FISH, in Zoology, a class of animals which have either a naked or fealy body, always having fins, but without feet. For a further description of the characters of this class, and of
of the different orders into which it is distributed; see Precis. See also Ichthyology.

Fish, or Fishes, Anatomy of, has engaged much of the attention of physiologists, on account of its affording many examples of organs on a simple plan, or palpable scale, which in other animals poises either an obscure or minute structure. The brain, the car, the organ of feeding, the digestive and absorbent system, have been especially studied in two classes, with the view of illustrating their anatomy and functions in other creatures.

The continual residence and progression of fishes in fresh water necessitate peculiarities in their organs of motion, as well as a different mode of expunging the blood to the influence of the air, and consequently a different arrangement of the circulatory vessels than is usually met with in other animals; these parts of the anatomy of fishes are instructive both to the natural historian and to the physiologist.

The very extraordinary property which some fishes possess of communicating an electric shock, forms one of the most interesting subjects in the history of the animal economy.

In composing the present article, we have drawn our information, as far as our opportunities permitted, from actual dissection and observation; frequent references to the writings of other anatomists are therefore not introduced. It is necessary, however, to acknowledge, that we have derived great assistance from the comprehensive syllisem of M. Cuvier, particularly with respect to the anatomy of the rare and exotic species of fishes; and that we are indebted for several interesting facts to the very valuable, though copious, work, of Professor Blumenbach on comparative anatomy, translated by Mr. Lawrence.

Organ concerned in the exercise of the vital functions.

The mouth and its contained parts.—The position of the mouth of fishes is somewhat various. It may be stated generally, that it is situated in the front on the elongated, in the 

_Without the context, the rest of the document appears to be a continuation of the previous text, discussing the anatomy of fish, their unique features, and the role of the mouth in their feeding and respiratory processes. The text implies a detailed examination of various fish species, their physiological adaptations, and the importance of the mouth in their overall anatomy._

The mouth is a crucial organ in the feeding process of fishes, allowing for the ingestion of food. Different fish species have evolved unique mouth structures to suit their diet and habitat. For instance, some species have broad mouths to filter plankton, while others have elongated mouths for capturing larger prey. The internal surface of the mouth can be intricate, with various teeth and structures adapted for specific feeding habits.
FISH.

has, however, established four principal forms to which he thinks all the others may be referred: the first are the book-shaped teeth, which have sharp points bent towards the back part of the mouth; these are usually of a small size, and are very numerous, they are by the moll common: moll fishes have them in some part of the mouth. The second kind of teeth are truly conical in their form; the anterior teeth of the anarrhichas lupus afford the best examples of these. The third have the crowns either flat or blunt, and rounded; the pharyngeal teeth of the 

Cuvier in the fourth division of Cuvier includes the teeth with a cutting edge, or the wedge-shaped; these may either have the edge plain, as in the plaice (placentes platysis), or denticulated, as in the tench.

Different species of teeth frequently exist in different parts of the mouth in the same fish; thus, the genera teuthis, osaerion, and bolistes, have hook-shaped teeth posteriorly, and incisive in the front of the mouth. In the anarrhichas lupus, and some of the genus farrus, there are hook-shaped teeth behind; plates or flat-crowned in the middle of the mouth, and conical teeth before; the farrus foepar, and some others, have the front teeth incisive, the middle flat-crowned, and the afterhook-shaped.

Cuvier has given a description of the form and situation of the teeth in moll of the principal genera of fishes; but, as much minuteness or detail on this subject cannot prove interesting in an anatomical point of view, we shall confine ourselves to the more striking variations in the teeth of fishes.

In the genus raia the jaws are bifid with a number of teeth arranged in the manner of a pavement; these are usually of the same size, and disposed in squares closely set to each other. In some species, especially in the foreign rays, the middle teeth are the largest, and run in bands across the jaws: in some of these also this pavement of teeth is prolonged towards the palate; in the torpeda, and some other species of raia, each of the teeth is elevated in the middle into a spine or sharp point.

In the farrus genus (farrus) there are several rows of teeth; those of the front row are the largest and oldest, and stand up on the jaw; the succeeding rows are of later growth, and are laid down with their points turned towards the mouth; the number of the rows that are turned towards varies even in the same species. The form of the teeth in this genus is usually that of a triangular plate; they are attached at their base, and the other edges are more or less denticulated or grooved.

Among the brachyodonti there is very considerable variety. The genera bolistes and osaerion have eight teeth upon each jaw; in the former they are wedge-shaped, broad, and flat, and with oblique edges; in the latter they are compressed upon the sides. The pharynx of the bolesi is furnished above and below with two rows of fine, conic, close-fet teeth.

The lump fish (cyclus lupus) has one or two rows of small pointed teeth upon the jaws and the pharynx.

The frog-lit (lithos pikeatorius) has two rows on each jaw, a small one on each side of the palate, and the four plates of the pharynx furnished with tolerably strong hooked teeth.

In the fpatulatrix there are a number of very minute teeth upon the jaws and lateral parts of the palate.

In the farrus (aciper) there are no teeth of any kind found.

In the chimera the lower jaw furnishes two naked projections, which are flattened and sharp-edged, and the upper jaw has two others of nearly a square figure, which correspond to these. In the palate there are two triangular effuse plates.

Cuvier thus describes the singular formation of the jaws, which supplies the place of teeth, in the genera farrus and tetricinus.

The lower jaw of a farrus presents two eminences, which are used for mastication, i.e., the border of the jaw, which is parabolic, and a round disk in the middle. A large canal runs in the interior of the bone, and separates the mass of the disk from that of the border, and transmits to both these parts their nerves and blood vessels. The triturating surface of the disk exhibits some transverse and parallel lines; on cutting it in a vertical direction each of the lines is perceived to be the termination of a plate or lamina, which ascends a little posteriorly from the canal to the disk. These laminae are all laid one upon the other, and by this process the superior lamina is most exposed to friction, and consequently the shortest. They are evidently also the oldest; they are hard and consolidated together, in proportion as they descend they are finer and more separate from each other. The lower do not reach the triturating surface, but are covered by the bone of the jaw; these are quite distinct from each other, and shew the original and partial structure of the plates.

Each of these lamina is divided by a fissure in its middle. The inferior and posterior surface is tolerably smooth, but the opposite one exhibits, when viewed through the microscope, an extremely fine net work of little canals; this is occasioned by the impressions left by vessels which have run upon it, and which have run from the large canal where the bafes of the laminae red; in fact, the parietes of the canal are preceded by an infinite number of small holes, which lead into the intervals between the laminae.

The border is also furnished with laminae which increase in an opposite order to those of the disk; the anterior lamina being inferior and of the latest growth. The laminae also are parallel with the surface of the masticating border. The first lamina which is used presents its flat surface, and is consequently entirely worn before the one which succeeds it. The description here given of the lower jaw of the farrus applies equally to the upper jaw, provided the names of the laminae are changed according to their different position, as superior for inferior, and vice versa.

The genus tetricinus resembles the farrus; in having the lamellated borders, but wants the triturating disk. Each of their jaws is divided into two pieces by a denticulated fissure.

Fig. 1. Plate I. Anatomy of Fishes, exhibits the lower jaw of a farrus, cut through longitudinally; a, the central plate, or triturating surface; b, the friction of the laminae; the edges of which constitute the triturating surface; c, the large canal through which the vessels and nerves of the laminae are transmitted; d, the border of the jaw; e, the lamina which forms it; f, a smaller canal for accommodating their vessels and nerves.

Among the apodous fishes, the anarrhichas lupus has the teeth of the front of the jaws very strong, and conical in their figure; those of the side, and on the vomer, form large hemispherical tubercles; the internal row of each palatine arch is similar to the second, and the external to the first; the pharynx is set with small conic teeth.

The murena helena has the teeth compressed, with thin edges, and sharp-pointed; those of the common eel and the conger (murena anguilla and the conger) are small, straight, strong, blunt, and close set; the first teeth of the vomer in the helena is at a distance from the others, which it also much exceeds in size.

The
The jagular order of fishes also exhibits considerable varieties in the form and number of the teeth.

The _blennius_ species has a very regular close row on each jaw of long narrow teeth; the _blennius_ also has beside a strong hooked tooth placed at the back part of each jaw. The _trachinus draco_ possesses teeth in all the different situations except the tongue; they are very minute and close-set resembling the pile of velvet.

The _urolophus_ species has twelve or fourteen teeth, of hook-like, on the lower jaw, and numerous minute teeth on the upper jaw and pharynx, and two little lateral plates on the fore-part of the vomer.

In the _blennius_ species there is perhaps still greater variety than in the preceding orders; the individuals of the same genus often differing from each other.

The _flying gunnard_ (trigla volitans) has only small blunt tubercular teeth upon the jaws; the _armed gunnard_ (trigla cataphracts) has some close-set teeth, like villi, upon the branchial arches and vomer, and none at any other place. The _common gunnards_ have fine teeth upon the jaws and branchiæ, and a little plate on the anterior part of the vomer.

The _dog_ ( _cyprinus_ ) has some small hooked teeth upon each jaw, the vomer, and the branchial arches. The _ear_ _vomer_ has on the lower jaw only a row of teeth, so fine as scarcely to be felt.

In the genus _pleuronectes_ there is considerable variety with respect to the form and situation of the teeth.

The _chetodon_ have upon the jaws long, fine, fetaceous teeth, like the bristles of a brush.

The pharyngeal teeth of the genus _labrus_ are broad and hemispherical, and are disposed exactly like pavement; the anterior teeth vary in the different species.

The _labrus niloticus_, however, differs remarkably from the rest of the genus; the jaws are furnished with several rows of long, slender teeth, which have two or three points; the teeth of the pharynx are straight, flanger, sharp, and very long.

In the genus _paras_ , the lateral teeth of the jaws are arranged in the manner of a pavement, in two or more rows. In some species two of these teeth are distinguished from the rest by being larger, and of a more flattened oval figure; the anterior teeth vary much with respect to their form.

The _perch_, and the genus _babolobatus_, in general have numerous minute teeth, like villi, upon the two jaws, the anterior part of the vomer, each side of the palate, the tongue, and the pharynx.

The jaws of the genus _paras_ are naked, and project somewhat like the beak of a parrot; each mandible is divided by a middle line; the border is furnished with some little short cutting teeth, which are very closely applied to each other.

In the genus _ceola_ there is a single row of teeth to each jaw. Those of the lower jaw are remarkably spread out.

In the _abdominal order of fishes_, the genera _paras_ and _salmo_ exhibit great variety with respect to their teeth; in the latter genus particularly the differences are very remarkable.

The _salmo_ clarias has the teeth of the upper jaw straight, slender, and sharp, but those of the lower jaw are bent into the form of an overturned italic σ; they are long, compressed, and terminated by a point.

The _common salmons_ and _trouts_ (_salmo_ _fahari_, and _salmo_ _fario_) have hook-shaped teeth in all the parts of the mouth where they are met with in other fishes, and likewise upon the arches which form the external lip of these.

The _salmo_ _dente_ has ten or twelve large hook-shaped teeth upon the jaws; those of the pharynx are fine, like villets.

The _salmo_ _negro_ has the maxillary teeth facetaceous, like those of the _obtusodon_, but forked at the extremity, and the pharynx covered like velvet.

The maxillary teeth of the _niloticus_ _salmon_ are thick and truncated, and have the crowns furnished with two or three conical tubercles, like the molar teeth of some quadrupeds.

The _sera_ _salmo_ of _La Cépéd_ has ten or twelve teeth on each of the jaws, in the form of sharp wedges, with three or five notches on the edge.

The jaws of the _salmo_ _rhomboides_ have very small, short, flexible, facetaceous teeth.

None of the last mentioned five species have the interior of the mouth furnished with teeth in the same manner as the _common salmons_ and _trouts_.

The whole of the genus _cyprinus_ possesses only teeth in the pharynx. The superior pharyngeal bone presents a single plate; and the two inferior bones of the pharynx are each furnished with very thick, strong teeth, which vary in numbers and form in the different species.

The _carp_ ( _cyprinus carp_ ) has four or five of these teeth; the three or four posterior and superior of which are flattened and transversely grooved; the one most anterior is round, with a little point in the middle.

Other species of _cyprinus_, as the _auratus_, the _bipunctatus_, the _bream_, _tench_, and _rud_, have the teeth compressed, and their edge applied obliquely to the superior pharyngeal bone.

The _barbel_ ( _cyprinus barbus_ ) has nine pharyngeal teeth, four below, three in the middle, and two above; they are club-shaped, and end in points a little bent.

The _cyprinus_ _obulus_ has seven teeth in two rows, all pointed, and a little like hooks.

The _cyprinus_ _nuptus_ has twenty-one compressed teeth.

In the _niloticus_ _carp_ there are eleven of these, the points of which are worn down by friction against the plate of the superior pharyngeal bone.

The _genus_ _efox_ are well supplied with teeth. The _common efox_ (_efox lucus_ ) has teeth in all the parts of the mouth where they are found in other fishes; those of the lower jaw are tubercular, the others are hook-shaped, and the _efox_ _lurie_ has the maxillary teeth strong, hook-shaped, and in one row; it wants the lingual teeth.

There are three different structures to be observed in the teeth of fishes.

The first kind of structure exists in the conic and hook-shaped teeth, which are generally found in the inoffensive fishes; their teeth are implan ted in alveoli, as the teeth of mam malia; they consist of inoffensive substances, covered externally by a layer of enamel: after the eruption of the crown or external part, the roots of their teeth become anchyloped with the bone which contains them so firmly, that they cannot be separated without a fracture of the latter. The growth of the teeth situated in sockets is effected by the development of internal inoffensive layers.

The ground kind of structure is found in the teeth of the genus _speratus_. These are not immediately connected with the gums, but are contained in the gums, or soft parts covering them. They increase in the manner of the epiphyses of bones; their inoffensive part is at first soft and porous, and afterwards acquires throughout the density and hardness of ivory.

The third form of structure belongs to the flat or blunt teeth,
teeth, which are arranged in the manner of a pavement, as with the jaws in the ray genus, and in the palates of several other fishes. They are composed of a number of minute ossaceous tubes, arranged in the direction of the teeth, intimately connected together, and covered upon their external extremities by a common layer of enamel. From this structure Cuvier has distinguished these teeth by the term compound. They are not implaned in the substance of the bone, but adhere to the membrane which covers it; they evidently, however, consist of two parts corresponding to the root and crown; the former is marked by regular and close furrows, and contains a number of pores, which receive and transmit the nerves and blood vessels of the teeth; the tubes of the crown are more dense in their structure than the rest of the teeth.

The jaws of the anarrhichas lug宿 are furnished with a number of dentiform eminences, which are composed of ossous tubes, or fibres that run from the hinge to every point of the surface. The base adheres to the jaw by its circumference only; this circumference exhibits many foramina, through which the vessels and nerves pass to the tubes when in a state of growth. All these eminences are placed upon a substance much more fleshy than the rest of the jaw, which serves as the medium by which they are united. On the middle of each eminence a little tooth grows, but is cast off very early, so that, except when the fish is young, the uniform eminences alone seem to supply the place of teeth.

Fig. 2. of Plate 1. of the Anatomy of Fishes: a is the dentiform eminence; b, the small teeth on it. Fig. 3. of Plate 1. shows the surface on which the eminence is fixed.

The triturating surfaces of the jaws in the genera diodon and tetraodon might be considered as compound teeth; the laminae are analogous to the tubes, and are covered, like them, by enamel.

The mode of Jesseion of the teeth of fishes varies according to their structure. Those that grow in sockets are replaced by others which form at their roots, when the root of the old tooth becomes consolidated with the foot which contains it; it is nourished like the root of the bone, and acquires a cellular structure, which it did not originally possess. In proportion as the new tooth increases, the substance of the jaw grows into the cavity of the old one, which it fills up to the crown. This then separates from the root of its bone by a regular fracture which exhibits some radiated lines.

The new teeth in many species penetrate the cellular ossaneous substance, which fills up the cavity of the root, and exactly occupies the situation of the tooth that as cast off. In the large, pointed teeth, such as those of the genus oxus, &c., the eruption of the new tooth is on the side of the one that is shed.

In the anarrhichas lug宿, not only the teeth are shed, but those singular eminences on which they grow are also cast off, and replaced by others. These eminences appear to resemble in structure and mode of growth the horns of the deer; they are lined precisely in the same manner; to the which succeed grow on the side of the eminences they replace, and do not, until they increase in size, fill the vacancy left by the latter.

When the bony teeth of the rays are lost they appear to be replaced by others, which grow in the same situation.

The cutting teeth of the eel, as already mentioned, are in several rows. the anterior of which only is used by the animal; the posterior rows are of successive growths, and are designed to fill up the place of those in the front row, in the same manner, as the venous teeth of surfetes are succeeded by those of a later growth situated behind.

The laminae which compose the triturating surface of the jaws of the diodon and tetraodon are replaced in a manner analogous to the cutting teeth of the eel; these laminae grow and come into use successively, by which means the masticating surface is always preferred.

In the genus larus the teeth are replaced by others growing from behind, but which do not make their appearance until they are wanted. On examining the jaws of one of this genus, a number of tubercles are observed on the front part, which are the remains or roots of the teeth that have been worn down; and in the jaw is divided, a multitude of the germs of teeth will be discovered internally, which are afterwards to come into use.

The mechanism of the jaws, the small size and immobility of the tongue, the want of movable glands, and the small and position of the teeth, in fishes, all conspire to point out the manner in which these animals take their food, and that they do not, but with very few exceptions, make it, or even in any degree divide it previous to its being received into the pharynx.

Pharynx and esophagus.

The pharynx of fishes is rather distinguished from the rest of the esophagus by analogy of situation, and for the convenience of description, than from any resemblance it bears to the pharynx of mammals.

The passage from the posterior part of the mouth into the esophagus is diminished by the existence of certain bones, which are attached to the bases of the branchial arches, and enter into the composition of the palettes of the commencement of the air canal.

These are very properly called the pharyngeal bones; they are usually bevelled with teeth, as already mentioned; the left branchial arches and the pharyngeal bones can be approached by certain musculi, so as nearly, if not entirely, to shut up the communication between the mouth and esophagus: immediately behind the branchial arches and pharyngeal bones there is a very strong sphincter muscle, which surrounds the origin of the esophagus, and appears to be the continuation of those fibres which clothe the branchial arches. This muscle seems to have the power of perfectly shutting the pharynx. The design of the pharynx is evidently to enable the fish to convey its prey, without any preparation, and while it is still alive, into the pharynx. The teeth invented on the pharyngeal bones, and on the inside of the branch decreased are well calculated for assisting in this operation: to understand the effect of the teeth of a fish in the act of deglutition, it is only necessary to introduce the hand into the back part of the mouth, even after the animal is dead, when it will be found that the retreat of the hand is opposed by the points of a number of teeth at all sides. The construction of the interior parts of the mouth and pharynx appears to be entirely subserveint in fishes to the performance of deglutition.

In Plate 1. of the Anatomy of Fishes, Fig. 4. exhibits a view of the back part of the mouth or pharynx of the carp (cyprinus carpio): a, the inferior pharyngeal bones which with strong grinding teeth; b, the superior pharyngeal bones with flat surfaces; c, the inferior palatine of the mouth; d, the tongue; e, the branchial arches of each side; f, the aperture left between these parts which leads into the esophagus.

The esophagus of fishes is commonly very short; in some influences the mouth is almost to be luted to open into the esophagus; it is by no means unfrequent, on separating the jaws of a fish extensively, to bring into view the contents of that cavity.

The
The oesophagus is generally very wide, often of the same capacity as the stom-ach itself. A free passage into the stom-ach becomes necessary to those animals, on account of the size of the fishes they prey upon, and their voracity in catching them. Fishes rush upon whatever appears to be their prey impetuously, and sometimes without discrimination. In this manner they sometimes swallow other fishes that are not their proper food. We lately took a large flounder out of the stomach of a dog (Nass fischer), which bore all the marks of having refilled three times; it was from a knowledge of the rapacious habits of this fish, in fact, St. Peter's taking the tribute money out of its mouth probably originated.

The oesophagus is covered internally, as in other animals, by cuticle, which terminates abruptly at the stomach in some fishes; this is not perceptible; in which cases it is difficult to determine exactly the limits of these two portions of the alimentary canal. The internal membrane is usually white and smooth, and forms some longitudinal wrinkles, folds, or fricule. In severa of the rays and sharks genera this structure is very evident, although Cuvier describes the internal surface of the oesophagus and stomach in fishes to be alike. In the manta (rajus catvata) the difference between the structure of the oesophagus and that of the stomach is strikingly plain. In the dog-fish, the innermost line of the membrane of the oesophagus is numerous, prominent, and terminate in points which are directed backwards. These diminish the capacity of the canal, and thus serve to detain any fish the animal may swallow; but the most remarkable contrivance of this sort is that lately discovered by Mr. Home in the hakefish or hawk (fuguinus maximus). In this fish, in addition to the fricans observed in the other species of fuguinus, the oesophagus produces, around its termination in the stomach, a number of fringed processes, very much resembling thistle-knots; these appear to be muscular internally, and probably are capable of entirely closing the entrance of the oesophagus into the stomach. In fig. 5 of Plate 1. of the Anatomy of Fishes, the stomach and oesophagus of the basking fisk (fuguinus maximus) is represented upon a very reduced scale: a lheus the stipulated part of the oesophagus; b b, the fringed termination of that canal.

In the flatfishes, the parietes of the oesophagus have three strong longitudinal rugae, and some others between them of a smaller size. In the flataen (fuguinus platessa), the internal membrane produces spines like thole of the dog-fish, which, when minutely examined, are seen to be articulated upon the surface. The fuguinus pelagius, and fuguinus fuguinus, have long-lungitudinal folds in the oesophagus. The latter is likewise an oesophagus of some length: at the place where it joins the stomach, it forms a conical process or cul-de-sac of a conical figure, the end of which is terminated forward.

In the offation echidus, and some other fishes, there is a circular fold of the internal membrane, which clearly marks out the termination of the oesophagus; in other instances, this part may be distinguished from the stomach by the strength and arrangement of its muscular fibres, but in every instance, if the blood-veins of these parts have been previously injected with a coloured fluid, there will be no difficulty in determining which is the oesophagus and which is the stomach, the former being always less vascular.

The oesophagus in fishes is particularly well supplied with mucus, to facilitate the passage of the body through it: this mucus is furnished by follicular glands, which are situated behind the internal membrane; they are more numerous in some fishes than others; we have found them very plain and arranged in clusters round the oesophagus of the mullet.

There is on the oesophagus of the toadfish a very remarkable glandular apparatus for the secretion of mucus.

Of the Abdominal Cavity.

The abdomen of fishes is a distinct cavity containing only the vitals proper to that part; it differs therefore from the common cavity of the body in birds and reptiles; it however usually occupies the greater part of the trunk in fishes in which it is so remarkable the abdomen of mammals. Its parietes are chiefly composed of the portion of the great lateral muscles which are spread upon the under side of the body, the ribs being too short in fishes to form a frame for the abdomen; the cavity is everywhere covered with peritoneum, except next the spine, where it membrane is reflected across the air-bladder and kidneys, leaving these parts on the outside of the peritoneum. The folds of this membrane, which embrace the different abdominal viscera, are very thin, but the part which forms the abdomen is sufficiently strong.

In the moon fish (latrunculus melas), and in many other teleosts, it is flatted by Cuvier to be thick, flat, and as it were gelatinous: although in the flataen, and others of the branchiostegi, its texture is firm and does us looking.

The portion of peritoneum which lines the muscular parietes of the cavity very inquately-partakes of the colour of the external surface of the body, in consequence of there being a pigment placed behind it. In the platy (pharyngodon platessa) the two most of different colours, composing to one brown and white sides of the body in that fish.

In five fishes there are processes of the peritoneum which go on each side of the intercostal bones of the ten under the lateral muscles; these form faces for containing usually the organs of generation and part of the kidneys, and in some instances a convolution of the intestines, thus the bag which goes out on the dark side of the fisk receives a long coil of the intestinal canal.

There are some very remarkable circumstances to be noticed in the abdomen of the ray kind and the flataen (mappa): there have long been observed in the former two orders, one on each side of the anus, which lead by a short oblique canal into the cavity of the abdomen; they are wide enough to admit a goad equal to a large fisk, but contain within them a semicular fold, which acts as a valve in obstructing the passage of the water into the abdomen, but does not prevent fluids to pass out of this cavity. Doctor Monroe, who ascertained the discovery of these folds, was inclined to suppose that the sea water occasionally was admitted by them: he says, 'the great quantity, and evidently salt taste of the liquor of the abdomen, led him to look for passages by which the sea water might get into the cavity.' In one instance, he held the fish in a vessel, when he found that it contained about one forming to part of salt, which, however, he admits to be not much: the quantity that exists in common sea water.

"Fishers," he says, "I discovered that in the flataen, the bottom of the peritoneum is lengthened into the base of a funnel which divides into two branches which arise and convey to the lower part of the eulo agas. and open into the cavity of the abdomen from the obliquity of these branches, and their intimate adhesion to the oesophagus: neither water can be forced into them from the abdomen. Hence, while we suppose that in the living animal they take up fluids from the abdomen, in the way our partial flataen by the tuber, this is highly improbable: we must conclude that they serve to convey the liquor containing the cavity of the abdomen."

In the flataen (mappa bran.) Doctor Monroe has also described...
described and figured two openings near the anus, similar to those found in the fluke, and further, he discovered in the _anguilla_ a large minuminous funnel, situated upon each kidney, into the middle of the pelvis of which its bottom opens by a wide orifice. "We can live half or no doubt," he says, "that the lumen of the abdomen of the _anguilla_ passes into the pelvis of the kidney, for we cannot suppose that the urine passes through the holes decribed into the cavity of the abdomen, as the pelvis has large openings into the common cloaca, as in other fishes." (Monroe, loc. cit.) He concludes by expressing his opinion, that the design of the holes on the side of the anus is to admit the sea water, and that the funnels connected with the kidney are for the purpose of discharging it again. From the circumstance of the water of the abdomen containing so much salt felt than sea water, and even less than that found within the cranium of fishes, which is a salt cavity, he is disposed to admit it is in part a secretion from the arteries. In our opinion, it appears more reasonable and consonant with general analogy to suppose, that all the fluids moistening the cavities of these fishes are produced in the usual way, and that the openings are merely for carrying the superabundant liquor out of the body, than to imagine that an extraneous fluid should be admitted as the fluid placed of peculiar secretion; considering the matter in either point of view. In the second place, however, the anatomical fact of a communication between the interior cavities of the body and the external element, is not only highly curious, but without example in any other class of animals.

**Stomach.**

This cavity is commonly situated immediately behind the septum which separates the heart and branchiate from the abdominal venules to which it is attached, as well as to the surrounding parts by reflexions of peritoneum.

The form which the stomach of fishes most commonly possess has been very aptly compared to the head of the chemical vessel, called an alembic, supposing it to be inverted and a little elongated; the large opening correponds to the oesophagus; the small or lateral part to the contracted portion, which ends at the pylorus, and the bottom to the cul-de-sac of the stomach. The more common deviations are produced by the bottom of the cul-de-sac, or caecal portion of the stomach, being either longer or shorter than what has been described, or it being formed by a conic or cylindrical shape. There are also other varieties in the figure of this viscus which will be noticed in the following description.

The muscular coat of the stomach varies very much in thickness, and likewise with respect to the distinctness and arrangement of its fibres.

Between the muscular and internal coats there is often found a layer of mucous follicles.

The internal membrane varies very much as to thickness, and its surface is either smooth, reticulated, or plicated.

The structure of the stomach in fishes does not correspond with any natural classification of these animals, and therefore does not admit of a systematic description.

The rays have the stomach nearly of the common form. There are some folds of the internal membrane; in the _nudilis_ (roga elevata) it is a thick spongy mass, which peels off easily after maceration. The irregularities of the surface look like the rugae of the human stomach, they are not however produced by the folding of the coat, but by the thinness or actual deficiency of some parts of it, we observed very thinly scattered over in these manner round the depressions which Mr. Home has conceived to be the glands for secreting the gallic juice; in this as well as other inferences these glands bear no sort of proportion to the quantity of the fluid which physiologists have hitherto supposed requisite for digestion.

The stomach in the _anguilla_ consists of two portions; the first is much longer and wider than the second, which is straight, and has the appearance of an intestine; the two portions communicate by a small opening, which will only permit substances to pass into the second stomach, that are reduced into a smooth and fluid state. There are well marked longitudinal rugae in the first stomach, but those in the second are but little apparent.

In the _anguilla_ (anguilla maximus) the first stomach is reticulated at the beginning, and towards the pylorus has very prominent, longitudinal folds, and there is a globular cavity interposed between the pylorus and the intestine, which communicates with each by a very contracted aperture.

In the greater dog-fish (sphyraena canicula) the muscular fibres of the stomach are mostly longitudinal; they are numerous at the cardiac and pyloric extremities, but not well marked elsewhere. The muscles of the stomach are much stronger in the _anguilla_ (anguilla plebei) than in many other species; they are extended over the whole of both portions; the stomach is almost circular. The internal membrane in this species forms large and numerous folds, which have different directions; behind the internal membrane of the large portion of the stomach there is a glandular layer of a greyish colour and some thickness.

The _anguilla_ has two fortes of rume in the first stomach; one are longitudinal, and lie parallel to each other; the second are transverse, and perpendicular to the first.

The internal membrane of the first portion of the stomach in the _anguilla_ (anguilla plebei) has twelve or fourteen very large longitudinal and parallel folds, which are grooved transversely; the second stomach in the same fish is perfectly smooth.

The stomach of the _anguilla_ (anguilla plebei) is not to be distinguished from the other parts of the alimentary canal, except from its situation.

In the _anguilla_ (anguilla plebei) the structure of the stomach is singular; after being prolonged for some way as a simple tube, it is bent so as to make a complete turn, it becomes contracted on this side of the pylorus, and then again forms an enlargement of a pyramidal figure, the base of which corres ponds to the pyloric opening; this enlargement is produced by a very thick muscle, the fibres of which run obliquely from without inwards; the pyloric orifice is very small, and bounded by a circular fold. The internal membrane is smooth and without villi, except at the part corresponding to the enlargement, at which place there are thin, long folds of a pyramidal figure, the bases of which touch the pylorus, and are covered with a new-work, similar to that in the cef phagus of this fish.

The stomach of the _anguilla_ (anguilla plebei) is very wide, and fills a great part of the abdominal cavity; it has a round figure, and forms a cul-de-sac which is not as usual in the direction of the oesophagus, this canal and the intestine opening near each other. The internal surface of the stomach is smooth; there is a circular valve at the pylorus.

In the _anguilla_ (anguilla plebei) the alimentary canal proceeds from the mouth to the anus, as in the _anguilla_ (anguilla plebei), without forming any convolution: the part which corresponds to the stomach, according to Cuvier, the one twentieth of the whole; it is distinguished from the rest by a slight convolution, and by two layers of muscle: the external layer is formed of circular fibres, which surround the stomach; the internal layer
layer is longitudinal. The internal membrane has some large longitudinal folds.

The stomach in the genus *labius*, and in the *schracans*, bears considerable resemblance to that of the *sphygus*. It has thick parites plicated internally, and is distinguished from the other parts of the canal by its thick muscular coat; in the *labius* there is a denticulated valve interposed between the stomach and intestines. In the *schracans cristaec*, the part corresponding to the stomach may be known by its form; its parites are thin, transparent, and wider than the rest of the canal; its internal membrane is smooth, except next the oesophagus, where it produces some waving folds; from that place the canal gradually diminishes, its coats become thicker, and the internal surface villous and plicated.

The form of the stomach in the *abyss triglaeas* is very different from the usual one in fishes. It is the shape of a globe, a little extended at the cephalical and pyloric orifices, which are situated exactly opposite each other; the one before and the other behind. The coats of the stomach are thin and weak, and apparently without muscular fibres; the internal surface does not present any inequalities, and the orifices are unfurnished with any valve.

Cuvier describes the stomach of the *lupius pectoralis* as a big, having the same capacity and direction as the oesophagus, and extending nearly the whole length of the abdominal cavity. The internal membrane is confounded with the cellular coat, is very thick, soft, and pulpy, and forms a great number of thin procresses and large irregularly shaped rugae; the first are particularly remarkable around the cardiac, where they seem to produce many glandular mucus, some of which extend into the oesophagus. There are further to be observed some little orifices of cells equally small, placed in the substance of the internal membrane, which appear to be designed for the secretion of mucus. The aperture of the pylorus is much contracted; it is surrounded by a very thin circular border, which projects considerably into the intestine. The mucular coat of the stomach is very strong at every part, its fibres are longitudinal.

In the *lump fish* (*pleurotus lumpus*) the figure of the stomach is nearly that of two ovals united at their ends; the angle formed by their junction corresponds to the cephalic portion of the stomach in other fishes, and the other ends receive the oesophagus and the intestine; the stomach is smooth upon the internal surface, except near the pylorus, at which place there are some pleats; it exhibits a number of opaque spots, which are occasioned by the union of very few laminae, circularly situated between the muscular and internal coats. They have each a small orifice in the centre, and appear to be destined to secrete the mucus of the stomach; the muscular coat is confined to the second oval part of the stomach, and near the cardiac orifice; the parities are in other places thin and transparent.

In the *eel* the cephalic portion of the stomach is very much elongated, and of a taper or funnel-shape; the pylorus is situated very near the oesophagus, and appears to be formed by two portions; one from the oesophagus, and the other from the elongated part of the stomach, from which it would appear that all the food does not in this fish pass through that part; the internal membrane produces some longitudinal pleats at the pylorus, which become less evident and wavering towards the bottom of the funnel part of the stomach. The fibres of the muscular coat are circular; although they are longitudinal on the oesophagus; there is a sheath of the internal membrane, which contracts the aperture of the pylorus.

The *conger* has very nearly the same form of stomach as the *common eel*; the prolonged part is, however, less taper, the Vol. XIV. muscular fibres are more curved, and the pylorus is bordered by a broad lamina; the internal membrane is firm and white, and forms a few long folds which extend from the oesophagus to the bottom of the cul-de-fac, or cephalic portion.

The *jugal* order of fishes afford many examples of the usual or proper figure of the stomach.

In the *trachinus draco* the stomach varies but little from the usual form; it is somewhat larger than the oesophagus, and its parities are thrown into a few irregular and oblique folds, which are visible even on the external surface.

The genus *gadus* does not afford much singularity in the formation of the stomach. The caudal (*gadus morhua*) has the cephalic portion very short, and, in other words, the part which goes to end in the intestine runs near the bottom of the stomach.

The *bake* (*gadus merlangus*) has this part placed forwards, and the cachalot (*gadus morlingus*) has it still more so.

The liver (*gadus morhua*) has the cul-de-fac much elongated, but without any alteration in its capacity. In all these fishes the part which ends in the intestine is much contracted.

Amongst the *thoracics* we observe the following varieties of structure in the stomach.

In the *father loisher* (*cottus scorpius*), and *bull head* (*cottus gobus*), the stomach is very muscular and of an irregular shape.

The cephalic portion is considerably larger than the oesophagus; the part which ends in the intestine is situated near the entrance of the oesophagus. In the *goby* of the *Nile* (*cytus niloticus*) the cephalic portion is smaller than the other parts of the stomach; and the intestine arises far from the oesophagus.

The stomach of the *septentor barida* resembles that of the *nilotic goby*.

In the *lyre* (*cellfomus lyre*) the cul-de-fac is formed immediately at the commencement of the stomach, which is at first globular, and is afterwards contracted posteriorly to nearly the size of the oesophagus; on the right side of the dilatation, the part which ends in the intestine goes off anteriorly; the valve of the pylorus is produced by the projection of that part of the stomach into the intestine.

In the *remora* the right part of the stomach has not, as in general, a small bowel arising from the side of the cul-de-fac, but a short prolongation of that part which is bent forwards, and forms an angle posteriorly. The muscular coat is very strong, and the internal furnished with very prominent longitudinal rugae.

The figure of the stomach differs very much in the different species of the genus *pleurostoma*.

In the *turbet* (*pleurostoma maximus*) the middle portion of the stomach is a little enlarged, but the cul-de-fac is very short; the pylorus being nearly at the bottom of the stomach; neither the figure given by Cuvier of the *turbet*’s stomach, nor that contained in Blainius *Anatomia Animalium*, is correct.

In the *pleurostoma lucius* the stomach is wide, irregularly round, with thin coats, and smooth on the external surface.

The stomach of the *sole* (*pleurostoma flabellum*) has a bent figure like a portion of an S; there is a slight dilatation at the greatest curvature, which takes the place of the usual cul-de-fac. There is no contract on the canal at the pylorus; the dilatation between the stomach and intestine, however, is marked both on the outside, and internally, by a whitish line; the inner surface is thrown into loose irregular longitudinal folds.

Cuvier describes the stomach of the *pike* (*pleurostoma plena*) as forming a continuous canal with the oesophagus and intestine; there is, however, always a degree of dilatation at one side of the stomach, which varies according as it may be defended by food; this corresponds to the con-
Cuvier states the stomach of the genus *Labrus* to possess the ordinary form and structure. In the *gibbus verger* (*Labrus itaca*), however, we have found the cæophageus, stomach, and frill or small intestine, to make a continuous canal, without any material difference in capacity or in structure; each of these parts is rectituded upon the internal surface.

In the *perches* (*genus perca*) there is nothing in genera very peculiar to remark; the chief deviations from the common structure appear to be with respect to the length and form of the cæde-de-fac; this part is conical in the *perch* of the *Nile* (*perca nilotica*); it is deep in the *sea-perch*. *Blanes* gives a figure of the vilcera of the *perch*, in which the intestine appears continuous with the cæophageus, and the canal portior of the stomach is like a long bag, with a contracted neck.

In *the stickleback* (*gasterosteus pungitius*) the stomach is an oval figure, and without curvature.

The *red gurnard* (*trigla cuculus*) has the portion which ends in the intestine considerably enlarged.

The *piper* (*trigla lyra*) has the pylorus situated very near the cæophageus, which is straight. The body of the stomach is nearly of an oval shape, and the bottom of it forms a very short cæde-de-fac, less in diameter than the cæophageus.

In *the salmon* (*salmo salar*) the portion which arises from the body of the stomach to terminate in the intestine is an oval figure, and so large in proportion to the rectitude of the cavity, that it seems like a second stomach; its muscular coat is very strong, and the internal one has some thick longitudinal folds.

The *abdominal* fishes exhibit some more remarkable varieties in the structure of the stomach than the preceding orders.

In *the carp* (*cyprinus*) the stomach forms a continuous canal from the cæophageus to the intestine. In the *sea-pike* (*eœa belone*) also it cannot be distinguished from the adjoining parts of the alimentary canal; the stomach of the *common pike* (*eœa lucius*) forms no cæde-de-fac, the intestine going off at its bottom; but the situation of the pylorus is plainly marked by an annular constriction entirely, and by a circular fold of the internal membrane. The figure of the stomach is that of a very elongated bag, somewhat wider in the middle than the other parts; its muscular coat is strong; the internal membrane furnishes at frill some distinct longitudinal folds, which become numerous, and covered with papiller in the lower part of the bag.

In *the herring* (*clupea harenus*) the stomach at first paffes backwards, like the continuation of the cæophageus; it is then reflexed forwards, so as to form an acute angle with the first portion; the outside of this curvature produces a long, conical cæde-de-fac: the second portions are distinguishable by their structure, as well as their form; the frill has thick paires, and the internal surface plicated; the second has thin coats, and is smooth internally; the pylorus, which is the termination of the reflected portion, is much contractod.

The stomach forms a cæde-de-fac in the genus *salmo*, which, however, varies much with respect to its depth. In the *smelt* (*salmo eperlanus*) it is long and pointed, as in the *herring*. In *the common salmon* and *trout* (*salmo fario*) the cæcal portion of the stomach is very considerable. There is a kind of *trout*, found in the western part of Ireland, which, from the great strength and thickness of the muscular coat of its stomach, is commonly called the *gillaroo* or *gizzard* *trout*. It is not generally supposed to be a distinct species, but a variety of the *salmo fario*. Hunter states the paires of its stomach to be two-thirds thicker than those of the common *trout*; he did not, however, consider its stomach as serving the
the purposes, or as deserting the name of a gizzard; the internal surface is soft and villous, and therefore not fit for grinding the food; the contractions of the stomach are however sufficiently powerful to break the shell-fish on which this trout subsists, with the assistance of round, smooth floes, which are swallowed for the purpose. The common trout likewise takes floes into its stomach, with a similar design.

The stomach of the _fisculus bogre_ is an oval, or rather the shape of a flat, with a very wide mouth; its parietes are hard, strong, and thick; the portion which leads to the pylorus is short, and arises from the posterior third, which occasioned a considerable cul-de-sac.

There is no _cæcal_ portion of the stomach in the genus _murena_; that of the _anabipes tetraphthalmus_ is a canal curved upon itself, before it enters in the intestine, from which it is separated by a flight contraction, and a circular valve; the left side of the internal surface of the stomach exhibits thick folds, which form a net-work, apparently of a glandular structure; the other parts of the internal membrane are covered with fine villi.

Cuvier describes the _cæcal_ portion of the stomach, in the genus _mormyrus_, as being wide and short; we should rather say that the stomach is dilated into a bag, which lying transversely across the direction of the cæosophagus,resembles, in some degree, the form of this cavity in mammalia.

The most singularly constructed stomach in the whole class of fishes is met with in the mullet (genus _mugil_), of which Cuvier has given an imperfect description, and bad figure. In the common species (mugil _cephalus_), the stomach may be divided into three parts; the pylorus resembles in form and direction the cæosophagus, from which it commences; it leads to the back of a large muscular mass, into which it opens; the same canal is afterwards continued for a considerable way backwards, and is gradually contracted in capacity, until it finishes in a pointed blind extremity. The muscular mass has a figure not quite spherical, but such as would be produced by the application of two disks to each other; the largest diameter of it measures about an inch: the tubular part of the stomach opens into the centre of one disk; the intestine commences exactly opposite, or at the centre of the other; a straight canal leads directly through the muscle, which therefore corresponds to the pyloric portion of the stomach. It has, however, been considered by some zoologists, as an example of the true gizzard stomach in fishes, and not without foundation; the muscular fibres which compose the interior part of it are short, closely applied to each other, and interwoven so as to produce a mass nearly of an homogeneous structure; the fibres are more distinct on the external surface; they pass from the centre to the circumference, where they seem to coalesce with each other, and with a layer of muscle, which pallies round the mass as a ring: this arrangement of the muscular fibres bears some resemblance to that of the gizzard in birds, and certainly shews that the apparatus in the _mullet_ is capable of exerting an extraordinary degree of force. It should further be added, that the internal part of the muscular mass is lined with a cuticular coat of some strength: this is very easily detached by maceration, and is found to be confined, as in birds, merely to the grinding surface. As arguments against the supposition of the muscular apparatus in the _mullet_ performing the functions of a gizzard, it may be stated that the cavity it contains is too small to serve as a reserveroir for any quantity of food; that the cuticle is too weak to sustain the friction with hard bodies, and that the food must be in a great measure digested in the tubular portion of the stomach, before it passes into this. These objections we are disposed to allow to a certain extent; but that the aliment undergoes a further comminution and admixture, while moving through the muscular portion of the _mullet's_ stomach, we cannot entertain a doubt, both from the contemplation of the structure of the part, and of the intestines which succeed it, and from actual observation made upon its contents, immediately after the death of the animal.

Cuvier describes the stomach of the _white mullet_ (mugil _albula_), as differing only from that of the _mugil cephalus_, with respect to the shape of the cul-de-sac, and the muscular portion of the pylorus: the _mullet_ has the proper form of a bag, being wider at the lower part than above; the former is a figure of a globe, instead of being compressed or levelled on the inferior and upper surfaces.

The figures which illustrate the form and structure of the stomach are contained in Plate I. and II. of the _Anatomy of Fishes_. Fig. 5. of Plate I. exhibits a view of the stomach of the _baking shark_ (_dogfish maximus_) laid open on one side; _e_, the portion of the stomach next the cæosophagus, the inner surface of which is reticulated; _d, d_, the succeeding parts of the stomach, with longitudinal laminae or folds, which are particularly prominent near the pylorus; _e_, the purled, or contracted opening into the second stomach; _f_, the second stomach, partially seen behind the other; _g_, the commencement of the intestine; _b_, the biliary ducts, palling as a hard to the intestine; _j_, the spleen.

Fig. 6. of the same plate shews the globular cavity, or second stomach, and its communication with the first stomach and intestine: _a_, the external surface of the pyloric portion of the stomach; _b_, the intermediate cavity laid open, to bring into view the contracted aperture leading into the principal stomach, and the one into the intestine; _c_, the cavity of the first part of the intestine exposed; _d_, the commencement of the spiral valve; _e_, the projection into the intestine, upon which the small aperture of the second stomach is seen; _f_, the papilla, by which the biliary ducts terminate in the intestine; _g_, a portion of the spleen; _b_, twelve or thirteen biliary ducts, forming a single falciform, which proceeds to the intestine.

Fig. 7. of the same plate represents a portion of the stomach and cæosophagus of the _ruga _anchura_; _a_, the inner surface of the cæosophagus; _b_, the internal coat of the stomach, which is thick, soft, unequal, and, as it were, raised upon the surface of the other coats; the depressions seen upon it are produced by the deficiency of the internal coat itself; some small foramina are scattered over the surface, which are the glands supposed to furnish the gastric juice by Mr. Home, but which by others are commonly described as mucous glands.

In Plate II. of the _Anatomy of Fishes_, fig. 1. represents the stomach of the _tetraodon oblongus_; _a_, the cæosophagus; _b_, the beginning of the intestine; _c_, the stomach, of a globular figure. Fig. 2. shews the stomach of the _eel_ (muraena _anguilla_; _a_, the cæosophagus; _b_, the cul-de-sac, or _cæcal_ portion of the stomach of an elongated taper form; _e_, the intestine. Fig. 3. exhibits the stomach of the _sole_ (pleuronectes _solea_) which describes an S-like curve; _a_, the flight dilatation which corresponds to the cul-de-sac. Fig. 4. represents the stomach of the _plaice_ (pleuronectes _platea_); _a_, the cæosophagus; _b_, the inconsiderable dilatation which marks the situation of the stomach; _c_, the pylorus; _d, d_, the two short pyloric cæca; _e_, the single cæcum from the first portion of the intestine, as far as it is known, peculiar to this fish. Fig. 5. shews the stomach of the _obodon zebrus_; _a_, the cæophageal extremity; _b_, the pylorus; _c_, the portion of the stomach, corresponding to the cul-de-sac, which, in

this
this species, is turned forwards. Fig. 6, is the stomach of the Sparus fœminus: a, the oesophageal extremity; b, the intine, of a small size, arising near the oesophagus; e, the body of the stomach, which forms a perfect bag. Fig. 7, is the stomach of the mullet ( Mugil cephalus); a is the part continued from the oesophagus; b, the funnel, or "cul-de-sac; e, the muscular portion, which has been compared to a gizzard, on which the arrangement of the muscular fibres is seen; d, the intine; ees, pyloric cæsæ. Fig. 8, shows the same stomach, with the muscular part cut through longitudinally; a, the oesophageal extremity; b, the funnel seen behind; e, the muscular portion, in the centre of which appears the opening, through which the food passes to the intine; d, the cuticle lining this passage, puckered or folded on itself.

Intines.

There are, properly speaking, but two intines in fishes; the first corresponds to the small, the second to the great; these terms, however, are not applicable to the divisions of the canal in this class of animals, unless they were reversed, as that which would be called the great is often less capacious than the other. Cuvier has called the second portion of the intines in fishes rectum, to which part it is certainly more analogous than to the colon, or cæcum, although sometimes it experiences a considerable and sudden enlargement. The first and second portions of the canal are commonly distinguished from each other by an annular projection of the internal coat, which is generally thick and rounded on the edge, and appears to contain some circular muscular fibres, which, by their contraction, will increase the valvular obstruction to the passage of substances from one intine into the other; these parts are further indicated by a different structure in the internal membrane, and commonly, also, by a different arrangement of the fibres in the muscular coat. The capacity of the second intine, as already mentioned, is almost always either smaller or larger than the preceding part of the canal; most commonly it is smaller. The internal structure, characteristic of each intine, is most strongly marked in the one next the pylorus, and in the other towards the anus.

The variation with respect to the form, length, and structure of the intines of different fishes, do not accord with the natural divisions of this class of animals; remarkable deviations being often found among individuals of the same genus, and even sometimes in varieties of the same species, as will appear by the following table, and in the description of these parts in the principal genera.

Table of the proportional Lengths of the Intestinal Canal in Fishes, Extracted from Cuvier's "Très ons d'Anatomius comparée, tom. 3."

</table>

The numbers are divided into the following groups, according to the nature of the animals. The fish are placed in the following four orders, according to the description given by Cuvier: first, the lampreys; second, the true fishes; third, the cartilaginous fishes; fourth, the bony fishes.
(a) Measure of the alimentary canal, from the posterior parts of the mouth to the anus.

(b) Length, measured from the border of the lower jaw to the anus.

(c) Length taken from the end of the muzzle, but not including the leaf.

(d) Length measured from the end of the spiral valve to the anus.

In the lamprey (Petromyzon) the alimentary canal passes to the anus without anyensible dilatation or convolution; the abdominal cavity is however of considerable extent. The inner surface of the intinule is covered with fine longitudinal plicae; the reflection of peritremum, which corresponds to the mdeeneter, completely embraces the greatest part of the intinule, by being coiled upon it, in consequence of which it is allowed great latitude of motion in the abdomen.

The intinules of the ray and seahorse genera make no material convolutions, and appear remarkably short for the fish; the length, however, lost by this circumstance, is amply supplied by the structure of the first intinule; the internal membrane of which is converted into a spiral valve, which nearly fills up the canal from the pylorus to the commencement of the second intinule; the food, therefore, instead of passing freely to the anus, traverses a considerable circuit.

The spiral membrane is tolerably smooth upon its surface, but is extremely vascular; an injection of the blood vessels will render this part of a vivid red, and fearlessly show any effect upon the other parts of the alimentary canal. The valvular portion of the intinule in the Syphalus maximus terminates at the rectum in a foiliated appearance, resembling a rosy, by which the passage of the food is obstructed.

The second intinule of these fishes usually makes one or two slight curves; it has a smaller diameter and thinner coats than the preceding; the inner membrane is villous at the commencement. Cuvier has described a layer of a greyish, glandular substanee, as being interpolated between the muscular and internal coats; this has not been observed by us.

There is a remarkable glandular body connected by a slender tubular foot-folk with the rectum which is only met with in the ray and seahorse genera; in the former it is somewhere on the figure of the feed of a fish, with the lefleffar towards the intinule. We have observed it in the dogfish to be long, round, and pointed at the free extremity. Its substance is very dense and unyielding, resembling a good deal the texture of the human uterus; it contains a small cavity, which appears to have a smooth surface, but, if accurately examined, exhibits some cells or depressions, which would seem to be the orifice of mucous glands. In the Syphalus maximus, Mr. Hume found this gland deeply reticulated in the inner surface, and to contain a dark coloured glairy fluid. Doctor Monroe, in his Physiology of Fishes, called this body, from analogy of situation, appendix vermiformis, and supposed it to be designed to perform the same functions of that part in the human intinule. Cuvier, on the other hand, describes it amongst the anal glands of animals, to which clits of organs he thinks it most analogous. It appears to us to be a gland designed to supply the rectum with mucus.

In the Syphurus (Aegopis) all the parts of the intinule are extremely muscular; the internal surface is reticulated throughout the greatest portion of the canal; at the beginning the meshes are so deep as to produce cells; at some distance from the pylorus there arises a spiral valve, which is loth at nearly the same distance from the anus; its turns are much less frequent than those of the valve in the ray and dogfish. In the Syphurus it is sustained by a strong pillar which runs in the centre of the tube of the intinule, and which seems to be composed of muscule internally; the valve resembles flaps placed around a pillar, except that it is not unbrokenly attached to the centre, but rather coil upon it, leaving in some places the internal border at liberty, it does not form, therefore, necessary for the alimentary substanee to pass around all the turns of the valve. In the Syphurus there is interpolated between the reticulated membrane and the muscular coat a thick layer of a glandular substance, which is close in its texture, a greyish colour, and in which may be seen some small white branches. The last portion of the intinule canal has neither valve, reticulation, nor glandular substanee; its coats are thin, and its diameter diminished.

Cuvier describes the intinule canal of the Syphurus as being short, but contrived to retard the passage of the alimentary substances through it. It is very wide for two-thirds of its length, and is then suddenly contracted into a small canal; it next becomes dilated a second time, and forms an oval pouch, the cavity of which is divided by a circular valve: the successive enlargements and contractions produced by these are visible on the external part of the intinule: the pouch opens into a short and contracted canal, which is analogous to the rectum. The first portion of the intinule of this fish is much muscular, and exhibits a network on the internal surface, similar to that of the Syphurus; the meshes of which are, however, not strongly marked, except in the first two thirds of the intinule. The papillae of the pouch, containing the valves, are thin, but the short canal, immediately succeeding, has an evident muscular coat, and the internal surface longitudinally pleated.

In theunday pelagus the alenntary canal is without convolutions, as already mentioned, and prefers nearly the same diameter throughout its whole length; the first or small intinule has thin and transparent coats, and the inner surface is covered with longitudinal plicae, waving and matted together; it is separated from the second intinule, or rectum, by a circular valve; the latter canal has strong papillae, and upon the internal surface thick rugae running longitudinally, ferrated upon their edge, undulating, and sending branches to each other. The Syphurus acus differs from the Syphurus in wanting the rugae in the second intinule, which is smooth and covered with fine cuticle.

The operculum cubicus, in which the intinule is without convolution, has the first portion slightly pleated internally, and in the second more eminent rugae disposed longitudinally and parallel to each other. This part of the intinule is likewise more muscular, and separated from the first by a circular valve.

In the Balistes the first intinule is, for about two thirds of its length, thin, uniform in form and smooth internally; at the commencement of the last third it exhibits some dilatations, and towards the end becomes much enlarged, at which place the internal coat acquires a beautiful yellow appearance; a contraction of the papillae, and an annular projection internally, serve to distinguish the commencement of the second intinule, which is short and longitudinally pleated on the surface.

In the genus tetradon the intinules make two or three convolutions, but prefer near the same diameter throughout; a fold of the inner membrane is placed at the beginning of the second intinule, which has stronger coats than the intin.
The intestinal canal is longer in the *moor-fish* (tetraodon mola) than in the other species, and forms numerous convolutions. The first intestine is capacious, and has a strong muscular coat, which exhibits on the internal part of the gut very distinct longitudinal fæces; the intestine diminishes in width near the pylorus, and the thickness of its coats at it proceeds. There is also a thick white glandular layer between the internal and muscular coats, which disappears on approaching the second intestine; in which, however, it is again formed. The intestinal surface of both intestines is covered with villous processes, that are at first coarse, but become fine towards the commencement of the second intestine, in which they re-appear.

The intestinal canal of the *sea devil* (lophius piscatorius) has but little variation in its capacity from one end to the other; the folds of the internal membrane take a lozenge figure.

In the lump fish (elyotecpus lumpus) the first intestine is distinguished from the second by a circular valve, which projects into the latter; the muscular coat of the fish is also less thick and has the fibres circular, while in the second they are considerable, and are arranged upon the external part of the intestine longitudinally; both intestines are plicated on the inner surface, but the second has the folds larger and less regular.

In the anarrhichas lupus the second portion of the intestinal canal has thick coats, and an external layer of longitudinal muscular fibres; the two parts are indicated by the interposition of a circular valve, but the internal surface of both is covered by a number of fringed plicae arranged in different directions.

The several parts of the intestinal canal in general have little variation with respect to their capacity. In the genus *murena*, the conger (murena conger) has the second intestine wider than the first; it has also, particularly at the commencement of the canal, a glandular structure of the internal coat, similar to that already described in the *flureon*. In all this genus the distinction of the two portions of the intestines are marked by a similar valve.

In the uranostomus fischeri the first and second intestines are not distinguished by any valvular projection of the internal surface, but by the structure of their coats. They are at first thick and the canal small, soon afterwards the intestines become much enlarged, thin, and transparent, which structure is continued near the anus; the internal membrane produces in the first division of the canal a longitudinal plica, touching each other in a zig-zag manner; these gradually decline, and in the part corresponding to the rectum become strictly longitudinal and parallel, with small rugæ arising alternately on the fide. The canal experiences many convolutions.

The first intestine of the *sewer* (trachinus draco) is reticulated upon the inner surface; the second portion is thin.

In the genus *gadus* the first and second parts of the intestinal canal are distinguished both by a difference of structure and a valvular projection; the first intestine of the bate (gadus merluccius) has upon the inner surface fringed plicae, which gradually diminish towards the rectum. In the cod (gadus morhua) the canal is smooth internally, except at its first convolution. In the ling (gadus melus) the first intestine is plicated longitudinally; and in the whiting (gadus merlangus) the intestinal canal appears smooth on the inner surface; the rectum is very short, and wider than the first intestine.

In the *remora* (echeneis remora) the first intestine is rugous, the second smooth.

In the genus *cottus* there is a valve at the origin of the second intestine. In the *cottus niloticus* there is a glandular substance situated behind the internal membrane, reaching for some way from the pylorus, that increases the bulk of that part of the gut, the diameter of which is also very wide; the canal, after proceeding for a considerable distance, becomes again dilated at the small portion corresponding to the rectum. The whole extent of the small intestine exhibits internally a net-work, which has very deep meshes; in the rectum the same structure is observed, but the meshes are wide and shallower.

The intestinal canal forms three convolutions in the *serranus borrida*. The intestinal canal is slightly plicated and villous, and the plicae are thin in the first intestine; the rectum is somewhat larger, and has internally waving longitudinal folds.

In the *dory* (zeus faber) the two intestines are divided by a conical valve. The first is reticulated upon its inner surface; when viewed with a magnifying glass, we have observed each mesh to include a finer network within it, and the projections of the membrane, which form the reticulation, to end in delicate villous laminae; probably the same structure would be found to exist in the intestines of many other fishes, the rectum in the *dory* is without reticulation, and thin in its parietes.

There is some variety with respect to the structure of the intestines in the flat fishes (pleuronectes). The plaice (pleuronectes platessa) has the canal wide for some way from the pylorus, after which it gradually diminishes to a moderate size, and continues of the same magnitude to the anus; the inner surface is covered with well marked plicae arranged longitudinally, and others connecting them transversely; in the wide part of the intestine the plicae are so prominent that they float in the cavity, the border is plated like the ruffle of a skirt, and altogether they produce one of the most beautiful surfaces we have observed in the intestines of fishes. This plicated structure becomes gradually less evident in the course of the canal, and is nearly lost on approaching the rectum. That portion of the intestine plicces also reticulated plicae, but they are indistinct; the intestine becomes thick and fleshy near the anus. Cuvier affirms, that its diameter is twice as great as that of the preceding part of the canal; but in those instances we have examined, if any difference could be observed, the rectum was less than the adjoining part of the intestines. There is a circular valve at the commencement of the rectum.

In the turbot (pleuronectes maximus) the internal membrane of the first intestine produces fringed laminae, which are close together and reticulated; they gradually decline, and in the rectum, the origin of which is marked by a valve and a sudden dilatation, the laminae or plicae become very remarkable, floating in the cavity of the intestine. The canal is most muscular, from the first convolution to the pylorus, and in the rectum.

The first intestine of the brill (pleuronectes rhombus) is plicated internally, it is at first large and then becomes contracted. The rectum is smooth and considerably wider than the part of the canal immediately adjoining it.

In the sole (pleuronectes folies) the diameter of the intestinal canal is nearly the same throughout, although Cuvier affirms the contrary. The internal surface of the first portion looks as if it were grooved, the folds projecting very little, and being closely applied to each other; they pass in a waving manner.
manner in the longitudinal direction; near the pylorus, however, the folds are more prominent and puckered or plated upon the edges. The pits of the rectum are thin; the internal membrane forms in it a flight, imperfect, longitudinal folds. The two parts are distinguished by an annular projection.

In the Pleuronectes limanda, Cuvier states the intestine to be very wide at the commencement, and after diminishing to be enlarged again a little in the rectum. The internal membrane has flight rugos arranged in a lozenge figure near the pylorus, but farther on it becomes smooth.

In many of the genus chit budon the intestinal canal is very large; in the chit budon aceratus and chit budon zebrus the plicae of the intestine are thin, delicate, and transparent, and dilated in some places for containing the excreta. The internal membrane of the first intestine has the plicae disposed in a zig-zag manner near the anus, their coats become thickened and rugose internally.

In the genera labrus and parus the structure of the intestine varies in the different species; in the labrus niphon the rectum is fo wide, according to Cuvier, as to resemble a sac, into which the first intestine is inserted; a valve is situated at this place. In other species the sudden enlargement of the rectum also exists, but the valve is wanting in the gilbus sarafis (labrus tinca); the first intestine is of the same diameter as the stomach, with which it appears to be continuous, it is villous and reticulated on the inner surface; the rectum is very short and twice the width of the first intestine; its internal membrane exhibits a cellular appearance from the meshes of the net-work being deep.

The coats of the intestines in the sparus spinifer are thin, and the internal surface is without villi or plicae.

In the perch the first intestine is a little enlarged at the commencement, afterwards it diminishes, and again acquires bulk; the second portion or the rectum exceeds it in size every part of the canal. The internal coat of the first intestine furnishes numerous laminae, forming many-tined areola, which gradually become longitudinal and parallel to each other. There is a prominent funnel-shaped valve at the origin of the second intestine; as usual, this part of the gut has longitudinal fibres in its mucular coat. In this fish the structure of the rectum is singular, its longitudinal folds are denticulated upon the edge, and are crossed by other transverse plicae in a zig-zag manner; the folds which compose the angles that are directed towards the anus are more prominent than the rect and concave, so as to produce little cups or faces. The boga (perca labrax) has loo, plated, longitudinal laminae on the internal surface of the first intestine, exactly resembling those of the small intestine of the swine; the second intestine has remarkable thick coats, and is perfectly smooth on the inner surface.

In the stickleback (gasterosteus aculeatus) the intestine is very wide at its origin, it soon, however, becomes small, and continues so to the end of the canal.

In the mackerel (scomber faunurus) the internal membrane of the first intestine is nearly smooth, but that of the second is plicated.

Cuvier describes a very remarkable caecal process, or cul-de-sac, which is situated at the origin of the rectum in the piper (trijola fora), it palis for a short distance on the side of the first intestine, from which it is separated by a semilunar valve; it resembles, in form and position, a good deal the cæcum in mammals, of which no other fish affords a similar example.

In the tenia laevis the inner surface of the intestine is slightly villous; the two portions are not distinguished by a valve as usual, but near the anus the canal becomes greatly enlarged, and again diminished before its termination.

The intestinal canal in the genus cyprinus forms no dilatation or internal valvular projection, but usually diminishes in its course from the oesophagus to the anus, both in diameter and the strength of its coats.

In the carp (cyprinus carpio) the intestines make three convolutions and one-half; the internal membrane at the beginning of the first portion of the canal produces a reticulation, of which the intervals are very deep, refembling the cellular appearance of the intestine described in the flounder. This network gradually diminishes in the carp, until near the anus, where it again increases.

In the barbel (cyprinus barbus) the internal membrane furnishes a thick, with villous appearances; and are finely villous; towards the end of the canal the villi are less thick, and the plicae more compact and smaller, to give the appearance of a grooved surface.

In the sard (cyprinus ruthus) the inner coat furnishes beautiful plicae paling in zig-zag transversely; they are larger and closer at the commencement of the canal than in the succeeding parts; near the anus the edges of the folds have a fringed appearance.

The inner surface of the intestine in the cyprinus dolus is villous in every part, but there are no zig-zag plicae.

In the tench (cyprinus tinca) there are irregular zig-zag laminae, with fringed edges.

In the genus clupea the diameter of the intestinal canal is nearly the same throughout; the coats are thin and weak, the intestine is also usually short, they do not form any convolution in the herring (clupea harengus), and only two turnings in the anchovy (clupea harengus).

In the mullet (mugil cephalus) the intestinal canal is singularly long, and forms convolutions one around the other, but in the manner of the intestines of several birds, they are much more numerous than they are represented by Collin in his anatomy; we have counted eleven turns of the intestine, which were all visible on first opening the body; the convolutions are pressed together, and the interfaces filled with fat, so that the whole forms one mass which almost occupies the whole abdomen of this fish. The diameter of the canal varies but little throughout its whole extent; the internal membrane is without folds, but furnished with villous processes, which are thick, long, and distinct in the first convolutions, but as usual gradually decline afterwards.

In the gars fish (eox bisse) the intestine extends from the mouth to the anus without any convolution; it should be remarked, however, that the abdominal cavity is very long in this fish. Cuvier states the structure of the intestine to be the same throughout its whole length, and that the inner surface of it is smooth, and without villi; but we find in our notes that the internal membrane is villous, and, if minutely examined, is likewise reticulated; and that the villous structure is extended in two flaps upon the inner surface of the second intestine, and thus disappears.

The plicae of the intestinal tubes in the common pilch (eox lacus) are thick, and the origin of the rectum is marked by a valve, and also by an increase of volume; the internal surface of the first intestine is villous, and appears grooved; in the second the villi are very long and fringed.

In the salmon (salmo farus) the internal membrane forms in the beginning of the intestinal portion very long villi, which float into the cavity; these gradually diminish, and in the last part of the gut there are broad transversal folds, which become larger and more distinct as they approach the anus. The

**FISH.**

The intestine of the trout (*salmo fario*) wants the villi, but the transverse pile are more regularly placed than in the salmon.

Cuvier describes the intestinal canal of the *ichthys* (*polypterus* *nit-tabs*, Geoff.) as being similar to that of the *anguilla*. There is a spiral valve that commences immediately beyond the pylorus, and forms right turns, which are approximated and prolonged posteriorly; this valve does not extend to the anus, and the interval which wants it, Cuvier considers as the rectum; between the internal and muscular coats there is, at the commencement of the canal, a glandular layer, which increases the parietes, for the dilatation of a diametral to double their force, after which it is scarcely to be perceived in this part of the intestine. The internal coat forms a network, as in the *anguilla*, of which the mother becomes smaller, as they recede from the pylorus, and are almost entirely elided beyond the gland. The parietes of the rectum are very thin, and its inner coat shows some digit longitudinal folds.

In the *anabas* *tetrapthalmus* the internal membrane of the first intestine produces a fine and apparently glandular reticulation, and the parietes of the second intestine are very thick, and the inner surface pleated longitudinally.

Cuvier describes a curious structure in the intestine of the *anguilla* *lagre*; the beginning of the canal is wide, it then contracts and continues for some way of the same size; about the middle, the intestine is suddenly enlarged, and its coats become thin, and there is a kind of division of the first half of the canal, which opens into the second by a small orifice, bordered by a circular valve; at some distance beyond this place the parietes acquire thickness, and the diameter of the tube becomes small as before; and finally, this intestine terminates in the rectum, which is large and dilated at this place. The valve of the rectum is very prominent, its parietes are remarkably strong and muscular, the inner membrane has longitudinal folds; a similar appearance exists on the inner surface towards the end of the first intestine, but they are ramified nearer the pylorus.

The intestinal tube in the genus *mormyrus* has an uniform diameter, is smooth internally, and supplied with a valve at the commencement of the rectum.

From the preceding description it will be perceived that the intestines of fishes possess a more complicated and beautiful structure of the internal membrane than exists in any other class of animals; the alimentary canal of fishes, for this reason, as well as the nature of their food, is generally found to be short; the last division of it, which in mammals very properly receives the name of the *great or large intestines*, is, as before observed, often the shortest and most controlled part of the canal in fishes. The rectum in this class rarely serves as a re-servoir for faeces; its internal surface is often as well fitted for forming and abrading the cæsa as the first portion of the gut, and sometimes even more so; it may, therefore, be said of fishes that the whole tract of their alimentary canal performs, in a greater or less degree, the functions of the small intestines in other animals.

In Plate II. of the *Anatomy of Fishes*, fig. 9, shows the valvular portion of the intestine of the *sole* (*raja batis*) which is dried in order to render the turns of the valve more distinct. Fig. 10, exhibits a piece of the valvular part of the intestine of the *anguilla* (*angia faria*); *a*, the central portion; *b*, the coiled part; *c*, the internal surface of the parietes of the canal. Fig. 10, of Plate III. of the *Anatomy of Fishes*, gives a view of the internal surface of the first intestine of the *anguilla*, where the cæsa are connected with it; *a*, the surface of the gut deeply reticulated or cellular.

Fig. 11 of Plate II., a portion of the first intestine of the dory (*anguila faher*) on which the meso- and intermediate reticulation of the internal membrane are represented. In fig. 12, of the same plate, the internal surface of the intestine next the pylorus is displayed in the *burdock* (*ploroneeta maximus*); *a*, the laminated appearances of the internal membrane of the intestine in this fish. Fig. 13, exhibits a portion of the first intestine in the *platte* (*ploroneeta platffu*) laid open to expose the pukeled pit of the internal membrane. Fig. 14, of the same plate represents the abdominal visera of the *mullet* (*angia sebulae*) as they appear on opening the body; *a*, the oesophagus; *b*, the liver, containing the thomach; *c*, the numerous coils formed by the intestinal cavity in this fish; *d*, some of the pyloric cæsa, nearly of the same size of the intestine. Fig. 15, is a piece of the intestine of the *mullet* laid open, by which the villi of the intestinal surface are seen.

In Plate III. of the *Anatomy of Fishes*, fig. 1, exhibits a part of the intestinal canal, with the gland attached to the rectum in the dog-fish (*shpalus catadus*); *a*, the rectum; *b*, the glandular body, of an elongated figure in this species; *c*, a portion of the valvular part of the intestine left. Fig. 2, shews this gland in the *sole* (*raja batis*) magnified and laid open; *a*, the fundus; *b*, the neck of the gland; several irregular depressions are seen upon the inner surface. Fig. 3, represents the valve-formed termination of the valvular intestine of the *shpalus maximus* in the rectum, described by Mr. Home. Fig. 4, exhibits the inner surface of the rectum in the *burdock* (*ploroneeta maximus*); *a*, a portion of the first intestine, with slight, waving, longitudinal folds; *b*, the commencement of the rectum, marked by a valve; *c*, the internal surface of the rectum, forming very prominent, floating laminae; *d*, the anus. Fig. 5, shews the form of the rectum, and its connection with the first intestine, in the *pinellodus lagre*; *a*, the orifice of the rectum, which is enlarged, and receives the first intestine in the way of inflation; *b*, the rectum becoming again enlarged. Fig. 6, exhibits the cæcal process in the *pira* (*trigla lyra*); *a*, the first intestine; *b*, the part analogous to a cæcum; *c*, the rectum.

**Liver.**

The situation of this viscus is generally the same in fishes as in the preceding classes; *i.e.* it immediately precedes the stomach, which it covers more or less by its lobes. In the genus *ploroneeta*, however, and some other fishes which have the abdominal cavity short and round, the liver lies between the side of the stomach and first convolution of the intestine; to the former of which it is more immediately connected.

The liver is retained in its position by means of reflections of its peritoneal covering, which are attached to the septum that sustains the pericardium, and to the oesophagus, and likewise by the large veins that come from the liver to the junction of the subcelian veins.

The magnitude of the liver is in general very considerable in proportion to the size of the fish.

The colour of the liver varies; it is generally paler than in other animals; often an ash colour, and sometimes milk-white.

Its form is subject to continual variety; it is generally not divided into many lobes; most frequently, perhaps, only into two. As Cuvier has considered the divisions of the liver more in detail than we have done, we shall chiefly follow his description, given in the "Leçons d'Anatomie comparée."

In the genus *lamprey* (*petromyzon*) there is but a single lobe
The liver is much elongated, and has a good deal the figure of a tongue.

In the rays the liver is divided into three long lobes, which extend throughout the whole length of the abdominal cavity. Cuvier describes but two long and very distinct lobes in the genus *fuguhus*, but, besides these, we have noticed in the lobe *fuguhus caudatus* two very small, thin lobes, united upon the side of the stomach next the spine.

The *fuguhus* and *fuguhus* have two large lobes to the liver, which are subdivided in the latter into a great number of lobules.

There are three divisions made by shallow furrows in the *fuguhus* (*fuguhus pescatorius*), and one lobe only in the *fuguhus* pelagicus, the *tetraodon*, and the *lumpus* (*cyclopterus lumpsus*).

Amongst the apodal order of fishes, the *eel* (*murens*), and the *ammodictyes tubulans*, the liver is not divided, but merely a little notched in some species of the *eel*; but there are two lobes in the liver of the *anarrhichas lupus*, the *electrical eel* (*gymanostoma electri*), and the *frunatum paru*.

Of the *fuguhus*, the genus *gadus* and *blennius* have two or three long lobes.

In the *bipinatilus* (genus *merlangus*) the left lobe extends almost the whole length of the abdominal cavity, between the intenines and air bag.

The *thunnus* (*trachinus draco*) has the liver composed of one lobe.

The liver is triangular, and without division in the *cotus niloticus*, but the *cotus scorpius* has two lobes. There are also two lobes in the liver of the *scorpius scorpius*, although that of the *scorpius horridus* consists of a single lobe. There are two lobes in the liver of the *trigla cirripus*, of the *mullus barbatus*, of the *echeneis remora*, of the *pleuronectes flodus*, and of the *tetraodon* (*pleuronectes maximus*). The liver is without division in the following species of *pleuronectes*; the *plaice*, the *pleuronectes platessa*, and *limanda limanda*; there is a small lobe placed behind the principal one in the *sole*, of a singular shape, with two points like horns, which has not been noticed by Cuvier.

The liver has three lobes in the *fuguhus thunnus*; that of the head (from *fuguhus*), and of the pilot (from *fuguhus*), have two lobes. There are three lobes in the little *shad* (*aletus*), the common *shad* (*aletus*), and four in the *gasterosteus fuguhus*.

The divisions of the liver are equally various in the *piscis* and *fuguhus*; the liver is without lobes, and of the shape of an arrow; in the *rupe* it is likewise undivided, and triangular in the *fuguhus*; although Bloch says, there are two unequal lobes in the liver of this fish. In many other *fuguhus* and *piscis* the same phenomena occur. There are three lobes, deeply separated. In the *loper* (*seus fischer*) there are two lobes, one of which is very much larger than the other, and forms a kind of third lobe at its external corner. There are two lobes in the liver of the *chterodii eilii*, and only two large notches in the *chterodii spinosus*. The *holobranchius fuguhus* has three unequal lobes. The liver of the *fuguhus* *fuguhus* has three lobes; there are two in that of the *fuguhus* *fuguhus*, the *fuguhus* *fuguhus*, and likewise in the *fuguhus* *fuguhus*; but it is a single lobe in the other species of *fuguhus*.

In the genus *cyprinus* the liver is very deeply divided into lobes, of which the number varies according to the species; in the *carp* (*cyprinus carpio*) the lobes are so disposed amongst the different convolutions of the intenines, that it is difficult to ascertain their number; the liver in this species exceeds in proportional bulk that of every other animal. The liver does not divide into lobes in the *pike* (*esoc lucius*), in the *esocus esculentus*, in the *fuguhus* *fuguhus*.

In the *fuguhus* *fuguhus* and *fuguhus* *fuguhus*, in the *callias* tetraophthalmus, and in the *elatius* *auloides*. There are two lobes in many of the genus *riparius*, in the *florus glaucus*, and in the *tetraophthalmus maximus*. There are three lobes in the liver of the *florus lagus*.

It should be observed, that in the above instances there are usually several light notches and furrows upon the surface of the liver, which, I think, would, perhaps, consider as divisions of this viscus, although Cuvier has not done so.

The divisions of the liver, as well as its figure, are but of little importance in all animals; sometimes they are designed to accommodate the neighbouring viscera, and at others look like accident; but in no case can the form materially affect the functions of this organ.

The texture of the liver in fishes is remarkably soft; unless in a very recent state, it immediately gives way under the pressure of the fingers. From all the observations we have been able to make, however, it appears to possess the same structure as the liver in the three preceding classes; the ventricle terminates in pinnellous branches, even more evidently in many fishes than in birds or reptiles.

The liver contains a great quantity of liquid oil in those fishes that have not the fat dispersed over the different parts of the body; of those the *florus lagus* and *pygmy*. The *florus lagus* has the liver so rich with oil, that the inhabitants of Norway catch it for the purpose of obtaining its oil to burn. Mr. Hope states, that the liver of the *florus lagus* maximum yielded about three bogsheads of oil. The oil of fishes appears as if it were diffused in those parts which contain it, as it readily flows from them, but it is more probably deposited in large cells, which freely communicate, than in the common interstitial fibres.

The *bilary duct* of the liver in fishes, except in very few instances, do not communicate to form a common hepatic duct, as in other animals; they proceed directly as they leave the different lobes of the liver, to open either into the gall-bag or its excretory canal, or into both; in consequence of which the hepatic ducts are in general numerous and very small in fish.

In the *fuguhus* *fuguhus* a fasciculus of twelve ducts, like a navel string, proceeds from the liver to the intestine, from which it is preferred there is no gall-bag in this species.

In the *ray* genus there are several very slender ducts, which terminate in the gall-bag, and one large branch, which is furnished by the middle lobe of the liver, and communicates with the cystic duct.

In the *florus lagus* the different hepatic ducts produce a trunk, which, however, does not go on to the intestine, but terminates in the cystic duct.

In the genus *tetraophthalmus* there are three principal hepatic ducts, of which the first opens into the gall-bag, near the neck, and the other two enter the cystic duct at different distances.

In the *fuguhus* *fuguhus* there are two hepatic ducts, which end in the cystic; the one at its origin, and the other at some distance.

The *lumpus* (*cyclopterus lumpsus*) forms an exception to the general rule, with respect to the termination of the hepatic ducts; in this fish there is no gall-bladder, and the different branches from the liver form unite, to form a single duct, which proceeds directly to end in the intestine. The few fishes which do not possess a gall-bag have probably a similar structure, although it has not been examined.

In the *anarrhichas lupus* the hepatic ducts are extremely numerous; the right lobe of the liver furnishes three branches, of five or six branches, which enter distinctly into the gall-bag; the left lobe gives origin to three fasciculi; the fishe
has three branches which open into the neck of the gall-bag; the others are composed each of two branches, and end in the cystic duct.

There are three or four principal hepatic ducts in the elk, which terminate in the ductus cysticus near its origin.

In the cod (Gadus morhua) there are several small hepatic ducts, which form four branches; these, after passing some way, enter an enlargement of the cystic duct, which takes place near its entrance into the intestine. In the bale (Gadus morhua) there are many small hepatic ducts, which terminate in succussion upon the cystic duct.

The hepatic ducts of the Scarpaza borrida penetrate the cystic duct.

In the sole (Pleuronectes foleus) the ducts from the liver go chiefly to a dilated part of the ductus cysticus. In the brill (Pleuronectes rhombus) the cystic duct receives two from the liver before its dilatation; and one trunk, which is composed of several branches, enters the dilated part of the cystic duct. In the turbot (Pleuronectes maximus) some of the hepatic lobes open into the gall-bladder, and others into the dilated part of the cystic duct.

In the dog (Solea solea) there are two or three minute canals which pass from the small lobe of the liver into the neck of the gall-bladder, and four considerable ducts that go from the large lobe to the cystic duct, which they enter at different distances.

In the river perch (Percia fluviatilis) the hepatic duct opens into the neck of the gall-bag, and in the sea perch (Sciaena labrax) there are three principal branches from the liver which end in the cystic duct, at different distances.

The barbel (Cyprinus barbatus) has the hepatic ducts ending in the cystic.

The salmon sends hepatic ducts into the neck of the gall-bladder.

In the bichir (Polypterus niloticus) the trunk of the hepatic ducts is joined to the cystic.

In the Galsus bagre there are eight or ten little ducts from the liver to the cystic duct.

In all the inaptites we have examined, the entrance of the hepatic ducts into the cystic, or the gall bag, is not accompanied by any valve or projection of the coats; the structure of the hepatic ducts also appears to be simple, and the internal surface with not any valve or reticulation.

The gall-bag is not universally met with in fishes; it has not been found in the lamprey (Petromyzon marinus); in the pride (Pteromyzon branchialis) in the lump (Cyclopterus lumpus); the piper (Irisys lyra); the Pleuronectes radiatus, the perch of the Nile, and in many fishes; we have not observed a gall-bag in the counver (Trachinus draco).

These instances of the absence of the gall-bladder are fewer than those noticed in mammals, and in birds; a resolution in which the bile may be concentrated, it may be concluded, is therefore more necessary to fishes than to the hot blooded animals; the circumference of the bile all passing through either the gall-bag or its duct, when those parts exist, is a strong proof of this opinion.

Cuvier describes the gall-bag as being more variable with respect to position in fishes than in the other classes; it is situated horizontally or obliquely, in regard to the whole fish, and in those two cases its fundus may be either turned forwards or backwards; at other times it is placed transversely under the stomach, of which the Galsus bagre affords an example; it is sometimes in a degree imbedded or concealed by the substance of the liver.

The form of the bag is also subject to variety; it is most commonly either egg shaped or pyriform; sometimes it is globular; sometimes it is oval, with the end next the duct very obtuse or flattened; this we have observed in some of the flat fishes (Pleuronectes). In the Blott dog fish (Galeus catulus) we have found it of the shape of a tube, nearly two inches long; the duct arises from the end the farthest from the intestine, and is seen like a smaller canal, accompanying the other which composed the gall-bladder.

The bulk of the gall-bag is also variable; perhaps it might be stated that it is large in proportion to the rapidity of the digestion in the fish. The bag is large in the anarthritus lupus, the pike, the loutariu, and monfufa; (Cochinus moris) it is small in the Gyntus placitus, Scarpaza borrida, the river perch; several of the genus choto, the sole, brill, and some others of the Pleuronectes, also have a small gall bag, but in those the dilatation of the cystic duct makes amends for it.

The structure of the gall-bag would seem to be simply membranous, the parietes are thin and smooth on the inner surface, which do not exhibit any glandular appearance or reticulation.

The cystic duct in general passes off directly from one end of the gall-bag, without forming any contortion, as in mammals; it is also, as far as we have observed, a simple membranous tube, with a smooth surface internally, and the orifice by which it communicates with the gall-bag is unprovided with any valvular structure, by which means the bile flows through it without interruption.

The cystic duct transmits all the bile which passes to the intestine, with a few exceptions of those fishes which are unprovided with a gall-bladder; it therefore corresponds to the duodenum communicating with the intestine. In several fishes, as the cod (Gadus morhua), some of the Pleuronectes, as the sole, brill, turbot, and others, the cystic canal forms a remarkable dilatation previous to its termination in the intestine; this dilated part receives some or all the ducts from the liver; it is so large in the turbot, that Cuvier describes it as a second gall-bag, to which it certainly corresponds in its office, by accumulating and detaining the bile on its way to the intestine.

The cystic, or rather common biliary duct, usually discharges its fluid into the intestine, along with the pyloric ceca, by an opening in the midst of theirs; sometimes it ends in one of the ceca. This happens in the plaice (Pleuronectes platessa), the river perch, and the dog (Solea solea). The duct enters the intestine at some distance from the pylorus in the pike (Esox lucius).

In the Galsus maximus, the orifice through which the bile is poured into the intestine is placed upon a process like a nipple.

The magnitude of the liver, and the formation of the biliary ducts in fishes, plainly indicate two circumstances in their physiology, namely, that a large quantity of bile is secreted, and that this fluid passes in a concentrated state into the intestinal canal. It is remarkable that the bile is more slowly to be detected in the tract of the first intestine, and that even the faces in the left portion of the canal are less coloured by this secretion than in other animals; this factstrongly supports the opinion of the bile being deflected to assist in the conversion of the alimentary substance into chyle, in performing which it is itself decomposed and dispensed of.

The bile of fishes, as far as we are acquainted, has not yet been submitted to any exact analysis; it does not however appear to differ materially in its properties from the same fluid in other animals. It is usually of a deep green colour, although the liver is often in fishes of a pale yellow colour, which probably arises from the bile being for some time in the gall bag, before it is carried into the intestine. It is also more fluid than in mammals and birds, as might be
be expected in consequence of the gall-bag not being con-
structed to furnish a mucous secretion as in their animals.

In figs. 5 and 6, of Plate I. of the Anatomy of Fishes,
the letter f indicates the fasciculus of twelve biliary ducts,
which are found to pass from the liver to the first intenelles
in the fuguatus maximus.

In Plate III. of the Anatomy of Fishes, fig. 7, shows the
manner in which the hepatic ducts proceed to the gall-bag
and cystic ducts, a, the portion of the liver next the gall-
bag, b, the gall-bag, c, the dilated part of the cystic duct;
d, the hepatic ducts passing to the gall-bag; e, the
ducts from the liver to the dilatation of the cystic duct.
Fig. 8. of the same plate, exhibits the termination of
the biliary ducts in the volf fis (anarrhichus lupus). a is
the liver; b, the gall-bag; c, the cystic duct; d, a portion
of the intenelle, into which the cystic duct opens; e, fasciculus
of several hepatic ducts from the right lobe, going to terminate
diffinitely in the gall bag; f, fasciculus from the left lobe,
ending in the neck of the gall-bag; g, h, two other fasciculi
from the left lobe, which open into the cystic duct.
Fig. 9. of this plate, represents the hepatic ducts going to
the intenelle in the lump fis (cyzoloptrus lupus); a is
a part of the liver; b, the hepatic duct, coming from the
liver, and uniting into a common duct, which is indicated
by c; d is the portion of the intenelle into which the
common bile emerges.

In fig. 6. of Plate I. of the Anatomy of Fishes, the letter
f points out the nipple-shaped process, on which is seen the
office of the hepatic ducts within the intenelle of the fuguatus
maximus.

Ceca, or pyloric Appendices.

Cuvier has, with some propriety, considered these parts as
proceles of the intenelle canal, and has combined his de-
scription of them with that of the intenelles; in some fishes
they are so wide, that the alimentary tubercules may neces-
sarily pass through them, but in general they are very small
worm-like processes, with a cavity scarcely wide enough to
admit a probe; but whatever their bulk may be, they are
always continuous with the tube of the intenelle.

The internal surface of the ceca is extremely vascular,
even more so frequently than that of the adjoining intenelles.
When the internal membrane of the intenelle is plicated or
laminated, that of the ceca is sometimes reticulated; but in
general the structure of the internal surface of the ceca cor-
responds with that of the neighbouring surface of the intenelle,
although it may not be so fibrillating.

The cavity of the ceca always contains a quantity of
renaceous mucus, which may be more abundantly obtained
by pressing the parietes of the ceca between the fingers.
The ceca possess a muscular and membranous coat, like
the other parts of the intenelle canal.

The ceca in general bear considerable resemblance, both
in size and figure, to a cluster of worms attached to the
canal of the intenelle by one extremity; in some instances
they are confined to form trunks, which open into the
intenelle. In the spadasaria they are united two and two,
and produce seven principal branches, which at last join in
one trunk. In the furgas they are shut and wide, and
collected together into one mass, into the centre of which
they all open by very large mouths; the inner surface is
deeply reticulated, so as to give the whole mass, when cut
into, rather the appearance of a congest of cells, than a
collection of ramified tubes, which has led many authors to
describe this part in the furgas as a single gland analogous
to the pancreas; the muscular coat is strong, and has the
fibres distributed in different directions, and the opening of
the conjoint ceca into the intenelle is single, and would
be as wide as that canal if it were not for a narrow fold
which contracts the orifice a little. There is a greyish
glandular sustance very discernible behind the cells, similar
to the glandular layer already noticed in the intenelle of
this fish.

There is great variety with respect to the number of the
pyloric ceca, and in several fishes they are altogether wanting;
neither is their presence, however, nor their number, seems
to have much relation to the habits or general structure of
the fish, except in the ray and shark genera, in which the
ceca are wanting, and their places supplied by a real pancreas.

Besides, in the chondrostei the ceca are not found in
the genera spadus, ofraction, alfites, tetradon, and dodon,
amongst the branchii; in any of the apodal fishes: in
the uraneosus and blennius genera, in some species of
pleurodon etc.; in the ffrus spinifer, and the labrus tinta: in
the anaplus tropthphilus, many species of efox, the genera
cyprius and cfarilus, and probably others which have not
been examined.

Cuvier has taken the pains to reckon the number of the
pyloric ceca which exist in many fishes; we shall therefore
follow his account.

The ljbrus piscearius has but two, which are small
and somewhat pyramidal in their shape.

In the cyzoloptrus lumpus the ceca are small, form about six
ramified rays, and as they approach the intenelle they unite
and open into each other.

In the genus gadus, the number of the appendices varies;
they are often ramified, or united into trunks, which
open into the intenelle; there are four orifices of these in
the bag (gadus merlangus), and six in the cod (gadus
merluccius). In the bate (gadus morhubus) there is, in place
of the ceca, one large cul-de-sac, of which the bottom is turned
forwards, and which opens by a large aperture into the
commonest exit of the intenelle canal: there are eight ceca
in the gadus mehdes, thirty-two in the barbel (gadus
fianus), and thirty-four in the dog (gadus molva).

There are eight long and slender appendices in the swaner
(trachinus draco).

In the genus cottus the number of the ceca varies from
four to nine.

They are far in the remora (elichia remora). Twenty-
three ceca are found in the ferrall (sollus ferrallus), and
fix only in the mulus barbatus.

The florenches bovidae has four ceca: the number varies
much in the genus triceps: the pipe (trigla lyra) has from
eight to ten; the trigla esophrana has six.

In most of the pleurodon etc. there are but two ceca, as
in the turbos, the fish, the pleurodon lusmica, the fomden,
the shad. Cuvier also reckons two in the plaice, and only
one in the bolilus: as far as our recollection serves, there
are two very large ceca in the balilus, and in the plaice,
besides the two small conical dilatations at each side of the
origin of the intenelle canal. We have lately discovered,
about an inch beyond this, a third cecum, from the side of
the intenelle, exactly resembling in shape and structure
the two already described by authors. This is the more
worth of remark, as it is the only instance we know in
which the first intenelle of fishes furnishes any such process
except at the pylorus.

In the macrurus (foamder formaderus) the ceca are very
numerous; but there are only three in the foamer fajianus,
in the foamder thynus there are two, which divide each
into three branches. In the pla (foamer daller) there are
twenty-five; and in the sfae (foamer teusnarios) twelve or
thirteen ceca.
There are but two little appendices situated at each side of the pylorus in the stickleback (Gasterosteus aculeatus). The cæca are fine and small in most of the perches and fishes. In the common perch (Perca fluviatilis), and the Perca anguilla, there are but three. In the Perca baium there are four; six cæca are found in the Perca baium. There are seven or eight in the Sciaena aurota, five in the Sciaena labrax, and six in the Sciaena cirrosa, and much greater number in the other individuals of this genus. There are four cæca in the tench (Tinca tinca). The eelodon arcuatus has about thirty long, slender cæca; the cheilodon niger only five.

In the genus Sparus there are usually from three to five cæca; the Sperus falsa has four; the Sperus auratus, and Sperus fargus, have three; the Sparus pavo, Sperus mans, and Sperus brama, have each four, and there are five in the Sparus annulatus. The cæcal appendages are numerous in the genus Clupea. There are eighteen long, slender cæca in the anchovy (Clupea alosa); twenty-four in the herring (Clupea harengus), which open into the intestine by twelve orifices, ranged in a line; there are as many as eighty in the Clupea alosa.

The genus Salmo exhibits great variety in this respect; there are but six in the Salmo salar, although in the Salmo marron there exist one hundred and fifty; in the common salmon (Salmo salar) there are about seventy, placed in several rows, along the side of the intestine. There are two cæca in the mormyria labiatus, Geoffroy.

The common mullet (Anguilla cephalus) has six cæca; the Mugil alosa but one.

The only point of view in which we can consider the pyloric cæca is, as prolongations, or processes of the alimentary canal, designed to furnish an additional quantity of the intestinal mucus; this office is reconcilable to all the varieties of form and number, and the occasional absence of these parts, which could only affect the mucous secretion of the cæca with respect to quantity, and any deficiency of that fluid might be supplied by a more copious secretion from the intestine itself. This opinion seems supported by the relative magnitude of the cæca, and of the parts of the alimentary canal from which they arise. We have observed that the capacity of the stomach, or of the first part of the intestine, is greatest in proportion to the bulk of the fish, in those species where the cæca are either wanting or few, and that these parts are commonly small when the cæca are numerous or large.

In Plate II. of the Anatomy of Fishes, fig. 4, exhibits the three cæca in the plateae (Phlebourites platei): c is the pylorus; d, d, the two pyloric cæca, e, the third cæcum peculiar to this fish, arising from the intestine, a short distance from the pylorus. Fig. 12 of the same plate gives a view of the internal surface of the cæca, and the adjoining parts of the intestine in the turbot (Phlebourites maximus): a is the laminated surface of the intestine; b, b, the internal membrane of the two cæca, in which the laminated structure is less apparent. The letters c, d, e, of fig. 7, and the letter d, in fig. 14, of this plate, refer to some of the cæca in the mullet (Mugil cephalus).

In Plate III. of the Anatomy of Fishes, fig. 10, shews the internal structure of the cæca, and their connection with the intestine in the Sperus (Sperus fluviatilis): a, the cavity of the intestine; b, the cavity of the pylorus; c, the cavities of the cæca exposed by a section. The larger orifices belong to branches of the cæca; the smaller to the cells produced by the reticulation of their internal membrane; d, the large common opening of the cæca into the gut; e, the muscular coat which surrounds the cæca, and gives them the appearance of a single gland. Fig. 11 of the same plate represents the numerous cæca in the Sperus (Sperus fluviatilis); a is a portion of the intestine at the pylorus; b, b, the cæca in great numbers arranged along the intestine.

**Pancreses.**

This gland only exists in two genera of fishes, the ray and flœck; the glandular apparatus which has been described by some anatomists as a pancreas, in the flœck, is really, as we have before observed, only an arrangement of short cæca, having many communications with each other. The pancreas is situated immediately beyond the pylorus, upon the first intestine; its form is somewhat triangular, but very irregularly so; it is divided into lobes. In the smaller deg-fœck (Pampus catulus), we have observed the pancreas to be double, or of two portions, of which one is placed on each side of the intestine.

The texture of the gland is felt, compact, and uniform; its minute structure is, therefore, obscure; its colour is a rich reddish white: it has a much smaller proportional volume, than the pyloric cæca usually have, to those fishes in which they exist.

The fluid which this gland secretes, appears to resemble the pancreatic juice of the three preceding classes of animals, and not the mucus of the pyloric cæca; which circumstance, as has been before mentioned, affords a strong presumption that the offices of these two secretions are different.

**Spleen.**

This organ is supposed to exist in all fishes; we have, however, failed to detect it in two families of the Lamprey (petromyzon marinus); but, until assured by further observation, we are unwilling to assert positively, that fo extraordinary a departure from the common structure of the cæca does occur in this species; it may be presumed, however, that if this fish possesses a spleen, it is so insignificant as to readily escape notice.

The situation of the spleen, with respect to the adjacent viscera, is by no means uniform in fishes; it is perhaps most commonly placed on the upper side of the caudal portion of the stomach, that is, to lie, between its fundus and the fomach bladder, which lies along the back.

In the flœck and ray genera it projects from this situation, so that one half of it lies on the left side of the stomach.

In the angelfœck (Pampus fœnalis) Monroe observed two spleens, one of which was attached to the large, the other to the smaller curvature of the stomach. In the fœck (Pampus catulus) the spleen is divided by a dip fœrure, which is what we presume doct. Monroe meant by two spleens; one portion is on the left side of the fundus of the stomach, and the other paffes above it. Mr. Home represents the spleen of the fœnalis maximus as a chain passing round the stomach. Cuvier describes two branches of the spleen in the flœck (Pampus flœck), which are attached to the curvature that the stomach makes in this fish posteriorly. Doctor Monroe reckoned seven spleens in the flœck, but all very small; the largest, he says, did not exceed the size of a dried horse-bean, and the other fix were none of them larger than a dried garden pea.

The spleen is enveloped by the memency, near the commencement of the intestinal canal in the lampfœck (cypheterus lâmpus). It is fixed on the right side of the beginning of the first intestine in the flœck. In the cat it is placed between the stomach and the next portion of the intestinal canal. In the foarpeca it is found interposed between the pyloric extremity of the stomach, and one of the cæca. The remora has it situated between the liver and the stomach;
the like with that described in the other classes of animals. The arteries divide like the branches of a broom, and terminate in very minute ramulescles; the veins originate from cells, which, although not large, are sometimes very visible in consequence of their containing a dark coloured substance: when the texture of a spleen is unrevoluted, which is very easy from the looseness of its texture, the cells, if filled with this substance, appear like small grains of coffee adhering to the extremities of the vessels: this dark appearance of the cells is not general, nor do we believe constant in the same individual; it seems to be rather an accidental condition of the organ; after it has once been perceived, there is no difficulty in recognizing the same sort of granular appearance, of a pale brownish colour, in the spleens of other fishes. What is the substance which gives the granular appearance in the spleen of fishes? Is it the spleenic blood changed in its properties while passing through the cells? More observation is required to answer these questions.

digestive apparatus, and afterwards in the efferent vessels.

In the 

in a great many cells of very irregular shapes, and all communicating the one with another. The principal ab sorbent vessels pass through it.

This cellular receptacle of the chyle may probably perform the same offices of the absorbent glands in other animals.

The lymphatics of the liver, gall-bag, pancreas, and spleen, also accompany the blood-vessels of these parts; they freely communicate with each other, and, uniting with the absorbents of the stomach and intestines, they form a plexus on each side of the stomach, which proceeds along the sides and the back part of the cesophagus to the side of the spine, and near to the large veins analogous to the subclavian; at these parts all the absorbents of the different parts of the body are assembled.

The lymphatics of the kidneys and organs of generation, with those of the tail and posterior parts of the body, proceed along the spine.

The lymph of the head and lateral fins is conveyed into the common referentary, principally by means of a large trunk, which passes on each side of the head, and which receives posterior lateral branches from the adjacent parts.

The different absorbents of each side of the body, after communicating with each other in the subclavian plexus, furnish two short trunks which go to terminate, the one on the right, the other on the left subclavian vein, near the junction of those vessels with the internal jugular veins. These two trunks correspond in their office to the thoracic ducts of other animals, but do not serve as refts-pores, as they have lost capacity than the plexus from which they take their origin.

At the orifices of the trunks into the subclavian veins, there are placed two semilunar valves, to prevent the blood escaping into them. There is no other influence of valves throughout the absorbent sytem of fishes; although the vessels have a flattened, jointed appearance, as if their canal was interrupted by valvular contractions.

In the efferent vessels, of which the col and baddock are taken as examples, the lacteals are of a smaller size than in the 

The origin of the lacteals is from the subclavian veins, near the junction of the subclavian veins with the internal jugular veins. These lacteals communicate with the absorbents of the intestine, and, uniting with the absorbents of the stomach and intestines, form a plexus on each side of the intestines, which proceeds along the sides of the intestines, and near to the large veins analogous to the subclavian; at these parts all the absorbents of the different parts of the body are assembled.

The thoracic duct, after being joined by these vessels,

...
F I S H.

vessels, communicates with the net-work near the orbit; where its lymph is mixed with that of the lymphatics from the posterior part of the gills, from the anterior fins, the belly, &c. and then from this net-work a vessel goes into the jugular vein, just below the orbit.

The lymphatics of the left side agree exactly with those of the right. Hewson’s Account of the Lymphatic System in Fish. Phil. Trans. for 1769.

Neither Hudson nor Cuvier (who seems to have copied his description) have represented the common receptacles of the lymph in 

officinal fishes accurately. These parts do not deserve to be called net-works, but, as Dr. Monroe has named them, large cellular receptacles; they are particularly large in the haddock (gadus eglefinus), and cod (gadus morrhbus), and are most easily demonstrated by injecting with a fluid, or inflating any of the large absorbents in the neighbourhood of them. These receptacles are situated immediately behind the gills, and may be displayed by cutting through the integuments at that place; the receptacles have left scanty, but are still too much dilated to merit the name of a plexus of vessels.

The receptacles communicate by large canals, which cross from one to the other, behind or above the heart, and caecum.

In identity of the absorbents of the viscera already described, the lymphatics of the head and muscular parts of the body give origin to four principal trunks, and a plexus which terminate in the large receptacles, or common reservoir of the system.

The flow of these carries the lymph of the under surface of the body and tail; it is a considerable vessel, extending along the median line of fish; from the tail towards the head it becomes a little enlarged under the thorax, and communicates with the large receptacles, by means of some foramina which lead into a canal on each side, between the two ventral fins.

The next two trunks are also superficial; they run along the sides of the fish near the linea lateralis. From each side of these trunks a number of branches go off immediately under the skin, which produce a beautiful perpendicular appearance; these trunks open directly on each side into the common receptacles that are placed behind the gills. Before these vessels, Hewson describes a deep-seated fct. of absorbents, which accompany the ribs.

The fourth trunk is deeply situated and large, it commences near the tail, and lies between the roots of the numerous processes of the vertebrae; as it proceeds towards the head it collects the lymph, from the dorsal fins and adjacent parts of the body; having arrived near the head it sends a branch to each thoracic duct, near the part where they come off from their common trunks.

The lymphatics of the brain and organs of sense, and those from the mouth, jaws, and gills, form a complex anastomosis or plexus near the orbits, and send a vessel into each of the common reservoirs.

In the salmon each of the receptacles terminates in the jugular, by sending a canal into the upper end of the corresponding artery near the canalis jugularis and the internal jugular vein.

The entrances into the venous system are guarded in 

officinal fishes as in the flate, by semilunar valves.

As the absorbent vessels are unprovided with valves, the most usual way of expelling them, is to inject the fluid from one of the principal trunks: the belt for this purpose is the one which runs under the skin of the belly. By this means the most minute branches may be filled and expelled. Dr. Monroe succeeded in injecting from the trunk, the absorbents of the brain, of the membranes of the eye, and the ear in the flate (roja batis), by which he discovered that the lymphatics of the brain form an intricate plexus; he also filled the ultimate branches of the absorbents of the skin. These are most beautifully reticulated, and are particularly large and numerous upon the upper lateral surface of the flate, on which they terminate by foramina capable of being demonstrated. Dr. Monroe says, that not only water, but air, milk, quicksilver, and even oil of turpentine, coloured with the powder of vermis, were discharged upon the surface of the skin, by a vast number of distinct orifices, placed at regular distances from each other; yet the force with which these liquors were injected was very small, and there was no extravasation into the cellular substance any where under the skin, or in the interstices of the muscles. It is remarkable that the effusion of these liquors upon the skin takes place only upon the upper surface of the fish, where the skin is tough and scabrous: it however proves that it does not happen in consequence of extravasation, or rupture of the vessels, for in that case the effusion would be foamy or principally seen on the under surface of the fish on which the skin is much more weak and thin. Monroe concludes that the cutaneous lymphatics, situated on the back of the flate, are designed to absorb a portion of the water for the purposes of furnishing the salt liquor found in such considerable quantity within the cranium of that fish. See M’roo’s Physiology of Fishes, p. 34.

The facility of injecting the absorbents from their trunks enabled Mr. Hewson also to fill a series of very minute vessels, between the internal muscular coats of the intestines; and upon the plice, (or, as he terms them, vili) in these situations the absorbents anastomose and run together, so as to produce a very close and beautiful reticulation. If mercury be injected into this net-work at one part, it spreads over the intestine; and if the intestine be inverted, and the mercury squeezed, it is easily forced into the small vessels on the internal coat.

In one injection Mr. Hewson made of the flate of the cod, the absorbents were seen to pass through the external coats, dividing into smaller and smaller branches, without any appearance of a net-work between the muscular and villous coats, although considerable force was employed in the injection; from which he concludes that the absorbent vessels of the flate do not possess the same arrangement as those of the intestines. See Hewson’s Account of the Lymphatic System in Fishes. Phil. Trans. vol. ix.

In Plate IV. of the Anatomy of Fishes, fig. 1. represents the curvature of the flate of a flate (roja batis) with the cellular receptacle of the chyle in situ and of the natural size; a, the portion of flate; b, the cellular receptacle attached to it. Fig. 2. of the same plate, exhibits the receptacle magnified, and cut open, after having been previously inflated and dried, in order to expose its internal structure; a, indicates the cellular part; b, b, the absorbent vessels passing longitudinally through the receptacle and communicating with its cells; c, 3.0. Plate IV. displays the common receptacle of the chyle and lymph in the haddock, (gadus eglefinus) with some of the lymphatic trunks which enter it; a is the receptacle distended by injections; it appears like a large sac situated immediately behind the gills; in order to expose it the gill-cover is cut away; b the branch; c is the absorbent which runs along the middle line of the belly, and communicates with the receptacle by branches sent in between the abdominal fins; d, the lateral absorbent trunk, which enters the recep-
receptacle directly; \( e \), the lateral subcutaneous duct, obliquely sees, running parallel with the lateral absorbent vessel.

Heart.

Fishes have not, properly speaking, a thoracic cavity, although their heart and gills are very distinctly separated from the abdominal viscera, by means of a septum, which crosses the body immediately before the liver. This diaphragm is not muscular, as far as we have observed, but receives a slender muscle on each side from the scapula. It is usually thick and firm, and is apparently composed of tendinous fibres, intertwined together like the muscular fasciculi of the internal surface of the human auri, and the web thus formed is further strengthened by the peritoneum on one side, and the pericardium on the other.

The heart is situated in the middle line of the body, between the branchiae each side, and farther forward, that is, nearer the head than in other animals; the space between the mouth and the belly being generally very inconsiderable in fishes.

The pericardium is larger, and of a rounder figure than the heart; this is necessary on account of the irregular form of that viscus.

The external reflection of the pericardium is in general a stronger membrane than the peritoneum; it appears to be tendinous in structure, although commonly very thin.

We have not observed any material deviations from the common structure of the pericardium, except in the lamprey (petromyzon marinus), in which we have lately discovered a mossy formation of the part. The pericardium in this fish is composed of firm cartilage, of a rounded figure, and so far imbedded in the anterior portion of the liver, that a great part of it is concealed from view until the substance of the latter be cut off; there are several fronds, or tendinous processes sent off from the internal surface of this cartilaginous vac, which are attached to the surface of the heart, and serve to sustain it in its proper position in the body.

The above structure in the lamprey is a confirmation of an opinion we have held, that the pericardium does not alter its figure with the contraction and dilatation of the different parts of the heart; from which arises the necessity of a greater quantity of aqueous fluid in this cavity, than is found in those containing the other viscera.

The pericardium of the skates (raja batis), as has been mentioned in speaking of the abdominal cavity, was discovered by Count Monroe to produce a funnel-shaped elongation towards the abdomen, which is divided into two branches or canals, terminating by open mouths in the latter cavity; as far as our observation goes, this structure is peculiar to the ray genus.

The heart in fishes is composed of two cavities only, an auricle for receiving the blood from the veins of the body, and a ventricle for propelling it to the branchiae. The dilatation of these parts is very evident, by which the figure of the heart is rendered peculiar, appearing like two bodies connected to each other.

The portion of the auricle, with respect to the ventricle, is subject to vary; it is usually placed anterior to it; it covers, and often passes beyond the ventricle in the genus gadus; the rays smooth bound (sigalus mycterus), and the dogfish (sigalus canicula), \&c.

The auricle is generally much more capacious than the ventricle. Its figure is not easily alligned; it is a sac, of which the lateral parts are dilated, and at the place where it becomes connected to the ventricle it is in a degree constricted, or forms a sort of neck. The parietes of the auricle are generally thin; its muscular fasciculi form no remarkable projections, and are distributed over the internal surface rather in the manner of a meadowwork or irregular ramification. The opening into the ventricle is usually furnished with two semilunar valves.

In the moonfish (tetragonodon molit) there are four valves of a square shape in this situation, and in other influences, as amongst the flarks (sigalus), the aperture into the ventricle is guarded by a single delicate valve, the border of which is attached by many points to the paries of this cavity. The opening of the ventricle into the auricle is situated rather superiorly, that is, somewhat on the side of the auricle next the spine; it is near the neck, or part which is united to the ventricle, consequently the auricle appears, on opening a fish, like an entire bag, depending from the ventricle, the communication with the cavum not being visible in that view of the parts.

The ventricle has, according to Cuvier, most commonly four sides; we should say, the most usual figure is that of a short pyramid with three sides, the base of which corresponds to the fourth. The ventricle is, however, globular in the smooth bound (sigalus mycterus), and triangular in the dogfish (sigalus canicula), and exhibits some other variations of form in different species. The parietes of the ventricle are strong and thin, and furnish many fasciculi on the internal part of the cavity, similar to those observed in the ventricles of other animals.

At the anterior part of the ventricle, and near the aperture into the auricle, there arises a short tube, from which the branchial artery is afterwards continued. Cuvier has called this part the footstalk or bulb of the branchial artery. Its figure is various; in the flurgeon (acipenser fluris) it is oval; in the ray and flark genera it is cylindrical, and in other fishes it is most commonly pyriform; the bulb is less muscular than the ventricle, but much more so than the artery; there is often a considerable layer of muscular fibres around it, which are continued upon the branchial artery. The internal part of the bulb is commonly made irregular by a number of strong longitudinal fasciculi. The membrane which lines the bulb produces some folds of a semilunar, or a parabolic form; these have their free edge turned towards the branchial artery, consequently perform the office of valves, in obstructing the return of the blood upon the ventricle. In the flarks there are two rows, of three valves each, the one at the orifice, the other at the termination of the bulb; there are also two rows in the flurgeon, the first composed of four valves, the second of five. In the ray genus, Cuvier reckons four rows, composed of the same number of valves, and in the genus gadus, the carps (cyprinus), and salmon (salmo), \&c. but two valves, placed at the entrance of the footstalk, and none at any other part.

Arteries.

We have already said that the heart of fishes is single, or consists only of an auricle and a ventricle; it consequently furnishes but one artery; this vessel is analogous to the pulmonary, as it conveys all the blood to the organs of respiration; being entirely subjacent to the functions of the gills or branchiae, it has been with great propriety termed the branchial artery.

This vessel arises from the bulb connected with the ventricle, of which it is in reality but the continuation, and from which, in some fishes, it is not very distinguishable.

In the skate (raja batis) the artery proceeds under the cartilage which joins the inferior extremities of the branchial
FISH.

2d branch of the artery of the brain goes forwards and
inwards, and again forms a junction with its fellow, and
the one which runs along the middle line of the lower surface
of the brain and spinal marrow. The 3d branch passes to
the origin of the medulla spinalis, and there gives off two
branches which extend to a vascular ring, produced from
the sides of the middle artery; the branch itself advances as
far as the eighth pair of nerves, where it sends off two other
branches, which unite to give origin to the middle artery
already mentioned. After producing this vessel the anterior
branch goes on distributing small arteries to the brain; it
pauses under the root of the fifth pair of nerves, to the tu-
bercles of the olfactory nerves, where it is expanded on
branches that spread in radii, or like the pessan scheme
of the portio dura. The intricate anatomomos produced by
this artery with its fellow, and with the middle vessel of the
lower surface of the brain, have been compared by Cuvier
to the Greek capital letter phi, accompanied with two semi-
circles affixed to it, in opposite directions, thus Φ. This
arrangement of the vessels of the brain may be considered as
analogous to the reticulo-sarcal of the carotid in quadrupeds,
and the circle of Willis in man. The artery which is distri-
buted to the brain in fishes appears, from its origin and course,
to supply the place of the vertebral artery.

The three trunks produced by the blood vessels of the
gills proceed inwards and backwards upon the inferior
smooth surface of the cartilage, corresponding to the cervical
vertebrae, and soon unite into one large vessel which is analo-
gous to the aorta.

At the place where these vessels are assembled to form
the aorta, there is given off a large branch, which cor-
responds to the subclavian artery, both in its situation, and
on account of the parts it supplies; it passes directly across
the cartilages which compose the pectoral member, or great
fin of the skillet, into which it enters, and immediately divides
into two great branches, which take the course of the broad
cartilage that forms the rays and muscles of the fin, the
one passing anteriorly, the other backwards, and each distrib-
uting branches in the direction of the muscles of the
fin.

The subclavian, according to Cuvier, furnishes posteriorly
a small artery, which goes to the ovary in the female, and
to the testicle in the male, and is analogous to the femoral.

Before the subclavian penetrates the fin it gives off a re-
markeable branch anteriorly, which passes along the fore part
of the gills; it there sends communicating branches to the
vessels that are immediately produced from the gills, and
likewise some which are distributed upon the gills themselves
for their nourishment, which are consequently analogous to
the branchial arteries of those animals which have lungs.
It detaches also, inwards, some arteries to the heart and
trunk of the branchial artery, which supply the place of the
coronary arteries; and, finally, it is lost in branches which go
to the muscles and parts about the upper jaw.

The aorta proceeds in a straight line upon the under sur-
face of the cartilages composing the dorso vertebral, on
which there is a groove for its reception, and when it arrives
at the tail it becomes completely enclosed in a canal, which
is made by the inferior spinous processes of the caudal ver-
tebrae.

Soon after entering the abdomen the aorta sends off the
celiac artery; this vessel passes backwards, and is distributed
in particular to the spiral valve of the intestines, to the liver,
and to the stomach. The first branch accompanies the
cylic duct to the commencement of the intestines, which it
penetrates very near the pylorus, in order to ramify to in-
finity upon the spiral valve: some of its small branches also
When the celiac has arrived at the internal edge of the stomach, it divides into two branches, one inferior, of which the ramifications are detached at right angles, from right to left, under the inferior surface of the stomach; the other is superior, and is distributed to the corresponding surface of the same organ, and gives likewise some small arteries to the left side of the spleen.

The next branch of the aorta is the mesenteric artery. It passes to the right of the spleen, to which it gives two large branches that enter at one side, and furnish at the other side arteries to the pancreas; it afterwards follows the right side of the intestinal canal, to which it is distributed. Its chief branches, to the number of nine or ten, detach themselves at right angles at nearly equal distances from each other, and cross and surround the intestine. The succeeding branches of the aorta are much smaller than the preceding.

The two first go to the commencement of the oviduct, which they furnish with many branches, particularly at the superior part; but before arriving there each of them tends an artery to the muscles of the spine analogous to the dorsal branch of the intercostals, or of the lumbers in mammalia.

A third branch furnishes some arteries to the spinal column and to the commencement of the kidney, and goes particularly to the oviduct.

A fourth artery arises from the aorta, and is sent exclusively to the kidney, at the side of which it detaches a small lumbar artery, which is distributed to the parietes of the belly, to the muscles of the spine, and to the vertebral column.

Three other arteries, having a similar definition, arise more posteriorly from each side of the aorta.

Finally, there proceeds from the aorta a large branch on each side; it soon sends off a renal artery, which advances the length of the kidney, distributing its branches to it, after which it continues its course outwards in the most posterior part of the abdomen, and produces an artery analogous to the epigastrie, and then escapes into the cavity, and is expended upon the anal fin.

The arterial fylum of fishes in general does not differ materially from that described in the skate; the gills being four, they consequently furnish one branch less than in the genus ray, or the shark. The aorta in some of the cartilaginous fishes, instead of passing in a groove as is usual, is contained in a canal formed in the bodies of the vertebrae; this is remarkably the case in the sturgeon (acipenser fluvius), and the lamprey (petromyzon marinus). The coats of the aorta adhere firmly to the sides of the canal, so that it would appear in these fishes the blood flows through the aorta as through a passive tube.

In those fishes which have ribs, the aorta gives off a number of branches to the intercostal spaces, which correspond to the intercostal arteries. These vessels, however, distribute branches to the kidneys before they pass to the parietes of the belly.

The splenic artery is not generally as it is in the skate, a branch of the mesenteric, but of the celiac, or that artery which supplies the first portion of the alimentary canal, the liver, and spleen.

Cuvier states that there are generally in fishes two mesenteric arteries, and describes them in the treat (falso faro).

Vol. XIV.

The first, or anterior mesenteric, he says, is detached from the aorta very near the middle of the body, and at a distance from the trunk of the celiac; it advances for a little way in the substance of the mesentery, and divides into two branches, of which the one goes forwards and the other backwards, parallel to the intestinal canal; it supplies with branches which form right angles with the artery that furnishes them, and which having arrived at the intestine, wind round it in a serpentine manner, and give off branches that extend forwards and backwards along it.

The posterior mesenteric artery arises from the trunk of the aorta at some distance from the first; it passes backward parallel to the intestine, and distributes its branches to the posterior portion of it: these go off at acute angles, and are not serpentine, as those of the anterior mesenteric artery. This vessel likewise sends branches to the bladder, which also receives others from the posterior intercostals.

Although the arteries of fishes have no peculiar origin, and are sent to parts differently constructed than those in mammalia, they bear considerable resemblance to the arteries of that class. From the preceding description it will be seen that almost all the arteries of fishes admit of the same names that are applied to the vessels of mammiferous animals.

The mode in which the aorta is formed in fishes, makes it impossible for the heart to communicate its impulse to the arterial system: the circulation of the blood in these animals is therefore carried on slowly, and unaccompanied by the pulse, or that salutary motion that is observed in the principal arteries of the hot-blooded animals: consequently also with the offices of these vessels, their parietes are thin, and appear to be deprived of the middle or contractile coat.

The arteries of fishes very much resemble in their structure the veins of other animals; they further agree with veins in the circumstance of having the branches of large capacity, and often as large as the principal trunks of the body.

In Plate IV. of the Anatomy of Fishes, Fig. 4, exhibits a view of the heart and branchial artery of the skate (raja batis); a, the ventricle of the heart; b, the auricle; c, the bulb of the branchial artery; d, d, the places at which the femoral valves are found; e, e, the two first branches of the branchial artery; f, f, g, h, their division into three branches defined for the three posterior gills; i, the continuation of the trunk of the branchial artery; k, k, the two branches in which the artery terminates; l, l, the two branches which go to supply the two anterior gills; the numbers m, m, n, n, indicate portions of the five gills which are left on one side, in order to show a little of the course of the branches of the branchial artery along their convex edges.

Fig. 5 of the same plate shews the formation of the aorta and some of its principal branches in the skate, the parts on the lower side of the body are cut away to bring into view the objects of the figure: a is the trunk of the returning artery (or vein, as it is often, though improperly, termed) of the anterior gill; b, the continuation of this vessel distributed to the front and external parts of the head; c, a communication between the returning artery of the first gill with that of the second, pointed out by d; e, the trunk formed between those proceeding to form the aorta; f, f, f, small arteries sent from this trunk to the muscles and other external parts of the head; g, the anastomosis between the two returning arteries of the second gill; h, the second artery of the second gill; i, i, the returning arteries of the third gill; j, their communication; m, n, the arteries of the fourth gill; o, their anastomosis; p, the branch of the first trunk sent to the brain; q, the second arterial trunk which forms the aorta; r, the arteries from the

35
FISH.

The gills united as the others by a cross branch; 2, the third arteral trunk which produces the aorta; 2, the commencement of the aorta formed by the confluence of the three arteral trunks on each side; 6, the branch of the aorta which corresponds to the subclavian artery; 3, the branch of this artery which goes forward, communicates with the external ends of the returning trunks of the gills, and sends off the branches analogous to the bronchial and coronary arteries, and others to the muscles of the jaws; 7, the division of the subclavian artery in order to supply the great pectoral fins or wings of this fish; 4, the caval artery, 2, the melaenitic; several small arteries are seen to arise from the succeeding parts of the aorta which go to the organs of generation, the kidneys, &c.

Veins.

The aperture by which the venous system of fishes terminates in the auricle of the heart is very small, in proportion to the size of that cavity, and to that of the adjoining trunk. The contracted opening into the auricle may, in a certain degree, perform the office of valves, or at least diminish the current of the blood upon the heart.

The common venous sinus with which the auricle immediately communicates, pales on each side transferably and backwards; it is formed, according to Cuvier, by the confluence of five principal trunks: 1, the posterior vena cava; 2, the trunk of the vena cava hepatica; 3, and 4, the two inferior vena cava; 5, a trunk which conveys the blood from the parts in the neighbourhood of the gills.

The posterior vena cava receives the deep-fated venous branches in the neighbourhood of the spine; the trunk itself accompanies the aorta, and, like that vessel, is included between the inferior spinal processes of the caudal vertebrae; and in those fishes which have the aorta lodged in a canal in the bodies of the dorsal vertebrae, as in the lampey (petromyzon), and theurgeon (acipenser), the posterior vena cava is accommodated in a similar manner; the posterior cava is in general an inconsiderable trunk with respect to capacity, it is however very long, and is without dilatation, being nearly of the same size throughout; this vessel is not described by Doctor Monroe, and appears to have entirely escaped his observation, although, from the number of species in which we have seen it, we believe that it is constantly to be found in this class.

The vena cave hepatica of the several lobes of the liver unite immediately before their termination in the common sinuses under the heart, they are always considerably dilated; Monroe states that in the flat (riga baits) they form between the liver and the heart finishes, the diameter of which is ten times greater than that of their openings.

The two anterior cava are the most important veins in the body; they receive the blood from a great part of the muscular substance of the fish, the organs of generation, &c. They lie contiguous to each other in the abdomen, and are greatly dilated. They form large receptacles of blood, according to Monroe, above the ovaries in the female, and the testicles in the male fish, at which place these veins communicate freely with each other.

The blood of the anterior and lateral parts of the body, especially in the flat hodanopterygii, and the fishes with large pectoral fins, is conveyed by trunks of some size, which correspond to the jugular and subclavian veins of other animals.

The latter trunk appears to be the continuation of the common sinus, into which the other trunks open by orifices smaller than the vessels themselves, the edges of which are prominent and leafy, or floating, so as to perform, in some degree, the offices of valves. Dr. Monroe says, that he observed within the external jugular veins, and at the termination of the internal jugulars, a pair of valves, similar to those in the veins of the human subject. At the termination of the renal veins, and large branches of the hepatic veins, he found single membranes fixed by threads from their edges, resembling the coronary vein of our heart; and at the termination of the other large veins, especially near the heart, he says, there are not only constricted orifices, but doublings at their edges, which have so far the effect of valves, even in the dead body, that we cannot fill completely all the veins, by throwing an injection in at one of their branches. Page 18. Monroe's Physiology of Fishes.

It should however be observed, that the veins of fishes are not valvular in their course, like those of mammalia.

It is unnecessary to give a particular description of the venous branches, which produce the trunks above-mentioned; these, as far as we have observed, accompany the ramifications of the arteries, and are single vessels of a somewhat greater diameter than the artery.

The coats of the veins of fishes are extremely fine and thin; fo much so, that they would seem to be incapable of suffering much dilatation without being ruptured.

We have frequently observed that the veins of fishes appeared as if they were in a great measure emptied of their blood, particularly in the dilated parts of the anterior cava, which vessels would seem to have a capacity beyond their usual contents; the great size of the principal venous trunks of fishes is therefore, probably, not so much the consequence of long continued dilatation, as original organization. It appears to be a circumstance in the structure of these animals, adapted to the flow motion of their blood, and not as Dr. Monroe supposes, dependent upon the pressure of the water on the surface of their gills, causing an accumulation of the blood in the interior parts of their bodies. The existence of several venous trunks for collecting the blood from the smaller branches appears also to be a provision to obviate the faults which would arise, if all the blood was slowly accumulated in one or two trunks.

Fig. 4. Plate IV. of the Anatomy of Fishes, presents a view of the principal venous trunks in the flatfish (riga baits); 4 is the common sinus, in which all the veins meet, seen passing from each side behind the articule into which it opens; 6, a part of the vena cave hepatica taken out of the liver; they pour their blood into the sinuses, opposite to the auricle; p. p. the two anterior vena cava; g, the place at which they communicate with each other; a and s, the veins analogous to the internal and external jugulars; at the trunk, which corresponds to the subclavian veins, a, v, two branches of the subclavian, which collect the blood from the great pectoral fins, x, a large vein from the muscles, and other parts behind the abdomen, which opens into the subclavian.

Vital Temperature.

All the hot-blooded animals possess a degree of temperature suited to the functions they naturally perform; which cannot be materially altered without inconvenience to them; and any considerable deviation from which is resented by an effort of their vascular system; this we have termed their standard heat. The temperature of fishes, both from their organization, and the element they inhabit, is in general low; one of their chief characters is being cold blooded. There is however a good deal of variety in the natural temperature of different species; those that live in the sea are some degrees colder than the fresh-water fishes; and those...
tho' those that are alive, and frequent the surface of the water, as many of the genera _cyprinus, salmo, &c._ have a higher temperature than the more sluggish species. We may state the standard heat of the one kind of fishes to be about 60° of Fahrenheit's scale, and that of the other about 50°.

As the vital heat is less independent of the external temperature, in proportion to the lowness of the standard, or, in other words, as the heat of the animal is more inconstant when it is not naturally high, we find that the temperature of fishes, commonly, is nearly the same with that of the water in which they reside. In some experiments we made upon _carps_ and _els_, we did not discover any material difference between their heat, and that of the water in which they were placed, until the latter was heated, or cooled, many degrees beyond its ordinary temperature.

Mr. Hunter's experiments on this subject were attended with a similar result, although they appear somewhat inconsistent with each other, as he has stated them.

Upon one occasion he put an _el_, its heat being 42°, which was nearly that of the atmosphere, into water heated to 65°, for fifteen minutes; and upon examination it was of the same degree of heat with the water. In another experiment, he says, he put a _turbid, _white heat was 63°, into water at 65°, and after remaining there ten minutes, the ball of the thermometer being introduced both into the fish and rectum, the quicksilver rose to 52°.

Having removed a _turbid_ out of a pond, the water of which he had ascertained to be 67° and a half, he introduced the thermometer into its rectum; the quicksilver rose to 69°; so that the difference between the water and the fish was 6° and a half.

These two last experiments do not quite accord with the two following. Having put an _el_, the heat of whose mouth was 30°, into a freezing mixture, its temperature fell to 0°. The animal, he says, at that time appeared dead; but was alive the next day. He took a living and dead _turbid_, and a living and dead _el_, and put them into warm water; they all received heat equally fast: and when they were exposed to cold, both the living and the dead admitted the cold likewise with equal quickness.

It is beyond all doubt that fishes readily suffer great alterations in their natural temperature, and that this is not attended with any fatal injury. It has been ascertained that they can be even entirely frozen, and afterwards restored to life; and it may be credited that the freezing of the fish in the Philippines, and fishes swim in the heat of 187° of Fahrenheit.

Mr. Hunter affirms that he never succeeded in freezing whole fishes, and afterwards recovering them; although his experiment of freezing the _el_, as above-mentioned, would lead us to make a different conclusion. He froze, he says, the tail of a _turbid_ (as high as the anus), which became as hard as a board; when it thawed, that part was white, and coarse, and when it moved, the whole tail moved as one piece, and the termination of the frozen part appeared like the joint on which it moved.

He also froze the tails of two gold fish until they became as solid as a piece of wood. They were put into cold water to thaw, and appeared for some days to be very well; but that part of the tails which had been frozen had not the natural colour, and the fins of the tails became ragged. About three weeks afterwards a fur came all over the frozen parts; their tails became lighter, so that the fishes were suspended in the water perpendicularly, and they had almost lost the power of motion; at last they died. The water in which they were kept was New River water, changed every day, and about ten gallons in quantity. See Hunter's Animal Economy.

From these experiments it would be inferred, that even parts of fishes will not admit of being frozen without disorganization.

**Ornament of Respiration.**

All truly aquatic animals possess certain parts of a laminated or tufted structure for minutely dividing the water, and extracting from it the air with which it is intermixed. The gills of fishes are peculiarly well contrived for this mode of respiration, both from their position and organization. The gills of fishes are fixed on each side of the neck; they have always a very free communication with the cavity of the mouth, of which they may be generally considered as constituting the posterior parries. They are covered externally in the _chondropterygi_ by the common integuments, and in the other fishes usually by a boy or cartilaginous operculum, which is, in most instances, increased by the addition of some radiated bones that are covered by a procbls of the skin.

In the _chondropterygi_ the gills are fixed by being connected externally to the integuments that enclose them, which are perforated by a number of foramina, varying according to the genus; but in the other orders of fishes the gills are unattached at the external side, and the branchial aperture is finge and capable of being much enlarged and diminished by the elevation and depression of the operculum, which is moved by certain muscles in the manner of the lid of a box.

The branchial arches are furnished upon some cartilaginous or pinnate arches, which are placed so that their cavity is turned obliquely forwards towards the mouth, and their convex sides are directed backwards and outwards. These arches are constructed to admit of their bashes being contracted and dilated, and of being approximated one with respect to another; for which purposes they are provided with numerous and complicated muscles. The motions of the branchial arches are also connected with those of other parts in their neighbourhood; the pharyngeal bones, hyoids, &c. although chiefly intended for deglutition, enter into the mechanism of the respiratory organs; and the branchial arches on the other hand are employed in deglutition; so that all the parts situated about the origin of the oesophagus have complicated functions, as will appear when they are more fully described along with the other organs of motion. It is insufficient at present to state, that by the motions of the different parts with which the branchial arches are connected, their vascular surfaces are expanded, contracted, and pressed against the water, which runs over them.

The real organs of respiration in fishes are the great number of laminae which are fixed upon the convex sides of the branchial arches. These laminae in the _brachii_ and _oecus_ fishes are arranged in two rows upon each branchial arch, of which there are generally four on each side. The laminae are very narrow, elongated, and pointed at their free extremity, and are usually united to each other by their internal edge for about two-thirds of their extent from the base; they are commonly fixed to each other, producing the appearance, in a very great degree, of the teeth of a comb, or the barbs of a feather. Each of the laminae contains a very delicate plate of a cartilaginous structure, by which they prefer their form and position against the force of the water. Their superficialis is to the long the edges, but we have lately discovered that the intermediate surface is covered with extremely fine thin villous processes, by which means the respiratory surface is infinitely extended.
The branch of the branchial arch, which proceeds along the convexity of the arches, furnishes to each pair of laminae two vessels; the larger of which is inserted into the internal edge of the lamina, and the other runs along the external edge and distributes branches, which supply the blood to the laminae for the aorta. The artery of the internal edges anastomoses at some distance from the extremity of the lamina, with a branch which passes transversely from one lamina to another, and thus establishes a communication between all the internal branchial arches of the branchial artery. The minute or ultimate ramifications of the branchial arches are supplied by the small or subordinate laminae, which arise from the sides of the other.

Cuvier describes the branch of the hiipraepax as being differently organized from those of other fishes. They are composed of eight rows of tufts united by pairs in such a manner as to correspond with the four ordinary gills. The external rows have only five tufts; those which succeed have six; there are seven in the third; and in the middle rows there are eight tufts. The consequence of this being a different number of tufts in the several rows is, that the entire gills appear of a round figure. Each of these tufts, of which the extremity is round, is formed of a cartilaginous lamina, which is fixed upon the branchial arch; and others, in the ray genus, some other little membranous vascular lamina, very distinct from each other, and arranged upon the cartilaginous lamina, in the direction of the branchial arch.
rows of lamina are placed with respect to each other in the case; a, is the branchial arch cut transversely; b, the section of the branches of arteries which transmit the blood to the gills, and return it afterwards to form the aorta; c, a lamina of each row crossing each other, which is the position they have in this fish, in which they are not united to each other. Fig. 8. of the same plate, presents a single lamina of the case, considerably magnified, in order to show the villous processes we have discovered to exist upon its surface. Fig. 9. is a lateral view of a portion of the gill of the flate (pogge botitis); a, the basis of the gill or branchial arch; b, the surface from which the lamina proceed, and to which they are connected by the greatest part of one of their edges; c, the fine edges of the laminae. Fig. 10. of this plate, shows one of the lamina of the first order of the flate, magnified; a, the border which is attached; b, the edge which floats, is seen furnished with villous processes; c, the intermediate surface, covered with fine subordinable lamiae.

Fish.

Kidneys and urinary Bladder.

These glands usually bear a greater proportion to the size of the body in fishes, than in any other class of animals. They not only extend the whole length of the abdominal cavity, but often pass as far forwards as the sides of the coelophagus, and back of the cranium, and sometimes go backwards along the spine, considerably beyond all the abdominal viscera. They are proportionably small in the ray and flarks genera.

The kidneys are always closely applied to the surface of the vertebral column, from which it is difficult to remove them; the surface, which is next to the spine, is consequently very irregular, particularly in offious fishes. The greatest part of the kidneys is covered on the upper surface, by the air-bladder, when this organ exists.

The form of these glands is somewhat various; sometimes, as in the carp, &c. there is a transverse lobule on the external side of each kidney, at the anterior part, which gives them an uniform figure. This lobule projects obliquely from the internal side in the dory (zeus faber). The kidneys are sometimes of nearly the same breadth at every part; in other instances they are considerably smaller anteriorly. They are generally but imperfectly divided into lobules, which gives an obscure notched appearance along their external edge; there are two posterior lobes which project backwards for a greater or lesser distance.

The proper coat of the kidneys is extremely thin. On the under surface they are covered by the peritoneum, which closely adheres to them.

The usual colour of the kidneys is a dark reddish brown. Their texture is soft and fragile, and yields equally in all directions to the pressure of the fingers. In the ray and flarks genera their substance is formed of a lighter red colour than in offious fishes. In every instance the kidneys have an uniform structure. They are very vascular, being supplied by numerous arteries from the adjacent trunks.

The unirhena ducts are numerous, and distributed throughout the whole substance of these glands. They are, at their commencement, fine and transparent; but as they become larger their coats appear opaque, and of a silvery hue. There are no cells or retevors in the interior of the kidney, into which the unirhena canals pour out their fluid, as in mammalia; these vessels coalesce to form the ureters, as in birds and reptiles.

These ducts run generally along the under surface of the kidneys, imbedded in their sublamine, and acquire magnitude as they proceed. In the fqualus maximus, according to Mr. Home, they run along the inner edge of the kidnies.

An urinary bladder, such as exists in other animals, is wanting in a great number of fishes; but in its place we generally find a dilated canal into which the ureters open. This canal is sometimes so wide as to approach the appearance of a sac or bladder; it is generally capable of containing a certain quantity of urine. Its coats are stronger than those of the proper urinary bladder, and it is often plicated or laminated upon the inner surface.

When the urinary bladder exists, it is a thin pellucid bag. It is found in many cartilaginous fishes, as the fregfish (lophius pescatorius); the lamp fsh (cygapturus lumps); moon fsh (stroodon molis). &c. &c. and the number of offious fishes in which it has been observed to exist is much greater. In the carp (cyprinus carpio) the bladder is of a spherical shape; in the father-loffer ( cottus foirinus) it is more elongated in its form, and of considerable size in proportion to that of the fish to which it belongs.

The urinary bladder discharges its contents usually by an opening distinct from the anus, and placed a little farther back than that aperture.

There is no proper urinary bladder in the ray and flarks genera. The ureters terminate in a cloaca as in birds. Mr. Home has, however, observed in the basking flark (fqualus maximus) that the ureters terminate in an oval cavity just within the verge of the anus, which has an imperfect septum separating it into two parts, the ureters opening on the opposite sides of this septum; this cavity must, therefore, be considered as the urinary bladder. This cavity opens externally in the male, by an infundibular process which corresponds to the penis. Dr. Sor Monroes has likewise called the part which conveys the urine into the cloaca in the common flate the urinary bladder.

It is impossible to assign the use of the bladder or any refervoir for the urine in fishes; these animals continually resinding in the water, one should have supposed that no inconvenience could have arisen from the expulsion of their urine as fast as it was secreted; perhaps part of their urine is absorbed, as in other animals, and carried back into the fyst, for which purpose it is necessary to detain it for some time before it is ejected.

No accurate examination has been made of the chemical properties of the urine of fishes, as far as we are acquainted. Although exceedingly transparent, it possesses more of the urinous flavour than the contents of the bladder in reptiles; it may, however, be questioned, how far the fluid found in the bladder of reptiles is really urine: this will be considered in its proper place.

Anatomists have agreed in denying renal glands or capsules to the whole class of fishes; there are in the dory (zeus faber) two ah-coloured glandular bodies, about the size of small peas, placed upon the posterior extremity of the kidnies; these glands are of a firm, tough, tender, not susided throughout one, and are attached to the kidnies, and also to the posterior end of the air-bag, by some ligamentous-looking cords. We have not yet examined other fishes; we are, therefore, not prepared to say how far these glands may be compared with the renal capsules of other animals, or whether they may be not connected with the offices of the air-bag in this particular fish.

Fig. 11. of Plate IV. in the Anatomy of Fishes, represents the dilated canal, which takes the place of the urinary bladder in the dory (zeus faber); a, a, are portions of the two ureters which end in the fundus of the sac; b, the wide part

62.
of the canal; c, the contracted part, which goes on to terminate behind the anus; the canal is laid open to shew that it is plicated on the inner surface.

Organ subservient to the generative Functions.

Male parts of generation.—If we except the borders, or organs of protection, in the genera 
raja and fuguus, there are no external parts of generation in the class of fishes. From the manner in which these animals in general accomplish the act of generation, a penis would be perfectly useless to them, and the organs for preparing the male semen would be exposed continually to injury, if placed on the outside of their bodies.

The parts reputed to be the organs of protection in the ray and fuguus kind, are situated at the sides of the anus, between the two ventral fins. They consist of three parts, articulated with the pelvis, resembling additional abdominal members. They are composed of thirteen cartilaginous joints, of different sizes and figures, which are moved by certain muscles covered by the common integuments, and connected with a singular gland.

The first part is formed by three short cartilaginous pieces, articulated one to the other. The second part is likewise composed of three cartilages, which are long, and not moveable upon each other. The two external pieces interrupt a canal which proceeds to open in a hollow formed in the third part. This canal is made up of seven cartilages, all moveable on each other; it receives likewise one of the pieces of the second part, which goes on as far as its extremity.

The second part admits of flexion outwards upon the second, and of extension, and the whole member is moveable from without inwards. These motions are performed by the means of two muscles. One of these arises from the pelvis and terminates at the commencement of the second part. It is covered with the flexor of the ventral fin. The other muscle is smaller, and placed upon the first; it arises from the first part, and is inserted at the commencement of the second.

There is a third muscle which takes its origin from the third part, and envelopes the second, except a small portion of its external side, and is inserted by a flender tendon upon the inferior and external side of the last piece, and is affixed at the superior side to an extended border that is presented before the piece, which has the figure of a blade. The use of this muscle is to open the canal already mentioned, which is closed by the elasticity of the parts composing it.

The gland is situated at the exterior of the middle part of this apparatus. It is an oval figure, and surrounded by a thick muscle; it furnishes a very viscid fluid, and its excretory duct opens into the groove that is formed by the two cartilaginous pieces of the second part, and is lost in the hollow of the third.

Naturalists are not agreed with respect to the use of these singular members. Cuvier thinks that they are only employed in swimming, as the large one of their muscles is also the depressor of the ventral fin, and as their parts are not provided with muscles, to be approximated with sufficient force to act as organs of protection. Bloch, and many others, supposing that they were designed to hold the female during coition, Geoffroy believes that they are introduced into the cloaca of the female, and perform the office in some degree of a penis. We are not inclined to adopt the last opinion. If this apparatus was intended for swimming alone, why should it be peculiar to the male? And if for protection, a gland to secrete a viscid fluid would not only unnecessary, but inconvenient. The ray and fuguus genera should therefore, perhaps, be considered as exceptions to the general observation, that fishes do not possess a penis.

The testes of the genera raja and fuguus differ very much from those of other fishes; they bear a greater resemblance to the same organs in some reptiles than to those of their own class. Each testicle consists of two parts united together. The one is an uniform glandular mass, somewhat like the texture of the testicles of other fishes; it is flattened and imperfectly divided into lobes. The other portion is made up of a great number of small spheric bodies, on the external surface of each of which there is a slight depression, like an impreffion made by the head of a pin; these bodies are united to each other by some strong filaments, and are included in a fine membrane. This tubercular substance forms the principal portion of the gland, and is divided into several lobes or masses of different sizes. When examined with a magnifying glass it appears to consist of very minute round grains.

The testicles of these fishes give origin to a real epididymis, which is evidently composed of a convoluted tube. It is thin, where it is connected with the gland, with which it appears to be continuous; it forms a large mass of an oblong shape.

From the lower part of the epididymis the vas deferens proceeds forth; it is a canal of considerable size, and as it proceeds along the spine, towards the anus, forms a great number of sigmoid figures or coils upon itself. These become less sinking, and the duct enlarges as it approaches a fissure near the cloaca, in which it terminates in such a manner, that although they form a common receptacle, there is not a free communication between them.

Monroe states that these fisc contain a green coloured fluid, and he considers them analogous to the prostatic gland; they appear to us to correspond much more with the vesiculae feminales, if they be looked upon as any thing more than a dilatation of the vas deferens. Monroe describes the dilated part of the vas deferens, before its communication with the fusc, as a vesicula feminina, in which he is evidently wrong. He was led into this error from considering the vesicae femininae of mammalia as mere reservoirs of the fisc.

The vas deferens and fusc of each side open into a cylindric papilla, which is visible in the cloaca.

The testicles of the other orders of fishes are two elongated bodies, sometimes cylindric or conic in their form, but most commonly injected or divided into ovoidal bodies; they are of a pearl grey or ash colour, soft, pulpy, and homogeneous in their texture, resembling very much medullary substance; their surfaces renders their intimate structure very obscure, but they appear to be composed of an intertexture of fine membrane and pulvaceous matter. They do not furnish any epididymis, nor, properly speaking, a vas deferens; but open at their posterior extremity almost immediately at the foramen, behind the anus, which is a common opening for transmitting the urine and fisc. The testes of fishes are popularly known under the name of the milt or soft row.

These glands increase remarkably in size during the feaon that the females expel their ovum: they are then full of a white thick fluid, like milk, which is no doubt the male semen. At this period they make so material an addition to the bulk of the body of fishes, that these animals are then only fought after as articles of food.

In Plate V. of the Anatomy of Fishes, fig. 1. exhibits a view of the generall organs in the male fish (raja batis); a is the white medullary portion of the testicle; b, the tubercular portion; these parts are cut away on the opposite

nate; the one on the right side is laid open to expose its
cavity and connection with the vas deferens; $f$ is the
circular papilla upon which the conduits of the femail termi-
nate.

Female organs.

In the genera *Raja* and *Spalaxis* these parts are more pecu-
liarily formed than even the male organs of these fishes.
They resemble in a very great degree the female organs of
birds.

The ovaries of these genera consist of clusters of round
eggs of various sizes and different shapes of growth. The
membrane which envelopes the ovaries nearly surrounds each
of the ova, which therefore, especially when mature, appear
distinct and have some liberty of motion. These ova conjoin
only of the yolks, and are of a pale yellow colour. In their
mode of growth, connection with the ovary, and man-
ner of exclusion from it, they very much re semble the
*vitreus vitellorum* of birds.

Although in these genera there are two "oviducts", they are
conjoined at their extremities to form a single aperture, which
is placed immediately behind the septum that divides the
branchial and abdominal cavities. This part of the "oviducts"
may be considered as analogous to the *infundibulum* in birds.
The ovarian tube of each side at first proceeds for some way
outwards and backwards, at which place its canal is
finally, and its processes thin and pleated longitudinally up
on the inner surface. It then suddenly enlarges, and incloses
in its coat a large glandular mass, something between a
square and kidney shape; this body is composed of a num-
ber of white tubes, which are so divided as that their ends
are turned towards the cavity or internal part of the gland;
at one side of this mass there is the appearance of a spiral
of tubes or fibres, which crosses the other structure, and is prob-
able a muscle for contracting the cavity. The internal
membrane of this part is smooth, and so thin and transparent
that the tubes are very visible through it.

The interposition of so large a gland in the course of the
ovarian duct is unquestionably for the secretion of that
remarkable "bony covering or shell" which is found on the ova
the fish, and yet it should be observed, that we have
not been able to discover the orifices of the tubes upon the
internal membrane of the oviduct, nor have we succeeded in
expressing the smallest quantity of fluid from the tubes into
the cavity of the gland.

The portion of the oviduct which succeeds the gland is
greatly dilated, its processes are thin, and the internal sur-
face (on the face at least) is covered with fine transverse
folds, or rather linear impressions, not resembling the place of
an interline, which are thin productions of the internal
coat.

The oviduct terminate by a corrugated or puckered
opening on each side of a conical-cylindrical cavity, within
the anus, which some authors have described as a *uterus*,
and others as the *coalica*. The latter name appears to be the
most correct; as this cavity receives the urin, and comnic-
cates with the rectum. The orifices by which the ovi-
ducts terminate in the cloaca are surrounded by mucous
glands.

In the genus *Kleina* there are first some small ducts, of
which the extremity attached to the ovaries is open and
composed of which the extremity attached to the ovaries is open and
spiral out. After a short space they suddenly enlarge, and
form a considerable glandular mass, of which the branches
of tubes that compose it are perpendicular to its parietes
From these glands to their termination the oviducts are
membranous, and of great capacity; where they terminate
they are conjoined and open externally by one common
 aperture.

In the *offensive and in the cartilaginous fishes*, except those
already described, the ovaries consist of two membranous
faces or bags, the cavity of which is occupied by numerous
leaves, formed by reflexions of the membrane; the folds
are usually placed transversely; they contain the ova
within their duplicature; they are copiously supplied with
blood-vessels, and exhibit (especially after injection, with
a coloured fluid) a very beautiful and variegated foliated
appearance.

The ovaries of different offensive fishes are of various forms;
they are usually elongated and pointed at either end. In the
*dog* (Zeus Faber) they are flat, and approach a square
figure; in many fishes they have four corners, which are elon-
gated forwards and backwards. In some of the *pluranectidae*
and in some other fishes, a part of the ovaries is extended
backwards in that process of the abdominal cavity which is
continued along the external parts of the spines of the
caudal vertebra.

We have observed but one ovary, of a pear shape, in the
*perch* (*Perca fluviatilis*); perhaps some other fishes may be
found to have single ovaries.

The ovaries of offensive fishes increase prodigiously during
the season for depositing their ova. At this period they
increase in size all the rest of the viscera; although after the
season of spawning they are the smallest viscera in the body;
the variations in their bulk depend upon the number of ova
they contain, for their parietes are at all times nearly of the
same thickness.

Fishes in general surpass all other animals in fecundity.
M. Rouftee, a laborious French anatomist, has taken the
pain to reckon the number of ova contained in the ovaries
of several species. He found in the *furzeon* (Acipenser fluviatilis)
146,785 eggs; in the *mackerel* (Scomber ondourus) 129,000;
in the *perch* (*Perca fluviatilis*) 69,216; in the *carp* (*Cynicus
carpio*) 107,450; and in the *pike* (*Esox lucius*) 30,450.

The ovary of those fishes which are not viviparous are all
small, and of the same size; they are generally about the
bulk of pin heads. They are not expelled from the ovary in
secession, as in the *Chelon, Trachurus*, but in large quantities,
like the spawn of frogs; which they further resemble in being
impricated, and undergoing their changes outside the body
of the parent.

Except in the viviparous fishes also there are no oviducts;
the ovaries terminate immediately at a particular aperture
placed behind the anus.

From the preceding description it will be perceived, that the
mode of generation in the genera *Raja*, *Spalaxis*, and *Kleina*
is essentially different from that of fishes in general. In those
genera the eggs do not leave the ovary until they acquire
a considerable magnitude; their structure is completed in their
passage through the oviducts, in which also they are most
probably impregnated. During the residence of the egg in the
oviduct its contents are changed in their organization,
and the fetus is formed in the same manner as during the
incubation of the egg of birds; and when the ovum is
discharged from the body of the fish, the fetus, its parts, and
admits the water in which the fetus floats, filled nourished by
the yolk which remains attached to its interior.

At this period we have discovered that their exit is
provided with external branchial appendages exactly similar
to those met with in the tadpoles of some reptiles. It is

When
Fish.

When these fall off, and the yolk is consumed, that the young fish seeks its own sustenance.

The shells of the eggs of the *rana* and *fishus* genera, after being evacuated by their inhabitants, are commonly from their lighter end on shore, and are found in some places under the name of *sea bits*. For a further account of the history of the ovum, and the changes it undergoes in fishes, see the articles OYUM and INCUBATION.

The second figure of Plate V. of the Anatomy of Fishes, gives a view of the female organs of the *pate* (*rana latos*); a, the first portion of the ovarian tubes; b, their junction and aperture, by which they communicate with the cavity of the abdomen; c, e, the glandular bodies; the one on the right side is laid open to show its composition to be of tubes; d, d, the succeeding portions of the oviduct, which are very capacious, and perform in some respects the offices of uterus; e, a mature egg seen in the enlarged part of the oviduct; f, f, the ovaries containing eggs of various sizes; g, g, the termination of the oviducts in the cloaca; b, the cloaca; the opening by which it receives the urine; k, the anus.

Organs employed in the Excretion of the animal Functions.

Brain.

The dura mater in fishes resembles very nearly the common pia mater; the distinction of two layers is not evident; and those broad reflections of the internal layer which exist in mammals for separating the different divisions of the cerebral mals are wanting. The dura mater approaches, in the large fishes, nearly to a cartilaginous nature.

As the cavity of the cranum is much larger than the brain, there is a considerable space left between them, which contains a quantity of gelatinous matter in the cartilaginous fishes, and commonly an oily fluid in the efferent fishes. There is also a considerable quantity of salt water found in the cavity of the cranum, which has been supposed by doctor Monroe to be sea water carried thither by absorption, as we have mentioned in speaking of the salt liquor met with in the cavities of the abdomen and pericardium of fishes.

The fluid of the cavity of the cranum is very frequently flavened by admixture with blood, which appears to be extravasated in it in small quantity.

These fluids are contained in a very loose cellular texture, which corresponds to the tunica arachnoidea of other animals. Monroe found the surface of the brain covered with a number of small pheroidal bodies; these are probably contained in the tunica arachnoidea.

The pia mater closely invests the surface of the brain as usual; it likewise lines the ventricles, and produces a plexus analogous to the choroid plexus; which however does not float in the cavity of the ventricles. Cuvier describes also two other productions of the pia mater, situated in the fourth ventricle, which appear to be at liberty.

The brain of fishes parallels the characters described in that of birds and reptiles in a still more remarkable degree than this organ in either of those classes. It is very small in proportion to the size of the whole body, and bears even a greater disproportion to the bulk of the nerves which arise from it. Cuvier states the proportion of the brain to the rest of the body to be as 1 to 2456 in the white fish (*fishus carbo*), 1 to 1344 in the great dog-fish (*fishus caninus*), 1 to 1356 in the *pike* (*fox lucius*), 1 to 350 in the carp (*eigrinus* *carpi*), 1 to 1817 in the *silurus glanis*. The greater size of the brain in the carp accords with the well known docility and intelligence of that species; and the small proportion which the brain of fishes generally bears to the size of the body, is what might naturally be expected from the dulness and incapacity of this class of animals in general. On looking at the brain of a fish one is struck with its dissimilarity to the cerebral mals of man or quadrupeds; it appears like a succession of tubercules scarcely conjoined together: the eminences which nearly correspond to the cerebrum and cerebellum are not distinguished from the others, which give origin to the nerves, and in some cases might be overlooked from their being smaller.

The cerebrum is always composed of two hemispheres, as in other animals; it is smooth and without convolutions: those parts called corpus callosum, fornix, &c. cannot be distinguished at the junction of the hemispheres.

There is a cavity in each hemisphere which corresponds to the lateral ventricle; it is not, however, prolonged and reflected so as to form those parts termed *bursa* in mammals.

The floor of the ventricles is plain in the ray and *fisk* genera, but in most other fishes there is an elevation, usually of a semicircular figure, from the external or convex side of which a number of medullary *flutes* go off in a radiated manner upon the internal parietes of the ventricles: this eminence corresponds to the corpus striatum; it varies with respect to size in different species, and also sometimes in its figure: according to Cuvier it forms in the *calotis* (*calotis merlangus*), an elevated oval body.

Between the corpora striata there is a small chink, which opens into the third ventricle.

The anterior commissure of the brain is situated a little below these eminences.

There are some tubercles within the hemispheres, which Cuvier considers analogous to the tubercula quadrigenes, although their situation is not the same. They are placed, as in birds, before and above the thalami nervorum opticos.

In the genus *eigrinus* there are four of these tubercles, two anterior and two posterior; the former are extremely long, cylindric in their shape, and bent outwards and backwards, taking the curvature of the lateral ventricles, the cavity of which they fill: they are marked posteriorly by a longitudinal furrow; the posterior tubercles are round, and much smaller than the anterior.

The col (*murena anguilla*), badcock (*gadus eglephus*), and herring (*clupea barbata*), have but one pair of these tubercles, which produce a remotic eminence before the cerebellum, between the posterior extremities of the corpora striata. The *pike* (*fox lucius*), trout (*salmo fario*), salmon (*salmo salar*), and perch (*perca fluviatilis*), have four tubercles which are distinct, round, and small; the posterior pair is larger than the anterior. These tubercles are not found in the ray and *fisk* genera.

The *thalami nervorum opticos* are two distinct tubercles situated below the hemispheres, as in birds; each of them likewise contains a ventricle.

The cerebellum is generally large in proportion to the cerebrum, and in some instances even exceeds it in size: it is sometimes rugous on the surface; it is always a single tubercle without lobes, and usually of a heart shape, the apex of which is turned backwards; sometimes the superior part is the most prominent. When the cerebellum is cut into, the section it exposes some indistinct pale coloured lines; but that arboriform arrangement of medullary substance, called *arbor vitae*, does not exist.

The fourth ventricle is generally large; with respect to the other cavities of the brain, it not only passes under the cerebellum
cerebellum as usual, but ascend for some way in its sub-

flance.

We have next to consider those additional tubercles of the brain of fishes upon which its character depends, and which constitute in general the greatest part of its bulk; they are placed before the cerebrum and behind the cere-

The anterior tubercles give origin to the nerves, which go to the organ of smelling; they are therefore commonly named the olfactory tubercles. They are usually a single pair. In the ray and shark genera they are united and form one mass, which extends in fize all the rest of the brain: the figure of this mass is a little variable, and is difficult to describe. In the thornback (roja elevata), it is somewhat of a triangular figure, one of the files or the base being turned forwards; in the lesser dog fish (scylius catulus) the fore part is circular, and the back a little concave in the centre. The olfactory tubercle in these fishes has been described by some authors as the cerebrum, and by others as its anterior lobes.

The olfactory tubercles are long and narrow in the Sturgeons (acipenser fluviatile); they are oval masses, smaller than the hemispheres in the lamp-fish (Cyclopterus lumpus), and in the moon-

fish (teledon melas). In the genus Gadus they are round, and in the cod (Gadus morhua) they are nearly as large as the hemispheres: according to Cuvier they are round and elongated on one side in the swaffiis (labrus), and in the carp (cyprinus); but Ebel and Scarpa have delineated them in the common carp (cyprinus carpio), of an egg-shape; they are oval in the Silurus glanis.

There are four olfactory tubercles arranged in pairs in the flat fishes (pleuronectes), the herrings (elupea), the pikes (esox), the perchs (perca), and in the genus Silurus; the anterior pair is in the common pike (esox lucius) so small, that they might readily escape observation; the posterior pair, although larger, are not equal in fize to the hemispheres.

In the eel (genus anguilla), there are three pair of olfa-
tory tubercles; the first pair are then mall; the second somewhat larger; and the third, or posterior, considerably the largest, being about the magnitude of the hemispheres.

The olfactory tubercles do not in any species contain a ca-
vity or ventricle.

The tubercles situated behind the cerebrum are peculiar to the clafs of fishes; they are in general a single pair, but in some species there is a third single tubercle placed in the middle immediately before the other two, and behind the cerebrum.

Some anatomists suppose that the lateral tubercles are analogous to the corpora olivaria of mammals, and the mid-dle tubecl has been described as a second cerebellum: the latter is evidently erroneous; but the former appears to be perfectly well founded: the corpora olivaria and these tubercles correspond both with respect to situation and in giving origin to the posterior nerves of the brain: it would be more correct, however, to lay that the corpora olivaria and these tubercles are the tubercles on an abridged scale.

The posterior lateral tubercles are large and irregularly furrowed in the ray genus. In the whiting (gadus merlangus), and the cod (gadus morhua), the tubercles are oval, and placed above the medulla oblongata. They are similar in the common and coarser eel (muraena anguilla and m. conger); they are inconsiderable in the pike (esox lucius), the salmon (salmo salar), the trout (salmo fario), and the perch (perca fluviatilis).

In the carp (cyprinus carpio) the posterior lateral tubercles are extremely large; they equal in fize the hemisphere of the cerebrum; they have somewhat the figure of kidney.

The fifth likewise poises the middle tubercle, which is large, and of a round figure.

There are no cavities in the posterior tubercles of fishes.

There is nothing very peculiar to remark with respect to the origin of the nerves in fishes.

The olfactory nerves are produced from the tubercles placed before the cerebrum, as already mentioned; they generally appear as the continuation of these tubercles; this is particularly evident in the ray and shark.

In the carp and Silurus glanis, &c. the olfactory nerves arise by two or three filaments from the tubercles. The optic nerves take their rise, as usual, from the thalamus nervorum opticorum; immediately after their origin they decussate, or cross each other. In oblong fishes this is most obvious; in which the optic nerves may be seen lying one arcoss the other, and only connected by cellular substancs.

The right nerve goes to the left eye, and the left nerve to the right eye. Many anatomists have supposed, in consequence of the decussation of the nerves being so palpable in fishes, that something of the same kind takes place in other animals, by which they have explained the sympathy that is well known to exist between one eye and the other, in the superior animals; there is, however, sufficient connection between the two sides of the brain, to account for the sympathies of the organs of vision, without ascribing it to the decussation of the optic nerves.

Ebel and Scarpa have stated, that in some fishes the optic nerves have an investment of pia mater, containing very elegant longitudinal folds.

The third and fourth, and fifth pair of nerves arise as near as may be from the same parts of the brain which furnish them in mammals.

The fifth pair are produced by a common trunk with the poria dorai of the fesenthe pair, is quite distinct from the auditory; and arises in common with the par vagum, or the eighth pair, of which it might, with equal propriety, be considered a branch.

The nerves analogous to the eighth pair arise from the side of the medulla oblongata, and the back part of the posterior lateral tubercles of the cerebrum, when these exist. There is no nerve analogous to the ninth pair, or hypothalamic nerves in fishes; although Ebel has figured a large nucleus in the carp, (cyprinus carpio), which he describes as the ninth pair. Much confusion exists amongst authors on this subject; thus Ebel confounds the eighth with the ninth pair; Monroe calls the olfactory tubercles the anterior prominences of the brain; and describes the sixth for the fifth pair of nerves; Scarpa delineates the hemisphere of the cerebrum under the name of the « foided prominences » of the brain. See Monroe's Physiologif of Fishes. Anatomie D'inhaltions de Aninu & Olufat, by Scarpa, and Observations Neurologiques on Aquat. comparantes, by Jo. Godof. Ebel.

The brain of fishes has been hitherto but little studied in its physiological point of view. Its structure is in this clafs of animals, however, promises to illustrate the functions of the different parts of the organ, as they are so distinct, that their proportional magnitude and importance may be fairly ap-

Vol. XIV.
their organ of sense, under the immediate impulse of which their actions are directed; and that they have little capacity for combining or associating their sensations; a conclusion which exactly accords with what has been observed respecting the habits and manners of this class of animals. We believe, if the same rule for judging of the mental faculties be extended to other animals, that it will answer equally well; and that the fallacious powers will be found proportioned to the relative magnitude, and the distinctness of the parts of the brain which give origin to the senses; and that the intellectual faculties will keep pace with the development of those parts which serve to unite the preceding. It is possible that this rule may be employed, to calculate the comparative excellence of the fallacious, and intellectual faculties of individuals in the same species. Perhaps even by these means some steps may be made towards ascertaining the shades and varieties in the mental character of men.

The hypothetic connection of the different parts of the system, doubtless depends upon the union of the nerves in the common lefthorium, which being imperfect in fishes, it became necessary that their optic nerves should be contributed to the sides opposite to their origin, on account of the organs of vision acting confeniently, or in harmony, with each other.

In Plate VI. of the Anatomy of Fishes, fig. 1, exhibits the upper surface of the brain of a fish (Cyprinus carpio); a, the olfactory tubercles; b, b, the two hemispheres of the brain; c, the cerebellum; d, d, the two lateral tubercles placed behind the cerebellum, analogous to the corpora olivaria; e, the simplex tubercle behind the cerebellum; f, the medulla oblongata.

Fig. 2. shows the brain of the carp, in which the hemispheres of the brain are cut, and turned to each side, in order to bring into view the anterior tubercles which fill the lateral ventricles, and which are fupposed analogous to the niter; g, indicates the tubercles in question, the other letters indicate the same parts as in the preceding figure.

Fig. 3. is the same brain, with the nates separated at their posterior part, in order to expose the posterior tubercles, or those corresponding to the tubercle of the niter; b, b, are these parts; the references of the other figures are the same as in the first figure.

Fig. 4. is another view of the same brain; the nates and tubercles, or tubera quadriruga, are raised to show the corpora striata, and the opening into the other ventricle, &c. h, h, exhibit the striated backs; i, the figure which leads into the inferior ventricle; k, k, the thalamus nervorum opticonis, which are fearcely visible. The other letter, have the same figurative as in the preceding figures.

Fig. 5. is still the same brain, with the hemispheres removed, in order to expose completely the thalami n versus opticonis, which are designated by the letters f, k.

Fig. 6. shows the brain of the carp, with the cerebellum divided and turned towards each side, to expose the fourth ventricle; the references are continued the same.

Fig. 7. is the brain of the carp, viewed upon its under surface. The parts seen in that position, which have been already represented in the other figures, are indicated by the same letters. The nerves are numbered according to the names they usually bear, as the 1st pair, or olfactory; the 2d, or optic, and so on; the decussation of the optic nerves is pointed out by the letter m.

Fig. 8. is a representation of the upper surface of the brain in the cell (murina angusta). The letters a, a, a, a, a, a, designate the six olfactory tubercles; b, b, the two hemispheres of the brain, which are not larger than the posterior olfactory tubercles; c, the cerebellum; d, the medulla oblongata.

Fig. 9. exhibits the inferior surface of the brain of the cell (murina angusta), the other letters correspond with those of fig. 8. In both these figures the nerves are indicated by their numbers.

In Plate VII. of the Anatomy of Fishes, fig. 1, is a view of the head of the thrush-back (fregusus domesticus), dissected to expose the brain and organs of sense: a is the large medullary mass formed by the olfactory tubercles; b, b, the two hemispheres of the cerebrum, called by Linn. olivar-desubercum of the brain; c, the cerebellum depressed along the middle, but not divided into two lobes; d, a portion of the brain, which must be considered either as a division of the cerebrum, or the middle posterior tubercle; e, e, the lateral posterior tubercles; f, medulla spinalis. Where the nerves are seen in this figure, they are expressed by their number.

In the dissected head of the fish (fregusus lucius), shown by fig. 1. in Plate VIII. of the Anatomy of Fishes, a, a, indicate the two principal olfactory tubercles; b, b, two inconsiderable enlargements of the root of the olfactory nerves, which might be considered as larger tubercles; c, c, the two hemispheres of the cerebrum; d, the cerebellum. In this figure, likewise, such nerves as are seen to arise from the brain are expressed by their numbers.

In fig. 4. of Plate VIII. of the Anatomy of Fishes, the olfactory tubercles of the carp (Cyprinus carpio) are shown: a, the cerebrum; b, b, the olfactory tubercles; c, c, the origin of the olfactory nerves by filaments; d, d, the trunks of the olfactory nerves. The other nerves that appear are indicated by corresponding numbers.

Nerves.

The course and distribution of the first or olfactory pair of nerves are pointed out in the description of the organ of smelling.

The termination of the optic nerve is described in that part of the article which treats of the eye of fishes. The component filament of the optic nerve are particularly evident in this class of animals, and may be demonstrated without any preparation. They are commonly flat; and Cuvier describes them as being sometimes formed of a very thin medullary lamina, folded on itself, and attached into the figure of a cord. This is particularly observable in the cell (madia morio), and the fregusus shopus (sphecus).

The third, fourth, and fifth pairs of nerves in fishes differ so little, with respect to their distribution, from the same nerves in other animals, that they do not require to be described.

The fifth pair of nerves, as before-mentioned, arise by a common trunk with the auditory nerve. In the fregusus (ranga batis) they form two trunks in the cranium, and appear to coalesce in passing out. On the outside of the cranial there are again two nerves produced: the one is the ophthalmanie; the other passes under the cartilage behind the orbit, and immediately divides into three branches: one of these is a nerve which has not been hitherto accurately described; the other branches correspond to the superior and inferior maxillary nerves.

The ophthalmanie branch of the fifth pair passes out of the cranium into the superior part of the orbit, and then divides into two branches; of which one proceeds across the orbit, under the rectus superior and externus, and the external oblique muscles of the eye; the other crooks above all the parts in the orbit. These two branches, on arriving at the nasal cavities, unite to form a single nerve. Previous to this reunion, the superior branch of the ophthalmanie gives off a branch to the organ of smelling. This forms an anatomic.
tomus with another branch, which is sent off from the conjoined nerves of the ophthalmic.

After passing beyond the nasal cavity, the ophthalmic breaks into a long saccus, from the sides of which a great number of short branches arise, which are lost in the gelatinous substance that is on each side of the middle cartilage of the front, and upon the edge of that cartilage.

The remarkable anastomosis of the ophthalmic nerve, and its distribution in the front, is represented in Plate VII. of the Anatomy of Fishes, and fig. 1, shows the origin of the ophthalmic from the fifth pair; r, the superior branch passing over the muscles of the eye; t, the inferior branch going between the muscles of the eye; u, the coalition of these two; v, the first branch sent to the organ of smelling; w, the second branch given off from the united nerve; x, the anastomosis of these branches; y, the distribution of the ophthalmic nerve in the front. This plate exhibits the parts as they appear in the thrushback (roja elevata), in which they do not differ materially from the description we have given of them in the flat (roja batia).

The branch of the fifth pair of nerves, which we mentioned as not being accurately described by other anatomists, proceeds in a straight line from its origin, under all the parts of the orbit, to reach the transverse cartilage, situated on the external side of the organ of smelling. As it penetrates this cartilage, one part of the nerve forms a sort of bulb or ganglion, from which a number of fine filaments depart like rays; these are abruptly, and almost immediately, lost in the membranous structure which forms the centres of the albuminous-gelatinous ducts, to be hereafter described. The other portion of the nerve is distributed in long branches to the same gelatinous substance of the front. This branch of the fifth pair is the most remarkable in the fifth pair's body, on account of its giving the only example of a gangliform enlargement of a nerve, (those of the organs of sense excepted) and from the peculiar mode of its termination. It is difficult to determine whether the singular conformation of this nerve be designed to betell a more delicate sense of touch on the fin, or to produce, with the albuminous-gelatinous ducts, an electric apparatus similar to what exists in the tortoise, &c. The latter, from analogy of structure, is very probable; although the electric property, if it exist in the ray kind generally, has not yet been detected by its effects.

The inferior maxillary nerve of the flat (roja batia) goes forwards under the orbit, and sends off several small branches, which penetrate and are lost in the operculum of the nasal cavity, and the integuments before the upper jaw; it then runs round the external part of the upper jaw, concealed by the large muscles which surround the ends of the jaws, and divides into several branches, which are distributed to these muscles. One of these branches goes on to be expended upon the integuments of the lower jaw.

The facial nerve, or that which corresponds to the portio oculi of the seventh pair, is much larger in the cartilaginous than the bony fishes. It forms two branches soon after its origin: one of these ascends in the cranial cavity, through which it passes, and is lost upon the integuments.

The other branch goes through a particular foramen, into the cavity of the ear, passes beneath the principal cartilaginous body, and there forms the remarkable anastomosis with the auditory nerve, from which the ampulla of the posterior semicircular canal is supplied. The trunk afterwards penetrate the cranium, and re-appears upon the external part, where it is lost in a number of branches in the bony parts and integuments of the head.

The auditory nerve of the fifth pair in fishes is analogous to the portio maxillaris of the fourth pair in other animals; and, like it, is distributed exclusively to the interior of the organ of hearing. It is described and figured in that part of the article where the ear is treated of.

The eighth pair of nerves in fishes differ materially from the same nerves in other animals, with respect to their course and ramifications. This depends upon the situation and structure of the parts they supply, in order to preserve an analogy with the nerves of this name in the other classes of animals. The first and most important branches are sent to the branches: these may be considered as supplying the place of the par vagum of mammalia. They are situated most anteriorly, and are usually four on each side; they separate from each other immediately upon leaving the cranium, and proceed to the branch x. When they approach these, each branch divides into two; one of which runs to the groove situated on the convex edge of the cartilages or bones that bear the branch, and feeds off numerous filaments to the lamina of the gill; the other branch passes in the corresponding groove of the cartilage of the branchial cartilages or bones, and is distributed in a similar manner. The anterior branch of the first branchial nerve, however, returns into the cranium, in order to be distributed to the ear.

The second branches of the eighth pair most commonly come out of the cranium as two or three distinct nerves, but sometimes they are furnished from the same trunk, as the last branchial. One of these nerves is lost upon the branchial muscles. The second, which is larger, is distributed to the side of the oesophagus, as far as the stomach. The third branch is conjuncted with the cervical nerves that go to supply the pectoral fin.

The last branch of the eighth pair has a very remarkable distribution; it is situated posteriorly to the others, at its origin; it proceeds almost directly outwards, and backwards towards the integuments of the side of the body, immediately after which it runs as far as the tail, when it terminates in fine filaments, upon the rays of the caudal fin. This singular nerve is nearly of the same size throughout its whole length; it has no palpable communication with the intervertebral or other nerves; and its course corresponds to the lateral line on the side of the body. It bears a greater analogy, perhaps, to the nerves accessorius than to any other, although its termination is much more remote.

According to Cuvier, the eighth pair of nerves in the eel (Anguilla) consists of a single trunk, which does not divide until it reaches the parts to which it is distributed. In these fishes the long lateral nerves are situated nearer to each other, and more towards the back.

The gill-pharyngeal nerves, as before mentioned, do not exist in fishes.

The cervical vertebrae cannot always be distinguished from...
from the dorsoal. Cuvier affirms that there are never more than four spinal nerves, which deserve to be called centralis; and frequently there are none to which this name can be applied. The first nerves of the spine, however, furnish those of the pseudaral member in fish of the same species, as will be hereafter described, and likewise a nerve which is distributed to the epiphysis, which divides the bony part of the spine; and which, therefore, may be considered analogous to the phrenic nerve of other animals.

The dorsoal, lumbar, sacral, and caudal, nerves of fishes resemble each other in their course and distribution, with the exception of those which supply the pseudaral and the dorsal rami of the rays; generally all the spinal nerves pass out of the vertebral canal, and are immediately distributed to the muscles and integuments adjoining. The nerves of the spine analogous with the great sympathetic, but do not produce a series of ganglia, as in other animals.

The intercostal, or great sympathetic nerve, comes out of the cranium, by the canal of the first vertebra; it is but a small filament extended along each side of the spine, without any tendinous enlargements or ganglia. It distributes branches round the principal arteries of the viscera, which supply the place of the different pleuric nerves of mammals.

The brachial nerves, or those which supply the pseudaral fins of fishes, are furnished by the two first vertebral nerves. The anterior of these is situated so near the eighth pair in some fishes, that it might be mistaken for a branch of the latter; it passes out, however, through a foramen peculiar to itself. The second vertebral nerve lies more behind the cephalus, and more towards the middle line of the body. These two nerves proceed directly to the internal lamina of the cephalus, where they are conjoined without being intermixed. The first vertebral then forms two branches, which send off filaments that anastomose with each other, and are distributed to the adductor muscles of the fin. One of the branches of the first vertebral nerve is sent to the hepatic ganglion of the brachial and abdominal cavities. This filament is considered by Cuvier as analogous to the phrenic nerve.

The two cords, formed by the vertebral nerves, pass through the hole situated before, and on the outer side of the articulation of the fin with the shoulder, where they unite and produce an irri radication of nervous filaments, several of which are lost in the external surface of the body. These two nerves proceed directly to the internal lamina of the cephalus, where they are conjoined without being intermixed. The first vertebral then forms two branches, which send off filaments that anastomose with each other, and are distributed to the adductor muscles of the fin. One of these filaments runs under the skin that covers the rays of the fin.

The brachial nerves are remarkably large, and are formed of a great number of nerves, from the spinal marrow in the flat cartilaginous fishes (genus raja). There is first a thick cord produced by the union of twenty vertebral nerves. This cord passes through the middle of the cartilaginous bar upon which the rays of the wing or great pseudaral fin of these fishes are articulated; it then proceeds forwards along this cartilaginous bar, and sends off a number of branches which run outwards along the rays of the anterior part of the fin, supplying the muscles placed between these rays, and the integuments, as far as the external edge of the fin.

A second cord is thus formed by the four or five next vertebral nerves, which divides at the roots of the rays of the middle part of the fin into four or eight filaments; these are distributed in the same manner as the branches of the first cord.

Afterwards each two vertebral nerves, as far as the forty-fourth, are united into cords, which penetrate the cartilaginous bar, and supply the posterior portion of the fin.

These different cords, which result from the junction of the vertebral nerves, may be considered as representing the brachialplexus of other animals.

The pelvic nerves, or those which supply the pseudaral fin of the flat cartilaginous fishes, are disposed in the same manner as those of the pseudoaral fin. Four or five vertebral nerves unite to form a single cord, which penetrate the cartilage that forms the rays of the fin, and is expanded in filaments, in the muscles of the fin. There are usually four more vertebral nerves sent to the posterior part of the pseudaral fin, upon which they are distributed in the same manner as the preceding cord.

The nerves of the pseudaral fin in fishes are filaments of the vertebral nerves, which are distributed to the intercostal spines. These filaments supply the muscles of the rays, and may be traced upon the skin to the edge of the fin.

The nerves of fish are distinguished from those of other animals by the want of ganglia, and their great magnitude in proportion to the bulk of the brain, and of the whole body. Monroe has described the coats of the nerves of fishes also as being covered by a number of spheroidal bodies.

Organs of Touch.

Fish are provided with any members capable of encompasing external bodies, and consequently possess the sense of touch in but an imperfect degree. The only parts in which any peculiar feeling appears to reside, are the cirri, the tentacula, and the extremity of the fist.

The cirri are situated upon the lips or about the mouth; they are commonly pointed taper processes, which in some instances appear to be composed chiefly by the common integuments; in the cod (gadus morhua), however, there is a very firm cartilage, and perhaps the same in other species.

These parts are not better supplied with blood vessels or nerves than the adjacent parts, and their surface is smooth and without papilla; from which circumstance it is probable, that they do not enjoy any peculiar feeling or sense of touch except what they derive from their form and prominent situation. Cuvier mentions only one process of this kind in the genus gula, in which he differs from other naturalists, who allow to some species three, four, and five cirri. There are two long cirri in the Calamus (Mullus). In the gudgeon (Cypinus gula) there are two, in the carp (Cypinus carpio) there are four short cirri, and in the barbel (Cypinus barbus) there are four, two from the sides of the mouth, and two from the summit of the head.

There are several cirri in the pogge or armed bull-head, (Cottus cataphractus) which appear like a beard, there are six or eight in the genera catus and silurus; in the latter two are placed before the eyes, like the antennae of insects, and four project from the under lip, which the animal is said to catch every year.

The cirri are numerous around the mouth in the frog-fish, (Iphitus pteractinus), and the gadaus taru.

The tentacula appear better calculated than the cirri, from their figure, for receiving the impressions of external bodies. In the gallargus and crested bream there are two tentacula on the top of the head, which form tufts, or are fimbriated at the end.

The tentacula are most remarkable in the genus Iphitus; the
the anterior tentacularum of the _lophius hispidus_ is divided at the extremity into two branches, the ends of which terminate in feathery filaments; the other tentacular are very long and conical, and end in filaments.

The _lophius piceatorius_ has some long tentacles on the head, which it has the power of moving in different directions. It is supposed by some naturalists, that it employs these tentacles in angling for its prey, and hence it derives the specific name _piceatorius_.

The principal part of the fene of touch appears to be the end of the snout; the sensibility of this part, however, does not depend upon any peculiar organization of its surface, but arises entirely from being largely supplied with nerves.

The ophthalmic branch of the fifth pair of nerves in the _thornback and skate_, after distributing branches to other parts in its course, as already described, runs along the edge of the cartilage which forms the middle of the snout, and sends off a great number of short filaments which are lost upon this cartilage, and the gelatinous substance on the edge of it, as far as the very point of the snout, where these nerves terminate in some fine filibrils; the last branch of the _superior maxillary nerve_ of the fifth pair exhibits, in fishes, a similar distribution along the edges of the cartilage inferiorly.

According to Cuvier, the ophthalmic and superior maxillary nerves terminate in small branches, which are sent to the hooks of the snout in the _jouq-fish_ (_anguila pristis_), and in the spines or tubercles of the snout in the ray genus.

In the _liver dog-fish_ (_anguila catulus_) the ophthalmic nerve goes on to the end of the snout, where it terminates in several short branches.

In _offious fishes_ the snout is also supplied in a similar manner by a large nerve.

The above account shews, that the snout of fishes strongly resembles the bill of birds, as far as regards its sensibility and its functions as an organ of touch; through its means the animal will be adverted of the approach of any foreign body, but it is by no means calculated to take cognizance of the qualities of substances applied to it.

In Plate VII. of the Anatomy of Fishes, fig. 1. exhibits the distribution of the ophthalmic nerve in the _thornback (aja elevata)_; _x_ indicates the origin of the nerve, _y_ its ramification in the snout; _z_ indicates the point of termination of the nerve.

Fig. 5. of Plate VIII. shows the ophthalmic nerve as it appears in the _pike_ (ipse lucius); _f_ is the nerve passing to the snout; _g_ is an artery derived from the internal carotid, which accompanies it.

In Plate IX. of the Anatomy of Fishes, fig. 2. exhibits the external part of the snout of the _frog-fish_ (_lophius piceatorius_); _e_ is the nerve passing to the snout; _s_ and _c_ numerous branched cirri around the lower jaw; _d_ is a long tentacular from the front of the snout, with which this fish is supplied to angle.

**Integuments.**

Fishes are covered by skin like other animals, in addition to which they have a peculiar integument formed by the scales.

Although fishes inhabit the same element as the _estuaries_, they are not provided with a subcutaneous layer of fat. This seems to arise from the hardpan of their animal heat approaching so near the temperature of the water, that they do not feel in need of defence against the latter. It is to be observed, however, that some fishes have a considerable quantity of oil diffused amongst their muscular and under the integuments, examples of which are found in the genera _anguilla_ and _salmo_, &c.

The only fish which appears to have really an integument is the _moon-fish_ (_tetrodon mola_). There is spread under the skin of this species a layer of a fattylooking substance, of about two inches in thickness. Upon examination this matter is found, however, to possess all the chemical properties of albumen. The use of such a covering on this fish is not understood.

It cannot be properly said that fishes possess a _panniculus cornaceous_, or _muscular integument_ in many species the skin adheres to the muscles of the body, which serving, in some places, to be infibulated into it; by this connection the skin may exactly comply with the motions of the body, but we doubt whether any fish is capable of moving the skin differently or independently of the body. Cuvier describes a subcutaneous layer of muscular fibres in the _carp_ (_cyprinus carpio_), and some other fishes with large scales. It adheres to the inner surface of the skin, and is divided into two portions by a longitudinal line corresponding to the situation of the vertebral column. At this place there are impressions made by the tendons infibulated into the skin. They describe curves, the convexity of which is towards the tail. These muscular fibres seem to perform the office of confining the skin, and thus regulating, in a degree, the position of the scales.

The _skin_ of fishes consists, as in mammals, of the _cutis_, or _true skin_; the _colouring substance_, or _rete mucosum_; and the _inflexible integument or epidermis_.

The _cutis_ seems to possess essentially the same structure in fishes as in mammals, but more particularly resembles the cutis of _lizards_ and _serpents_.

The _skin_ adheres very firmly to the external surface of the muscles by means of a web of _aponereutic fibres_, which appear in some species, as the _sole_ (_pleuronectes foles_), the _common eel_ (_murena anguilla_), &c. as a complete integument. The skin, or the _aponereutic fibres_ under it, adhere to the muscles chiefly at the parts where the latter are divided into longitudinal scales; the middle portions of these scales are at liberty, and lie enclosed by this means in a sort of sheath.

The skin appears to vary in thicknesses according to the strength of the scales; it is very thick in the _ray_ and _stark_ genera, the _eels_ (_murena_), &c. and thin in those species which possess large scales, as the _carp_ and _bream_ (_cyprinus carpio_ and _e. brama_), hence in preparing these fishes for the table, the former are deprived of their skin, and the latter of some scales.

The _rete mucosum_ is very palpable in this class. It adheres to the surface of the scales, and produces all those brilliant colours, and varying metallic tints, for which the bodies of fishes are so remarkable. It possesses, in general, considerable firmness; and in some instances has a smooth membranous appearance, which, however, we believe does not depend upon a fibrous texture, but the compression of the mucous pigment.

The whole of the external surface of fishes is covered by a soft mucous coat, which corresponds to the _epidermis_; it forms a thicker layer in the fishes that have smooth skins, than in those with large scales. The epidermis is so soft and pulpy that it does not deflect the name of a membrane; it is very easily rubbed off the skin, and is also spontaneously shed; in both cases, however, it is speedily removed.

The surface of the skin of fishes is more or less smears with a flimsy substance of a peculiar nature. The apparatus by which it is secreted is one of the most curious parts of the anatomy of this class of animals. Beneath the integument there are a number of ducts, or tubes, which open by many orifices upon the skin, more particularly about the head, and those parts of the surface of the body which are the most exposed to friction. Their ducts are largest and most numerous in the _fishes_.
FISH.

Fish with soft skins, but we believe they exist in every species, even those with large scales, and with obvious integuments. They are most remarkable in the *scomb* and *ray* genera, in which they have an arrangement, not the same as in the offens fishes.

In the *fisheis* (rig-split) there is, on the outside of the branchial apparatus, a duct under the skin, about the thickness of a crown's quill, which is called or reflected in a waving line towards the head; one extremity of it is flint, and ends at the anterior edge of the head; the other passes round to the upper surface of the head, where it finds off upwards of thirty smaller ducts, that terminate by open ends upon the skin; other branches are expended upon the inferior surface of the front, dividing and uniting to form several curves and zig zags, without being materially diminished in their diameter; from one of which a large duct goes to the upper part of the front. There are not, according to Monroe, above six or eight ducts on the inferior surface of the fish's body.

On each side of the fish, a little farther forward than the foremost of the five breathing holes, there is a central part, from which several feebly, composed of a great number of ducts of a subordinate order or magnitude, go off in different directions, to open upon the greater part of the surface of the body. These centres present the appearance of an irradiation of opens osseous cells. A very considerable branch of the fifth pair of nerves, already described, after forming an enlargement, reflecting a giration, is injected into in fins, and finally lost in filaments upon the parietes of this structure, with which they become fo inextricably united, that it is impossible any longer to distinguish them. Monroe supposes that the nerves disappear in consequence of changing their structure, but it should rather be said that they become imperceptible by abruptly terminating; for how can they be called nerves after they cease to possess the characters of such? This affords the most striking example of the sudden termination of a nerve with which we are acquainted in the whole animal economy, and illustrates what we have observed elsewhere with respect to the nerves that go to the pimpls of feathers and bulbs of hairs, &c.

In the *scomb*, the principal subcutaneous ducts about the head are too large, that they would admit a goose's quill. In the *topa* (fjvalus gatus), according to Cuvier, there is but one centre of communication for the ducts, which is situated in the snout.

In the *offices* fishes the ducts are less numerous than in the *chondripterygiis*, they are likewise provided with centres of communication. The principal ducts are situated upon the sides of the head, or over the jaws; where they send off several short ducts to terminate upon the surface. The ducts of each side communicate with one another on the top of the head, and with one which extends along the side of the body parallel to the lateral absorbing vellum.

The pores by which the ducts open upon the skin of the head are very visible in the common *pike* (fisca lutia), and the *sea pike* (fisca Borne). Cuvier states them to be more distinct upon the head of the *chumera monstroso* than in any other fish.

The subcutaneous contained in the subcutaneous ducts of fishes has not yet been strictly analyzed as far as we are informed. It is a fluid transparent jelly. It resembles very much the matter found in the cells of the electric organs of fishes, and that which surrounds the ova of frogs. It appears to be a combination of albumen and gelatine, in which the proportion of the former is so great, that instead of being dissolved by water it is slightly coagulated, by coming into contact with it: we have submitted it to the action of tannin, with which it combines like common gelatine. It however refurns in no respect mucus; therefore, Dr. Monroe very improperly calls the tubes containing it, *muces deut*. See his *Physiology of Fishes*.

There can be no question, both from the parts of the body upon which this gelatinous substanee is principally shed, and its being most abundant in those species which are not protected by hard integuments, that it is a defensive secretion against the continual friction and washing of the water to which fishes are exposed. Cuvier however, and other anatomists, are disposed to think that the subcutaneous ducts are in a degree analogous to the electric organs of fishes, which opinion is rendered not improbable from the great size and singular termination of the nerve sent exclusively to the centres of the ducts in the *ray* kind. Perhaps delicate experiments might detect a degree of this electric property in all fishes; if so, this faculty will answer other purposes in their economy than to prevent them from the attacks of the larger species of their own kind. We do not pretend to decide upon these questions, which can only be determined by more investigations, that have yet been made upon the subject.

The distribution of the albumino-gelatinous ducts is represented in Plate X. and XI. of the *Anatomy of Fishes*. In Plate X. the upper surface of a *fisheis* (rig-split) is shewn; a. the centre of the ducts on the left side; b. fasciculus of ducts going towards the spine; c. e, other fasciculi sent to the anterior parts of the fish; d, d, fasciculi proceeding to terminate upon the outer and back part of the great fins; e, a long fasciculus running backwards to terminate near the tail; f, a large branch of the fifth pair of nerves passing outwards from the cranium; g. its singular termination on the common centre of the ducts of the right side; i j k l, the beginning of the large duct of the under surface of the front; m, the same duct seen through the snout; n, the duct which is reflected from the anterior surface of the front; r, s, t, several branches of this duct which open upon the skin, on the side of the front. Fig. 1. of Plate XI. exhibits the anterior quarter of the under surface of the *fisheis* (rig-split); a. the large peritoneal duct reflected upon itself on the external side of the branchial apertures; b, e, branches of the peritoneal duct that open upon the inferior surface of the body; e, c, other branches that surround the nasal cavity; d d, analogous with the duct of the opposite side; e, the point from which a large branch is sent to the upper part of the front; f, the extremity of the peritoneal duct which turns round to the upper surface of the fish; g, the bind extremity of the peritoneal duct; b, b, parts of the corresponding ducts of the opposite side of the fish; i, the centre of the ducts on one side; k k k k k, fasciculi going off from the centre in different directions to open upon the under surface of the body of the fish.

Fig. 2. of Plate XI. is a lateral view of the head and part of the body of the cod, (gadus morhua); a is the anterior portion of an albumino-gelatinous duct, which runs upon the side of the fish, and has numerous short branches terminating by open mouths on the surface; b, the superior branch of this duct, which unites with the corresponding one of the other side, upon the top of the head, as seen at c, and terminates in a blind extremity on the end of the front, as indicated by d; e, shows the inferior branch of the lateral duct, running along the upper part of the body; f f j k, branches opening upon the skin; g is another large duct lying on the lower jaw, which has no communication with the others; h, j, k, &c. are the short branches it sends off to terminate upon the surface.
The integument which furnishes the most effectual defence to fishes is produced by the scales, and the other ossous pieces, which grow on their skin. For the description of these parts, see the article Scales, in this dictionary.

Organ of Smelling.

The apparatus for receiving the sensation excited by odorous substances is more complicated in fishes than other animals, although the organs are less offensive.

The nasal cavity, except rarely, as in the frig. (Lophius pescatorius,) does not form any external projection; the organ of smelling, therefore, from not striking the eye, received little attention from anatomists, and no full or accurate description of it was given before the publication of Scarpa's book De Auditu & Olfacto; it was even formerly mistaken for the organ of hearing; and Blumenbach says, this absurd opinion has been revived in modern times, but we are unacquainted with any anatomist at present who entertains such an opinion.

In the chondropterygian fishes the organ of smelling is situated on the under surface of the fount; but in the ossous fishes on the upper and fore part of it; it is contained in an oval or round shallow cavity, which in the ray and sharks, and in some ossous fishes, as the gurnard, &c. is formed by an excavation of the cartilage or bones of the head, but in most ossous fishes it is partly composed of bone, and partly of membrane.

The nasal cavity has no internal communication with the fauces, nor is it connected with any sinues or hollow parts in the bones of the face; in the chondropterygii, however, there is a groove or hollow, leading from the edge of the organ of smell, under the operculum, to the angle of the mouth.

The apertures of the nasal cavities, or external nares, of the genera raja and squalus, are in a great measure covered by an operculum, composed of two irregularly-formed cartilaginous flaps connected and covered by the common integuments. The operculum is elevated at the pleasure of the animal, according to Scarpa, by a number of fine mucular fibres which arise from the end and fore parts of the fount, proceed obliquely backwards towards the angle of the mouth, and are inserted into the operculum. The nare are closed by some fibres which act like a sphincter.

We confess we have not been able to discern either of these muscles, although we have examined very large fishes for the purpose. As the operculum is open or shut, the water flows in and out of the nasal cavity with more or less force, and thus the odorous matter is exposed to the surface of the organ.

In the ossous, and molt other fishes, the apertures of the nasal cavity are crooked by a flexible septum or bar; in some fishes this ligament is narrow like a cord; in others it is broader, and formed with irregular edges; each aperture is thus divided, so as to prevent the appearance of two nares on each side, an anterior and posterior; the former always continues open, and preserves the same figure, but the latter varies in size, in proportion as the cord is drawn outwards or resects into the cavity of the nose.

The septum of the nare is drawn outwards by a fasciculus of mucular fibres which arise from the bones of the fount, and is inserted into the middle of the septum. When this mucle is not in action, the clasticity of the parts, and the impulse of the water, are sufficient to depress the septum, and force it within the nares. Under these circumstances the posterior aperture is contracted into the figure of a chink. Some fishes, as the carp, (Cyprinus carpio,) have the power of elevating the septum so much, that the aperture of the nare is drawn out as a tube.

The frig. (Lophius pescatorius) has the nares, and indeed the whole nasal cavity of each side, elevated upon the top of the fount, in the shape of two drinking glasses, which are movable in every direction.

The external integuments are reflected into the nasal cavity; on arriving at the bottom of which they seem to form the pituitary or olfactory membrane.

The immediate organ of smelling consists in all fishes of a number of fine lamina, upon which the olfactory nerves are distributed. The varieties in its structure depend upon the different arrangement of the lamina, and the form and mode of ramification of the nerves.

In the ray kind (raja) there are two series or rows of lamina, separated from each other by a ligament which extends through the middle of the nasal cavity, from one end to the other. The laminae are round upon the superior edge, and false upon the inferior margin. They are broader in the middle of the cavity than towards each end of it, corresponding to its oval shape.

The surfaces of the laminae that are applied to each other furnish a number of thin narrow laminae, which are arranged in a radiated manner.

The disposition of the pituitary membrane is similar in the *fish* genus (squalus).

The other cartilaginous, and the ossous fishes have the internal laminae of the nasal cavity arranged in radii, around an elevated tubercle. In the *fishe* (osteochori florus), the laminae ramify or divide upon their free border into thinner plates. The carp (Cyprinus carpio), and some others, have the central tubercle approaching an oval figure, which gives the organ a good deal of the appearance it has in the *ray* and *shark*.

The pituitary membrane is abundantly beamed with mucous mucus, as is usual in other animals; the glands which secrete it are evident on the membrane of the ray and shark; it is generally covered with red vessels, and sometimes with black, as in the *pike* (Esox lucius).

The olfactory nerves, after arising from the brain in the manner already described, proceed a considerable way forwards, either in a canal left in the bones of the head for the purpose, or in the continued cavity of the cranium, as the case may be, during which course they usually acquire a greater size than when they left the brain.

After the olfactory nerves pass out of the cranium, and arrive at the organ of smelling in the ray, they become enlarged and softer in their texture, and proceed transversely outwards along the middle of the superior surface of the organ, included in a firm sheath, which is perforated by a number of foramina on each side; through each of these foramina a branch of the olfactory nerve passes, and soon after divides into a tuft or bunch of fibres, which are distributed in a beautiful manner upon the lamina already described.

In the *ray* (squalus galeus) the olfactory nerve is at first very slender, it passes out of the cavity of the cranium through a particular foramen, and soon after forms a round ganglion, in which two sheaths of nerves are produced: the main branches to the olfactory laminae on each side of the ligament which divides the organ into two portions.

The olfactory nerves of *ossous* fishes usually begin to divide into branches on approaching the back of the organ; these again divide into others, which are distributed in a very palatable manner upon the olfactory laminae.

The carp (Cyprinus carpio), the *fishe* (Squalus galeus), the *bad* dog (Gadus aestivalis), and the cod (Gadus morhua), have each of the olfactory nerves enlarged into a remarkable round ganglion.
ganglion just before they penetrate the back of the organ of smell; from this ganglion a bundle of branches go immediately to be dispersed upon the olfactory lamina. It is probable that ganglia also exist upon the olfactory nerves of the other species of *gadus, cyprinus, and flanus.*

It would seem, from the greater extent and sub-division of the olfactory membranes, that the ray and shark genera have a more acute sense of smelling than the eels. All this class of animals possess it in a high degree, which is shown by their nicety with respect to the different baits employed in catching them; thus, a worm, which has lost its flavour by maceration will be refused by a fish; but the same worm, having its smell revived by incisions made on it, will be taken greedily; we cannot, however, determine exactly the degree of excellence of the sense of smelling in fishes, as the medium through which they receive the impression of odorous matter is different from that by which it is applied to other animals; but we may suppose their perception of odorous substances to exceed that of mammalia, as the latter have no different sense to this, when diffused in water, and brought into contact with their organs of smelling in that state. The structure of these organs in fishes would also lead us to make the same conclusion; for the magnitude of the nerves of smelling and the surfaces upon which these nerves are spread, are proportionally greater in fishes than in any quadruped.

In fig. 10 of Plate VI of the Anatomy of Fishes, will be seen the external parts of the organ of smelling on the under surface of the front of the thornback, raja clavata; a, a, the opereculum, partially covering the nasal cavity, exhibiting a thin layer of muscular fibres running obliquely from before backwards; b, b, the ducts containing gelatinous matter, seen faintly through the muscular fibres of the operculum; c, c, the cartilaginous folds placed around the nasal cavity, and forming the interior part of the operculum; d, the conjuncture of the cartilaginous folds seen through the mucous membrane; e, e, the ligament of each side which divides the olfactory lamina; f, f, f, f, the membranous plates or lamina arranged on each side of the ligament and g, g, the hollow folds by which the nasal cavity communicates with the angles of the mouth.

Fig. 1. in Plate VII. of the Anatomy of Fishes, exhibits a diffused view of the upper part of the organs of smelling in the same fish; a, a, the olfactory nerves enlarged, previous to their entering the sheath; b, b, the bulbs of the olfactory nerves seen passing across the nasal cavity, the sheath being laid open on one side, and removed on the other, the branches that arise from the bulb are exposed; p, p, the superior or convex edges of the laminae covered with membrane; g, g, the ramifications of the olfactory nerve brought into view by removing the membrane on the back of the organ.

Fig. 5. in Plate VII. of the Anatomy of Fishes, is a transverse section of the organ of smelling in the thornback; a, the bulb of the olfactory nerve; b, b, the ligament which runs through the centre of the olfactory lamina; c, c, the membranous lamina of the second order that arises from the sides of the other.

Fig. 6. of the same plate, shews about the half of the organ of smelling in the thornback, magnified; a, a, the lamina; b, b, the lamina of either side; c, c, one of the nerves given off from the bulb; d, d, the ramifications of the nerve upon the duplicature of the olfactory membrane; e, e, the membranes of the second order.

Fig. 7. of the same plate, represents the distribution of the olfactory nerve in the tope, (salamis galeus); a, a, the olfactory lamina from above; b, the trunk of the olfactory nerve; c, c, the bulb or ganglion; d, the facial of nervous filaments; e, the division of these into two parts, indicated by f, f, g, g, the double series of branches of the olfactory nerve distributed to the two fins of laminae.

Fig. 1. of Plate VIII. of the Anatomy of Fishes, exhibits a diffused view of the olfactory nerves in the pike, (perca lucius); a, a, the olfactory nerves when they first begin to break into filaments; b, b, the filaments distributed to the bottom of the nasal cavity; c, c, the anterior aperture of the nares; d, d, the posterior aperture; e, e, the bar or bridge across the nares; f, f, the fifth pair of nerves sent to the organ of smelling for common sensation.

Fig. 3. of Plate VIII. shews the external parts of the organ of smelling in the pike; a, the posterior opening of the nasal cavity; b, the anterior openings; c, the bar or bridge between them; d, the olfactory nerves for elevating the bar or septum of the external opening of the nasal cavity; the bar being removed, the bottom of the nasal cavity is exposed, in which are seen the radiant membranes or laminae of the organ indicated by the letters c, c.

In fig. 4. of the same plate, the distribution of the olfactory nerves is exposed in the carp, (cyprinus carpio); d, d, the trunks of the olfactory nerves; e, e, the trunks becoming calcified or composed of filaments; f, f, the bulb of ganglion of the olfactory nerves; g, g, branches formed off from the ganglia, and distributed upon the olfactory membranes; h, h, foramen left on one side, through which the branches of the olfactory nerve pass to the organ of smelling.

The diffused head of the frog, *fis* (lorius piscatorius) in fig. 1. Plate IX. of the Anatomy of Fishes, exhibits the confluence and termination of the olfactory nerves; s, s, the olfactory nerve passing through the cranium; y, y, the olfactory nerve continued along a canal in the front; z, z, the nerve spreading into filaments, previous to its distribution upon the laminated structure of the organ, indicated by *.

The second figure of the same plate represents the external part of the front of the same fish; a, the organ of smelling as it appears elevated upon a tooth; b, the organ of the other side with a part of it cut out, to bring into view the olfactory laminae.

Organ of Taste.

There is every reason for denying the sense of taste to the tongue of fishes. This organ in them wants almost all the peculiarities of structure which fit it for receiving the impressions of rapid substances. The integuments are without papilae, and do not possess greater vascularity, or a larger supply of nerves, than the covering of the other parts of the mouth, and in many species the surface of the tongue is beated with teeth. The movements of the tongue of fishes are also limited to elevation, depression, and a very slight degree of lateral motion; it is incapable of flexion or extension, which are the actions mostly employed in tasting; the extent of surface the tongue affords is usually very inconsiderable in fishes, as this member projects but a little way into the cavity of the mouth; and in the *cladodentognath* there is no prominence of the palate of the interior part of the mouth to be discerned. Lastly, the whole surface of the mouth in fishes being besmeared with a thick tenacious mucous, must very much obscure the perception of rapid substances.

In the ray genus there are two flaps of the integuments upon the edge of the mouth, somewhat of a triangular shape, with the free border denticulated, or rather fringed. These parts appear to us better adapted for receiving the impressions of taste than the tongues of fishes.
FISH.

It is most probable, that the sense of taste is extremely imperfect, if it exists at all in this class of animals; indeed, it could seldom be called into action, as most fishes choose their food by the assistance of the senses of seeing and of smelling.

Organ of Hearing.

As sound is always conveyed to the ear of fishes through the medium of water, they do not require an external concha, or any projecting parts for collecting the resonant vibrations. The whole of the organ is, properly speaking, internal, or within the head, in these animals.

Anatomists disagree with respect to there being any meatus auditorius externus, or external opening leading to the interior of the organ. It is only contended for in the cartilaginous fishes with free branchiae. Both Monroe and Hunter assumed the merit of discovering this part. The former described it in the skate (raja bati) in these words: "In the back part of the occiput, near the joining of the head with the fin, two holes, not larger than a thimble, or a small pin, are found at the two ends of the series, from one another; in a large fish each of these leads into a capacious winding canal or concha, which describes nearly a complete circle; the two conchæ are separated from each other by a thin partition; each concha terminates in a funnel, from which a small cylindrical canal, or meatus auditorius externus, is continued; the meatus is lodged in a hollow left between two thick cartilages; and as there is no membrana tympani, it opens, he says, into a large sac, which contains a white or opaque matter, with a quantity of clear watery-looking, but viscous matter."

This sac is the part upon which the auditory nerve is spread, as will be afterwards described.

He further says, "that generally some portion of a similar white matter is found in the meatus auditorius externus and concha, as if part of it passed off by the meatus, or was somehow necessary for communicating the impression of sound to the bottom of the ear."

In another place Doctor Monroe conjectures this "meatus auditorius externus performs the office of the Eustachian tube, at least fo far that tube may be supposed to serve the purpose of discharging useless or hurtful matter."

Monroe's Physiology of Fishes, p. 48, 49.

Mr. Hunter does not give any particular description of the external opening of the ear in the ray or eel genera, but frequently mentions it as a part he had discovered, and notices a passage in Willoughby's History of Fishes, in which there is some account given of an external opening on the head of the skate, in the neighbourhood of what Willoughby supposed to be the organ of hearing in that fish.

The existence of any opening into the interior of the ear from the external part of the body has been denied by a number of highly respectable anatomists.

M. Geoffroy, who described the organ of hearing before either Mr. Hunter or Doctor Monroe, mentioned an external opening, which he states as being difficult to find; he says it is concealed by the muscles, and situated near the condyles at their lateral external part; and in another place, he speaks of the auditory foramen being covered with the muscles and the fat. This account is different from the one given by Monroe and Hunter, that it adds no confirmation to their opinion.

Camper positively denies an external opening to the ear of the skate. He says, "L'organe de l'ouie e la raye n'a donc aucune communication avec l'air de l'atmosphere; mais il eft enfermé," &c. Camper, Mem. de Math. tom. vi. p. 194.

Vicq d'Azyr entertained the same opinion; in speaking of the cartilaginous fishes with fixed branchiae, he says, "L'organe de l'ouie n'a point chez eux d'ouverture externe." Vicq d'Azyr, tom. 7, p. 20.

To these authorities we may add that of Scarpa, who afferts, in the most positive manner, that there is no external opening to the ear of either the flat or round cartilaginous fishes; he supposes, that the foramina which Doctor Monroe discovered were the openings of some of the ducts containing gelatine, which are found in this situation; he even treats Doctor Monroe's account with derision; and considers it absurd to suppose that there should be a communication between the external element and the immediate fæt of the sense of hearing.

Scarpa, in denying an external opening, admits the existence of a conduit from the integuments into the vestibulum or sac containing the amylaceous substance.

In this Cuvier agrees with him, and we may add, that we have frequently and carefully dissected the organ of hearing in the ray and eel genera, but have never been able to discover the openings mentioned by Monroe and Hunter. What we have observed agrees almost exactly with the description given by Scarpa.

Behind the occiput, where it is articulated with the first vertebra of the neck, the skin is smooth and a little deprefed; if it be raised at this place two oval membranes present themselves, one on each side. These are pellucid, but at the same time dense and inyielding; they adhere firmly to the edges of two foramina, from each of which a funnel-shaped duct leads directly into the vestibulum. Scarpa considers these foramina analogous to the fissure ovale; the membrane which covers them, however, has some of the properties of the membrana tympani, and may have some effect in regulating or increaing the impression of sound; we perceive then that the cavity of the labyrinth is perfectly closed at every point, as well in the eonsus as in the osseous fishes; indeed, a different structure would be a departure from the plan of the organ in all other animals.

The membraneous labyrinth in the cartilaginous fishes with fixed branchiae is situated in a corresponding excavation of the sides of the back part of the head; it is so much wider than the part it encloses that they would not prefer their places, but from their connection with vessels, nerves, and processes of cellular substance, which pass to them in different directions: the cartilaginous labyrinth has no communication with the cavity of the cranium, except through the foramina, for transmitting the nerves to the ear. It is composed of very transparent, and much fitter cartilage, than the other parts of the head.

In the fishes with free branchiae, whether cartilaginous or osseous, the greatest part of the membraneous labyrinth is continued in the sides of the same cavity which holds the brain; there are, however, some depressions on the inside of the cranium for receiving parts of the ear, and some portion of the semicircular canals is situated round the projecting columns of bone, or in short osseous canals.

According to Cuvier, the large lateral depression of the cranium in the moon fish (tetraodon nuda), containing the ear, is divided by only two small cartilaginous columns, one of which is horizontal, and furnishes a pulley to the posterior semi-circular canal; the other is vertical, and affords one to the horizontal canal; but as the interval between these columns and the parietes of the cranium is ten times greater than the diameter of the canals, they are suspended in that space by vessels and cellular substance. The anterior vertical canal has even no column of this kind, and there is no depression for the sac in the base of the cranium.
In the *frogfish* (*lophius piscatorius*) the cartilaginous columns are broader, and approach more to the parietes of the cranium, and form two pelves, through which the posterior and horizontal canals pass.

In the *offeous* fishes there are larger columns or divitions of the cavity of the ear than exist in the *branchiostegous* fishes, and the pelves are lengthened into short canals, which include a certain portion of the membranous semi-circular canals, more especially the posterior and horizontal ones.

The anterior semi-circular canal is sometimes uncovered. In the *pike* (*Esoc Lucius*), the *eel* (*muraena anguilla*), the *roach* (*cyprinus rutilus*), and the *mackerel* (*scomber scombrus*), there is only a small offeous pillar corresponding to the space within the anterior canal. In the *dory* (*neus fischer*) this canal reaps in a furrow. In the *cod* (*gadus morhua*), and the *carp* (*cyprinus carpio*), the anterior canal is partly enclosed in one of bone, and the posterior and horizontal canals are almost concealed in the bones of the cranium.

When the face which contains the ophidian is at a distance from the sinus, the depression which receives it is deep. The *cod* affords an example of this, but it is more remarkable in the *carp* and *bunting*.

In these fishes the cell for holding the face surrounds it, leaving an opening only for the narrow canal which joins the face and sinus together.

In every instance amongst the *offeous* fishes, in whatever way the face and canals may be inclined, the sinuses and extremities of the canals remain in the cavity of the cranium; the nerves therefore, in passing to the face, do not go through any foramina in the bones. But in the *flounder* (*acipenier flarius*) there is an approach to the structure described in the *cartilaginous* fishes with fixed branchiae; each of the canals is entirely enveloped in a tube, considerably larger however than the one it includes; the face lies close to the side of the cranium, from the common cavity of which it is separated by a very thick membrane, secured there by several ligamentous procurses. The nerves are transmitted through holes in this membrane left for that purpose.

The parts which immediately constitute the organ of hearing are essentially the same in all the orders of fishes; they consist of membranous semi-circular canals, and certain dilated parts or faces, which contain calcareous substances, either hard or soft, and upon which the nerves of hearing are chiefly spread; all these parts are further completely filled up with a gelatinous fluid, or transparent pulp.

The structure of the canals and face is nearly the same in all fishes, they are as thin as membrane, but transparent and elastic, like cartilage, of the nature of which they should probably be considered: when these parts are cut alounder, they do not collapse, but present open mouths, like the fection of an artery.

All fishes have a few with respect to the number and direction of the canals; they are always three, an anterior, posterior, and horizontal; the first is situated forwards, is inclined backwards, and stands nearly upright; the second is directed backwards and upwards, and its position is also nearly vertical; and the third makes its circuit outwards, and in a horizontal plane.

Each of these canals forms an *amphulla* or spherical dilatation at one of its extremities; the *amphulla* of the anterior canal is placed at its anterior or inferior extremity; that of the horizontal canal at its anterior extremity, therefore, near the preceding; the *amphulla* of the posterior canal is situated at the inferior extremity.

The anterior extremity of the posterior canal, and the posterior extremity of the anterior canal, form a junction before they terminate in the face. The other extremities of these canals, and both the extremities of the horizontal canal, have distinct terminations. There are therefore five openings from the three semi-circular canals.

As far as respects the form and distribution of the semi-circular canals, the organ of hearing in fishes will be perceived to resemble the membranous labyrinth in the higher classes of animals: the circumstance in which it most materially differs is the existence of the face containing the cartilaginous bodies.

In the *cartilaginous* fishes with fixed branchiae, the face is triangular in its form; the internal angle, or that next the brain, communicates with the duct leading from the fenestra ovalis. The part corresponding to the second angle is round or oval, and situated posteriorly. The third angle has an anterior and external direction.

In these fishes there are three calcareous mallei, a large or principal one; and two smaller, of which one is smaller than the other, and therefore they are called the *offe* and *shoof* bodies of this kind. The confidence of these substances is soft, resembling a mixture of plaster of Paris before it is used for making a cast more nearly than any other substance with which we are acquainted; they have been likened to a soft mixture of chalk, and to flax, and hence they are called the *retaceous* and *anaglyous* bodies. The large retaceous body has somewhat the figure of a bivalve shell; one side is convex, and the other a little concave, with a groove along its broadest margin; the latter retaceous body is triangular; and the leaf has the figure of a kidney bean, but is a vast deal smaller in shape.

These bodies are not allowed to float at liberty in the face; some of their surfaces are applied close to the membrane, and the others adhere to the gelatinous pulp, which is moulded to their shape, and they are further retained in their situation by the ramifications of the auditory nerves.

In the fishes with free branchiae, there is considerable variety in the structure of the dilated parts, for containing the cartilaginous bodies, and in the form of these bodies.

The face in the *moonfish* (*tetraodon mola*) is cone-shaped; the pointed end is turned towards the brain, and the base receives the semi-circular canals.

In the *flounder* (*acipenier flarius*) the face is a broad flat disk, placed in a vertical direction.

In these, the *frogfish* (*lophius piscatorius*), and as far as it has been observed in all the *cartilaginous* fishes with free branchiae, the face is an undivided cavity; but in the *offeous* fishes, the coalition of the extremities of the semi-circular canals produce an intermediate cavity between these and the face.

Scarpa calls this part *fitium utriculiformis*, or the bottle shaped *fitus*. It might with great propriety be considered as analogus to the membranous vestibulum of other animals, although considerably different in its shape. The *fitus* is usually elongated, and tubular in its appearance, and distinguished from the face by a contraction: it contains the third ossicleum or cartilaginous body.

The face of *offeous* fishes is generally oval in its figure, and placed on the lower surface of the cranium, so as frequently to approach the one of the opposite side; sometimes there is a hollow in the base of the cranium for its reception, as already-mentioned. Cuvier considers the face analogous to the cochlea, on account of there being a feptum formed within them by their internal membrane and contained parts.

In the *pike* (*esoc lucius*) there is a small oval cavity lying behind and below the *fitus*, to which it is connected by a small canal. This part has been called the *appendix* of the semicircular canals by Scarpa and others; but it should rather be called an additional face. It has not yet been observed.
in any other fish except the pike; but there is nothing peculiar in the general anatomy of this species, which would lead us to suppose that it is confined to it. The appendix receives a branch from the first spinal nerve.

Among the cartilaginous fishes with free branchiae, the Proteus (Hoplites pfefferianus) has three calcareous bodies: a large one and a small behind it are continued in the face; the third is very small, and is situated in the cavity formed by the junction of the anterior and horizontal semicircular canals, just below the ampulla of the foramen. It is triangular in its figure.

In the herring (Ammodytes parisii) there is only one calcareous body: it is triangular, and consists of a hard nucleus, which is partly surrounded by soft cartilaginous matter.

The substances found in the face of the moon fish (tetrondon molus) appear more like mucus than chalk.

Probably many more varieties would be discovered in the cartilaginous fishes with free branchiae, if their anatomy were better known.

In all the echeneid fishes there are three calcareous bodies, which have commonly been called officula: their composition is, however, different from that of any other bones; they are extremely hard, of a nearly white colour, and almost transparent in their thinner parts. They appear to consist of pure calcareous matter, without any mixture of animal substance, and more nearly resemble the enamel of the teeth than any other part of the officous sytem.

There are considerable varieties in the bulk and form of the officula, respecting which we are indebted to Cuvier for some details.

The principal officulum is usually placed obliquely in the face. It is commonly an oval figure in the genus gadus; it is nearly round, with an angle internally, in the genus vulgaris, and in the species of cyprinus that have been examined, as the carp (C. carpio), the common (C. communis), the tench (C. tinca), and the roach (C. rutulus). In the genus falcus, the pike (Esox lucius), and the herring (Ammodytes parisii), it is irregularly triangular.

The officulum is small in the el (murena anguilla), the star gazer (uranoscopus fexace), the flat fish (placodentii), the dog (zeus fexace), and the pike (Esox lucius); of a middle size in the herring (chuba barcaurus); and large in the genus gadus, particularly the cod, in the carp (Cyprinus carpio), and a number of the thoracic fishes.

The chief officulum is convex on one side, and concave on the other; the external surface is rough; the internal is smooth, except a furrow which appears to form, with a production of the internal membrane of the face, a small canal which passes through the interior of the face. This furrow is commonly longitudinal; sometimes it is shaped like a horse-shoe. In the carp (cyprinus carpio), it is nearly circular; in the cod (gadus morhua), its place is supplied by an elevated ridge.

The anterior end of the officulum has frequently some projections from it. There are two of them in the pike (Esox lucius), the mackerel (scromber scrombrus), and the herring (chuba barcaurus). The officulum of the carp (cyprinus carpio) has three; the one in the middle projects like a style. The end of this bone is round and without points in the genus gadus and vulgaris, the roach (cyprinus rutilus), &c.

Some flukes are almost always observed to extend transversely from the furrow to the edge of the principal officulum; these are intended to lodge the numerous fibriae of the auditory nerves. These impressions are particularly remarkable in the carp genus (cyprinus), in which they have a radiated appearance.

The second or middle fixed officulum is commonly inserted behind the large bone, but somewhat more externally: its most usual form is semicircular, the concave side being anterior. Its size varies, but it is always much less than the principal officulum. Its figure is peculiar in the carp, in which it resembles that of the head of a spear.

The third officulum, as already mentioned, is situated in the sinus utriculiformis: it is sometimes so near the principal bone, that it is apt to escape observation; its figure varies. In the genera gadus, scromber, &c., it is triangular; in the gurnard (trigla), it is lenticular; in the pike, it is rounded and unequal. It is larger proportionally in the carp than in any other genus, and its surface is scabrous, and the edge serrated.

By these hard or extraneous substances being placed in the gelatinous pulp, and in contact with the nerves, it is evident that the impressions of sound are conveyed to these parts: they thus compensate for the want of an organous labyrinth, which most probably in mammals and birds has the effect of rendering the concussion of sound more sensible. Camper has ingeniously observed, that to be convinced that a hard body floating in a gelatinous substance is affected by the slightest external motion, it is only necessary to introduce some hard body into a glans of jelly, when the motion of this body will be sensible to the fingers holding the glas, on shaking the jelly, or giving the glas a little shock with the finger of the other hand. He mentions another simple and illustrative experiment, which consists in putting some hard body into a bladder containing a fluid, the slightest motion of which will be communicated to the hard substance, by which a strong sensation will be excited in the finger holding the bladder.

Two nerves, which correspond to the portio dura and portio mollis of the seventh pair, are found in fishes. The latter has a peculiar origin, not being a distinct trunk, but conjointed at its root with the fifth pair of nerves, of which it is usually reputed a branch, although, with more propriety perhaps, the fifth pair should be considered a branch of the portio mollis.

In the cartilaginous fishes with fixed branchiae, the auditory branch, or portio mollis of the fifth pair, after passing through the foramen, which transmits it from the cavity of the cranium into that of the ear, bends round behind the external parietes of the vestibulum, and divides into two principal branches, one of which is vastly larger than the other. The latter branch is distributed in a reform manner upon the posterior surface of the face containing the smaller craticeous body, and tends off two longer branches, which proceed to the ampullae of the anterior and homidinal canals, in which they are expended. The nerve or principal auditory nerve forms a taceuculus, the filaments of which divide, subdivide, and re-unite upon the posterior surface of the face containing the large craticeous body, so as to produce an intricate and close plexus, from the posterior side of which a nerve goes off to be distributed upon the face of the smallest craticeous substance. A branch, also furnished from the posterior side of the plexus, coalesces with one belonging to the portio dura, which passes through a particular foramen from the cranium, and arrives behind the large lac. From this anatomical branch, which supplies the ampullae of the posterior semicircular canal, is given off. The nerve afterwards proceeds
proceeds to the external part of the head, and is distributed immediately under the integuments about the occiput, and the beginning of the neck.

The portio mollis in offiuous fishes, which also is a branch of the fifth pair of nerves, almost immediately divides into two branches, of which one goes to the ampulla of the anterior canal, and the other passes under the sinuses to the ampulla of the horizontal canal. The second branch of the portio mollis further gives off a longer branch, which goes to the posterior part of the head, behind the superior margin of the cavity for lodging the face, and divides into many filaments, which are dispersed in a net-work upon the portion of the face next the brain. From the upper and posterior part of this reticulation a nerve is joined by a branch of the portio dura, and proceeds to the ampulla of the posterior canal.

In the offiuous, therefore, as well as the cartilaginous fishes, the ampulla of the posterior semicircular canal is supplied by an anastomosis of the portio dura and mollis.

Dr. Monroe and Mr. Hunter thought that the auditory nerves did not pass through the parietes of the membranous labyrinth in fishes; but, after running a little way upon the surface of the face and canals, became pellucid and disfused; the distribution of these nerves is very differently described by Scarpa and Cuvier; for the former traced the branches into the ampulla of the semicircular canal, in which they become soft and pulp'y, and with the assistance of the membrane produce a septum which nearly interrupts the half of the cavity. Cuvier states that the nerves of the face penetrate into the interior of the cavity, and are distributed immediately upon the calcareous bodies contained therein. As we have not at present examined this matter, we quote the authorities. See Hunter in Phil. Trans. vol. lxxii. part 2. Monroe's Physiology of Fishes, p. 59. Scarpa de Auditu & Olfaetu, p. 15. Cuvier's Lectures on Comparative Anatomy, translated, vol. ii. p. 468 and 546.

Hunter and Monroe have made some experiments to determine the possibility of hearing under water, which were very unnecessary, as it was well known that fishes were sensible of sounds produced even in the air. In fact, sound is communicated with greater or less facility according to the density and elasticity of the medium through which it passes; consequently it will be more readily propagated through solid substances and water than through air, and hence we find the organ of hearing less complicated in these animals that receive impressions of sound from the earth or water, than in those that inhabit the air; the ear of flies is admirably constructed for receivinghonorous vibrations in a dense medium; the great extent and elasticity of the face and canals; the existence of calcareous bodies, more especially when they are hard, and the large plexus of nerves, all seem calculated for this purpose. If the ear of fishes were provided with a tympanum, it would probably be of no use, unless it were filled with some fluid as denser, at least, as water.

In Plate VII. of the Anatomy of Fishes, fig. 1, exhibits a view of the organs of hearing in the thornback (raja elevata) in situ; a, anterior semicircular canal; b, posterior semicircular canal; c, the ampulla of the horizontal canal; d, cavity of the vestibulum, which contains the large sac laid open; e, the cavity of the vestibulum and the cartilaginous tubes which enclose the membranous canals being laid open; f, the anterior semicircular canal; g, the posterior semicircular canal; h, the horizontal semicircular canal; i, the cavity of the vesti-"
other extremity of the same canal; &c., the ampulla of the posterior canal; b, the other extremity of the posterior canal; c, the utriculiform sinus of the semicircular canals; f, appendix peculiar to the pike; i, the smallest ocellus seen through the sinus; f, the facial containing the other two ocelli. No. 5 indicates the trunk of the fifth pair of nerves; m, the auditory nerves; n, the branch of the auditory nerve to the ampulla of the anterior canal; o, the branch of the auditory nerve to the ampulla of the horizontal canal; p, nerves derived from the auditory going behind the small ocellus; q, the branch of the auditory nerve sent to the ampulla of the posterior canal; r, auditory nerves distributed upon the face next the brain; s, nerve analogous to the par vagum or portio dura; t, the anastomosis of the preceding nerve, with a branch of the auditory or portio mollis, from which the ampulla of the posterior canal is supplied; u, a nervous filament sent from the first spinal nerve to the bottom of the appendix.

Fig. 4. of the same plate explains the different cavities of the bones of the cranium, in which parts of the labyrinth are enclosed: a, the cavity of the cranium; b, a hollow, in which the face of the skull is lodged; c, a fenestra for containing the ampulla of the anterior semi-circular canal; d, the aperture leading into the passage which holds the horizontal semi-circular canal; e, the common foramen to the horizontal and posterior canals; f, the other opening, through which the posterior semi-circular canal passes; g, the foramen, by which the portio dura goes out of the cranium; l, canal of the spine; i, i, foramina for the exit of the fifth pair of nerves; k, foramen for the first spinal nerve.

In Plate IX. of the Anatomy of Fishes, fig. 1, is a section of the head of the frog-fish (loubius piscatorius); a, the anterior semi-circular canal; b, its ampulla; c, the horizontal semi-circular canal; d, its ampulla; e, the posterior semi-circular canal; f, its ampulla; g, the conjunctive of the anterior and posterior semi-circular canals; h, a large canal, into which all the others open; i, principal face containing the large ocellus; k, the facciulus of the lesser ocellus; l, the third or smallest ocellus seen through the membrane below the ampulla of the anterior canal; m, the nerve going to the ampulla of the anterior canal; n, the nerve of the ampulla of the horizontal canal; o, nervous filaments sent behind the seat of the third ocellus; p, filaments of nerves distributed to the capsule of the large ocellus; q, a filament which goes to be expended upon the capsule of the lesser ocellus; r, a long nerve sent to the ampulla of the posterior semi-circular canal; s, the portion of the fifth pair of nerves that go out of the cranium; t, the fourth pair of nerves; u, the third pair of nerves; v, the second or optic nerves; x, the first or olfactory pair of nerves.

Organ of Vision.

The eyes of fishes are usually situated on the sides of the head, in which cases the animal only beholds objects with one eye at a time; some remarkable exceptions exist, however, with respect to the position of the eyes in this clafs: they are turned directly upwards in the flounder (urinaeus). All the genus pleuronectes have both eyes placed on one side of the head, which, from the position of the fifth ocellus, is always the uppermost. In the callionymus and the ray genus the eyes have an oblique aspect.

The figure of the eye in fishes usually approaches that of a semi-sphere, the flat surface of which belongs to the cornea. In the ray genus the eye is flat also laterally, and has, consequently, the form of a quarter of a sphere. Some fishes have the cornea gibbous, and the eye of the same figure that it possesses in these animals which inhabit the air; the gadus lota affords an example of this shaped eye.

The sclerotic coat is dense, elastic, and cartilaginous in its structure; and although sometimes thin, it preserves the figure of the eye. In some species, more particularly among the cartilaginous fishes, it is thick. This is remarkable the case in the sturgeon (acipenser fluvius); in this fish the sclerotic composes the greater portion of the eyeball, the cavity for containing the transparent parts bearing but a small proportion to the rest of the globe. This coat is thin in the posterior part of the eye of the salmon (salmo fluvius), and hard and unyielding as bone on the fore part. The induration of the front of the sclerotic is also found in several other species.

The sclerotic of the ray and shark genera forms a tubular projection at the back of the eye; this is articulated with a piece of cartilage which is connected at the other extremity to the bottom of the orbit. The eye in these animals, therefore, is sustained upon a footstalk, upon which it is movable only to a certain extent.

The cornea, as before mentioned, is commonly flat in fishes.

The definition between this coat and the sclerotic is particularly plain in the tope (gonialus galerus); these two coats are conjoined by oblique edges, between which is interposed a fine compact cellular substance, which appears to be a production of the conjunctiva that passes into the eye to be united to the corneal lamina.

The conjunctiva is reflected over the external part of the globe of the eye in fishes as in other animals. This is satisfactorily shown in the cod kind (murina), in which it adheres so tightly at this place, that it is removed in flilping the skin off the rest of the body.

The choroid coat, and memhrana ruyischiana, are very different from each other in this clafs.

In the genera raja and flusus the choroides possesses the usual vascular structure, and is of some thickness and confluence; the ruyischian membrane is very thin and transparent, and between the two membranes there is spread a silvery pigment.

But in other fishes the choroides is very thin and little vascular. It is a white silver or gold colour. The ruyischiana has more confluence, and is composed of an infinite number of vessels interwoven together. It is a black colour. There is interposed between these coats a remarkable body called the choroid gland, which is not found in the chondropterygi.

The choroid gland has usually the figure of a thick flat ring; it encircles the optic nerve, but not entirely, as there is always a small deficiency in the ring.

In the cod (gadus morhua), the salmon (salmo fluvius), and the moon-fish (tetraodon melo), it has been observed to form not a true circle, but to be irregularly bent; and in the perca labrax it is composed of two pieces placed on opposite sides of the optic nerve.

The choroid gland is very compact in its structure; it receives a multitude of fine vessels which pass through the membrane ruyischiana; they are covered by a white opaque mucous, anastomose with each other, and seem to terminate in an infinite number of ramifications in the substance of the gland, which thereby acquires an uniform, vivid, red colour at every point, appearing more like a dried body than one coloured by blood-vessels, in which circumstances, and the obscurity of its texture, it bears a strong resemblance to the vascular bodies found in the swimming bladder of fishes. The circulation of the blood through the choroid gland appears to be slow and embarrased, as the colour remains in
the part in a considerable degree after it is macerated and preferred in spirits.

The choroid gland likewise receives a number of nervous filaments from the ophthalmic branch of the fifth pair, which proceeds for some way in the same sheath with the optic nerve.

Anatomists are not agreed with regard to the use of this singular part: some have supposed it to be a muscular apparatus, intended to alter the figure of the eye when holding objects at different distances; others, amongst whom is Cuvier, consider it as a gland which secretes some of the humours of the eye; this latter opinion is most consistent with the form and structure of the part, which are very unlike those of any other muscle; but, on the other hand, its situation on the outside of the ruyfiana, and the want of any excretory opening, are difficulties in the way of its furnishing any of the transparent parts of the eye; it appears to us to supply the place of the vascular structure of the choroidies, which membrane is always thin and deficient in blood-vessels in those fishes that possess the choroid gland.

The functions of the choroid case are not, we conceive, yet fully understood; it enjoys a degree of vascularity greater than is found for its supposed offices of secretion; we have examples of the same circumstance in several other organs in the body, but the most striking are the choroid gland and the vascular bodies of the swimming bladder of fishes.

The membra ruylchiana, near the front of the eye, sends off, in some fishes, a triangular process, which palls through the vitreous humour, and is attached to the side of the capsule of the crystalline lens, in the manner of the marfplum of birds. Some very evident vessels which come through the vitreous humour, are transmitted along this process. On the opposite pole of the capsule of the crystalline we have observed the dory (sens faber), and others, the mark of an attachment which appears to be produced by a vessel. This mode of connection between the crystalline and the internal coats of the eye appears perfectly analogous to the pellon or marfplum in the eye of birds, and no doubt answers a similar purpose.

The ciliary process have not been observed to exist in any fish except the tope (flupalus galeus), in which the lamina, according to Cuvier, project as much as in birds, and after forming a short point, which joins the capsule of the crystalline, they are continued with the rixle of the uvea.

Fishes want that coloured appearance of the bottom of the ruyfiana, which is called the tapetum; this membrane is black at every part, except in the ray kind, which have it transparent at the bottom of the eye, and therefore admitting the silver colour of the choroidies to be seen through it.

The iris is in general a very fine membrane in fishes, and so transparent that the uvea is visible.

The uvea has commonly a brilliant metallic colour, which makes the eyes of fishes for striking.

The form of the pupil is round in this clafs, with the exception of the genus ray, in which a very remarkable curtain or veil is continued from the superior edge of the pupil. It is nearly a triangular shape; the base is connected above, and the two sides hang down. There are notched, or rather divided into short stripes or shreds along the edge: they appear gilded externally, but are black on the inside. When the eye is unmoved, the veil is turned up between the superior edge of the pupil and the vitreous humour; but if it be depressed, either by external force or the will of the animal, the veil comes down and entirely covers the pupil. The torpeo has been observed to let down its veil in this manner always at the moment of communicating an electric shock.

In the ray and skat kinds, the carp, genus, and a number of other fishes, the optic nerve has been observed to enter the eye by a round hole, and to produce a tubercle on the inner side, from which the retina goes off in a radiated manner.

In the ray genus, the tubercle of the optic nerve is irregular in its figure, or papillated.

Cuvier has observed in several of the genera salmo, cupra, sponer, porca, gaudus, zeus, and tetradon, that the optic nerve, after entering the eye, and traversing the ruyfiana, forms two streaks or tales; these tails are parallel, but not contiguous, a production of the ruyfiana passing between them. The retina is produced from the opposite edges of these streaks, in the same manner as it arises in birds from the single white line.

The aqueous humour is very small in quantity, or totally wanting in fishes; it is also of a different consistence than in the animals which do not inhabit the water. It is viscid and liquidous.

The crystalline lens has generally in fishes very nearly the spherical form, and in some insects it is a perfect sphere. It is more dense and hard, especially in the nucleus or internal part, than in any other animal, except the cattle bife (eptis). As the aqueous humour is small, the crystalline is in the same degree large in this tribe of animals.

The vitreous humour of fishes is less in proportion to the other parts, and has more consistence than in the animals living out of the water.

Cuvier has furnished us with some tables, partly the result of his own observation, and partly derived from other sources, exhibiting the proportions that exist as to the form, magnitude, density, &c. of the transparent parts of the eye in different animals. We shall extract the following particulars, as serving to explain the optical properties of the humours of the eye in fishes.

The degree of convexity or approximation of the crystalline to a sphere is determined by comparing the axis with the diameter. In the human subject, the axis is to the diameter as 1 to 2.

In the following fishes as below:

</table>

The portion of the axis occupied by each of the three transparent parts of the eye is represented by fractions, the length of the axis being considered the unit.
the cod (Gadus morhua) and the ox (bos) ; distilled water being supposed a thousand.

In the ox. In the cod.

Of the aqueous humour 1000 1000
Of the vitreous humour 1016 1013
Of the whole crystalline 1114 1165
Of its external part 1070 1140
Of its nucleus 3100 1200

We have not proved the accuracy of this table, but it appears to be incorrect, particularly with respect to the density of the aqueous and vitreous humours, which are probably greater than are here represented.

We have not a sufficient number of experiments to determine accurately the refractive power of the different humours of the eye. All that have been made, however, as well as common observation, shew that the refrangibility of the humour is much greater in fishes than in terrestrial animals, by which means they are enabled to perceive objects through so dense a medium as water.

The eye in fishes is moved by six muscles, as in the human subject. The one analogous to the trochlearis does not, however, pass through a pulley.

Fishes are not provided with movable eyelids. In the salmon (Salmo), and the mackerel (Scomber), there is at each angle a vertical and immovable veil, which projects a little way over the eye. Moll offious fishes have something of the same structure.

In the moon fish (tetraodon molu) there is a very singular apparatus for covering the eye. This animal can entirely cover its eye by a lid, which contains a circular perforation. This aperture is shut by a true sphincter muscle, and is opened by five muscles which arise at the bottom of the orbit, and proceed in a radiated manner to be inserted into the eyelid.

Fishes, from the nature of the medium in which they reside, do not require any aqueous secretion for keeping the surface of their eyes moist; we therefore do not find a lacrymal gland in any species of this class.

The figures which illustrate the structure of the eye are contained in Plate IX. of the Anatomy of Fishes: fig. 5, exhibits a lateral view of the eye of the skate (Raja batis); a, the eye, flat above and anteriorly; b, the tube of cartilage; c, the cartilaginous peduncle or footstalk upon which the tube is articulated; d, a portion of the cartilage of the orbit to which the footstalk is connected. Fig. 6, is an anterior view of the eye of the skate, with the cornea removed, to bring into view the veil which is seen at a, covering the greatest part of the pupil. Fig. 7, is a section of the eye of the sturgeon (Acipenser Fluro); a, the thick mass formed by the fleshy coat; b, the cavity of the eye. Fig. 8, exhibits a portion of the skin taken from the side of the head of the eel (Muraena anguilla) including the spot covering the globe of the eye which corresponds to the conjunctiva. Fig. 9, shows the choroid gland in the carp (Cyprinus carpio); a, the gland; b, the optic nerve; c, the rufchiana, the choroides being removed. Fig. 10, exhibits the choroid gland as it exists in the cod (Gadus morhua); a, the gland somewhat irregular in its figure; b, the optic nerve; c, the rufchiana; d, d, velvets passing into the gland. Fig. 11, exposes the internal parts of the eye in the dog (Zanu fischer); a, the vitreous humour; b, the crystalline lens; c, velvets passing through the vitreous humours, distributing branches to this humour and the lens; d, production of the rufchiana attached to the capsule of the crystalline; e, the other point of the capsule which seems to have a particular connection with the adjacent parts. Fig. 12, is intended to contrast the spherical form of the crystalline of a fish at a, with the flattened appearance of the anterior part of the lens in a bird, as seen at b. Fig. 13, represents the tubercular termination of the optic nerve in the skate (Raja Batis); a, the optic nerve; b, the irregular or papillated tubercle formed within the eye; c, the retina. Fig. 14, shows the termination of the optic nerve in two threads, as it exists in the cod, and many other genera; a, the optic nerve; b, b, the threads or tails; c, the retina.

**Bones.**

Fishes have been divided by all naturalists into two great tribes, according to the structure of their skeleton; those of the one have been called the cartilaginous, and those of the other the offious fishes. This division, although justified by the difference in the composition of their bones, and proper as being confin'd with natural habits and structure, is nevertheless not strictly correct; for the skeleton of the cartilaginous fishes possesses some calcareous matter, and the bones of the offious fishes contain in general a much smaller quantity of earth than is found in those of other animals: if they were compared with the bones of mammals, or of birds, they would themselves deserve the epithet of cartilaginous. The composition is not uniform in the different bones of a fish's body; some contain a greater quantity of phosphat of lime than others; the cranium, spine, and the thick bones, are hard, white, and opaque in the offious fishes, but the thin bones are flexible and transparent; and in the cartilaginous tribe, although we can as readily cut with a knife many parts of their skeleton as we could common cartilage, yet their cranium and spine give considerable resiliency, especially in the larger species, and present more of a fibrous texture.

The structure of the skeleton is more purely cartilaginous in the fishes with fixed branchiae, as the ray and shark genera, than in the order of cartilaginous fishes called branchiostegi.

The colour of the bones of fishes does not appear to be subject to much variety; one species, however, the gar fish (Esox Belone), is remarkable by having the whole skeleton green.

The skeleton of a fish is, in its general form and mechanism, so very unlike that of other animals, that a person at first view would not suppose there existed the most distant analogy between them; but after examining the parts in detail, and comparing their relations to each other, we are astonished by the correspondence which prevails between them, and the pieces of the skeleton of mammals. Nature is always economical in her means, and never deviates from the type, or creates a new part, until all the modifications which the organ is capable of receiving be exhausted. The combination of simplicity of design with diversity of effect, cannot be more strongly illustrated than in comparing the anatomy of the skeleton of fishes with that of the other classes.

The skeleton of the chondrostegii, and of the genus ray in particular, differs as much in form as in composition from that of the offious fishes; it likewise bears less analogy to the skeleton of other animals; we shall therefore postpone its description until we have given an account of the bones of offious fishes, for which purpose we shall take in general the dog (Zanu fischer), as affording one of the best examples of the osteology of this tribe of fishes.

The bones which compose the cranium are all united by a species of sanguine fluid; they not merely overlap each other, but the edge of each bone forms a great number of irregular, sharp, thin procHces or spicules, which are inserted into one another; the union thus produced does not admit of
of any motion of the several parts, and the cranium appears to be composed of a single piece. Cuvier says that the bones of the cranium are anchylosed with each other; but we have not found the usual number of bones to be distinct in the cranium of even old fishes, but the portions of which each bone is originally composed to be separable from each other. To be satisfied of this fact it is only necessary to examine the skull of a fish that has been thoroughly cleaned and bleached by long maceration in the sun, and expose to the weather, many of which are frequently found lying on our shores: these skulls we have been enabled to separate into portions, corresponding to the frontal, parasit, temporal, sphenoidal, and occipital bones, and to divide again the frontal and occipital bones into two pieces each.

The external form of the cranium is very irregular, and varies in different fishes. In the doré it has two flat sides, which have an oblique direction, like the roof of a house; the top or part corresponding to the ridge is an irregular hollow or groove; the posterior part of the cranium is much larger than the anterior; it is truncated or flat, except two thin processes corresponding to the occipital ridge; the anterior portion of the cranium is slender, elongated, and slightly arched, somewhat resembling the superior mandible of a bird; under this part there is a very large vacuity, through which most of the nerves pass out. The inferior part of the cranium is depressed on each side, and then forms a remarkably strong process, which is analogous to the basi-fiallary, and extends from the condyle, with which the spine is articulated, to the bone analogous to the vomer, of which more will be said hereafter. The parietes of the cranium, corresponding to thesituation of the organs of hearing, are thin, cellular, and exhibit an irregular fossa externa; in many fishes the sides of the cranium are not flat and sloping, but spread out into a thin edge, nearly on a plane with the superior part; there is often also a sharp thin spine extended along the medial line of the superior part of the cranium, which, in some species, extends high, and projects considerably from the back of the head, in order to give attachment to the muscles and ligaments of the spine. The lower part of the cranium is most commonly, in offene fishes, enlarged on each side of the basi-fiallary process.

The cavity of the cranium has been thoroughly cleaned, is much larger than the brain; it is extremely irregular upon the internal surface, furnishing a number of craggy and spiculated processes, impossible to describe: it is not, therefore, adapted, as in other animals, to the form of the brain. It is more nearly oval than any other figure.

In the account given by Cuvier of the bones of the face, he does not appear to us to have named the different pieces according to their true analogy, or likened to the parts composing the face of other animals. In the doré, from which we take our description, the bones of the face are large and very distinct.

There is no effusum septum to the orbits; the eyes are separated from each other only by membrane. In the genus

FISH.

the anterior part of the os frontis, on each side of the nasal bones.

The bones which supply the place of the ethmoidal of other animals are situated before the os frontis, immediately

below the last mentioned; they extend obliquely from the frontal to the malar bones, with which they are articulated; they form the anterior margins of the orbits.

The nasal bones are supplied by a strong process of an arched figure, which is continued from the middle of the anterior part of the os frontis, under the posterior end of the inter-basal bones, which move thereon. From this bone there arises a thin plate, which is analogous to the effusum septum of the nasal cavity, and which is united to the vomer.

The vomer is a bone of a singular form, it is long, and paits in a straight line from the basifiallary process of the occiput, with which it appears to be really anchylosed, along the superior part of the palate, and ends anteriorly in a thick broad extremity, somewhat resembling in figure a horse's foot, which is commonly armed with teeth: this bone serves as the baffe to the septum of the orbits.

The bones we have called the malar, Cuvier appears to consider as analogous to the palatine; they are thick, short, and irregular in shape; they are articulated with the zygomatic bones, with those analogous to the ethmoidal, with the superior maxillary, and with the articular bones, which will be hereafter described; they send processes backwards and upwards, which contribute to form the vault of the palate.

The superior jaw is formed of four pieces, which are connected to each other, and to the adjoining bone, by ligament, in such a manner as to permit a considerable degree of motion; the two external pieces correspond to the superior maxillary bones; the intermediate ones to the inter-basal bones.

The maxillary bones are two arches placed with their convexity outwards; they are broader and thinner at their extremities than in the middle; near their superior end they furnish a thick process, which projects anteriorly like a small cone, and presents on the surface next the mouth a rounded ridge; from entering into the composition of the roof of the mouth, some perils would perhaps consider them analogous to the palatine bones. They are connected by ligament with the malar bones superiorly, with the coronoid processes of the lower jaw inferiorly, and anteriorly with the articular bones.

The part of the upper jaw that corresponds to the inter-basal bones forms the superior margin of the mouth, and is commonly furnished with teeth; it is composed of two pieces, which are united to each other by ligament and cartilage; each of these sends off posteriorly two thin plates, and one long round process; the first slide under the maxillary bones, and the round processes are tied together by ligament, and move in a sheath which is thus formed upon the nasal bone: a free motion of these parts on each other becomes necessary in the protrusion, the opening, and the shutting of the mouth.

The inferior jaw consists of two triangular shaped pieces, which are united to each other by ligament at their anterior part: the angle of those pieces that is placed upwards corresponds to the coronoid process; the articulation is situated near the posterior angle, and this last corresponds with what is called the angle of the jaw in mammals. The middle part of the pieces composing the lower jaw is either of extremely thin cartilage or membrane.

The lower jaw is articulated with a bone analogous to that to which Cuvier has given the name of the figure bone, ("os quarre") but which we have preferred calling the articular bone in the description of the anatomy of birds, from the circumstance of its being interposed between the articulation of the jaw and the cranium.

The
The articular bone is composed of several pieces firmly united together; they produce a considerable extent of surface on the side of the head in the dory: one piece, which is of some strength, is articulated with the under surface of the temporal bone, from which it proceeds downwards and forwards in a curved manner, declining in thickness as it descends: this piece furnishes the thin bone of the operculum, and receives the horn of the os hyoides: over this piece there is another thinner one laid; they are apparently anchoylofed with each other, and the external one commences a short distance from the cranium, by a sharp distinct point, and goes on to the articulation of the lower jaw: another ossous piece is articulated below, and anterior to the orbit with the inferior end of the malar bone, from which it proceeds directly downwards to join the anterior end of the other piece, and forms with it the articular surface for the joint with the lower jaw. The intermediate space left between these pieces, which is very considerable and of a triangular figure, is filled up with a very thin plate of cartilage, which is in parts ossified. The articular bone in fishes is evidently formed to carry the lower-jaw forwards, and thus to facilitate the protusion and dilatation of the mouth, and for affording a surface for the attachment of the muscles of the jaw; it is therefore found much larger in this class than in birds.

The part corresponding to the os hyoides is formed by two flat ossous plates, which meet together anteriorly upon the bone which furnishes the tongue, and separating from each other posteriorly encompases the gills; a small round branch goes off from the external end of each plate; these are analogous to the horns of the os hyoides, and become attached to the internal surface of the articular bone by ligaments, which allow the hyoides to move nearer or farther from the cavity of the mouth: each plate of the hyoides is composed of several pieces, the edges of which are in a certain degree anchoylized with each other: there are six pieces observable on each side in the dory. Cuvier states these to be the usual number.

There is a very thin ossous plate situated between the anterior ends of the two sides of the hyoides, and the junction of the f.e.palmus; it is connected by pieces of ligament to each side of the os hyoides, to the lingual bone, and to the scaphula, where they meet: this bone has almost exactly the outline of a heart, it has therefore been called the cordiform or heart shaped bone; it is peculiar to fishes, but does not appear to have any other use, than to afford attachment to the strong muscles situated at this place.

There are a number of bones that are peculiar to the organs of respiration and of deglutition in this class of animals, which require a connected description: these are the branchial arches, the pharyngeal bones and the bones which furnish the operculum or Gill cover, with those of the membranous branchiologe.

In describing the organs of respiration we have stated that each of the gills is furnished upon an arch of bone: each branchial arch is composed of two pieces or limbs, two of the ends of which are enjoined by ligament in such a manner, that the other extremities can be moved nearer or farther asunder, and thus the arch rendered narrower or wider: the inferior limb, or that next the cranium, measures about one-third of the whole arch, and the inferior about two-thirds of its extent. The branchial arches are placed, with respect to each other obliquely in rectell as they are commonly thinner, thin bones, and have four sides, or rather four edges and two sides: the convex edge is directed outwards and backwards: it is upon this the lamina of the gills are planted: the concave edge is turned forwards and upwards, towards the mouth. Along the external or anterior side there are usually a number of small ovisous eminences, placed at short distances from each other, which project a little beyond the concave edge: these do not commonly arise from the bone, but the membrane covering it: they are furnished with teeth, which are thence called the branchial teeth, as already described. The inferior extremity of the branchial arches is attached to the cranium along the sides of some small ossous pieces, which are situated in the lower part of the mouth, and appear as the continuation of the lingual bone: these bones vary in number in different species, but they are firmly united to each other, so as to form a part of the skull, to which the branchial arches are adhered like ribs. The inferior surface of these bones is smooth, but inferiorly they furnish some processes, through which some of the branches of the branchial artery pass to the gills.

From the posterior extremity of this piece of the cranium there arise two slender branches, which separate from each other in the manner of horns, and in form to the flattened surfaces or disks: these are the inferior pharyngeal bones, and are, as before observed, commonly covered with teeth.

The superior extremities of the branchial arches are indirectly connected with the base of the cranium: a slender footstalk is articulated at one end with the superior extremity of the posterior arch, and at the other with the base of the cranium; the superior extremities of the three anterior arches of each side terminate upon two flattened bones, which are called the inferior pharyngeal bones; from the upper edge of which a second footstalk goes off, and is attached to the cranium, on the inner side of the one just mentioned.

In consequence of this sort of connection between the branchial arches and the cranium, two add. cart joints are created, by which the fixation of the arches, and the approximation of the inferior pharyngeal bones to each other, and to the inferior pharyngeal bones, are more easily performed; the muscles likewise which move these parts can considerably power by their whole force operating upon the points at which they are inserted.

Cuvier states the connection between the branchial arches and the cranium of ovisous fishes in a manner somewhat differently than we have described it above. He says the superior extremities of all the four arches are attached to the inferior pharyngeal bones, when these exist, the two posterior arches by an articulation, which almos of a jaw motion; and the two anterior arches more closely; for this purpose, the fish arch bridnorca and leads to the pharyngeal bone a strong ligament from one of its branches, which the other is immediately joined to the cranium.

In the flerus anguillaris, which has but one large pharyngeal organ situated under the superior extremity of the last arch, this extremity unites with that of the third arch, and converges with that of the first towards the base of the cranium.

In the pale ( Gson holin) the two last arches unite at their superior extremities to the fish, which, as well as the first, is articulated with the cranium.

In the carp ( Terytira,) which has not movable superior pharyngeal bones, the superior extremities of the four arches are approximated and articulated with a common piece, which is united to the cranium.

In the front ( Terytira,) the superior extremities of the six arches are united by several pieces, the governor of which bears a small plate covered with teeth, at the place where it is united with the extremity of the last arch. The bone of which form the operculum are generally two.

The principal one has a triangular figure; it is very thin at every part, except at the superior angle, at which place it

Vol. XIV.
forms a sort of neck, and a little prominence or head, in which there is a depression that is joined to a corresponding process, on the back of the upper end of the articular bone. This bone of the operculum has a degree of rotatory motion, in addition to those of elevation and depression. The other bone of the operculum is long, narrow, and thin, and resembles the blade of a knife; it lies posterior to, and nearly parallel with, the articular bone; it is not joined to any bone by articulation, but is connected by ligaments posteriorly, with the triangular bone of the operculum, and the back part of the os hyoideum, and anteriorly to the angle of the lower jaw. The use of this bone seems to be chiefly to furnish the integuments which are extended over this part.

The **offense rays**, which support the **membrana branchiostega** are attached to the posterior margin of the broad bones of the os hyoideum; they increase in size from before backwards. There is an interval between the origin of the first three rays, and that of the four posterior rays, which, however, does not cause any material irregularity in the succession of the points of the rays. These bones are capable of being elevated and lowered, of being approximated and expanded. The elevation and expansion of the posterior rays are opposed, beyond a certain extent, by a process from their roots.

The **vertebrae** are divided by Cuvier into two classes; the first are the **abdominal** or **dorsal**, which have spinous processes from the superior side of the spine only; the second are the **caudal**, which have spinous processes from both the upper and lower bones of the spine; but this distinction is not quite correct, as the posterior abdominal vertebrae furnish short spinous processes inferiorly; the caudal vertebrae may, however, be reckoned with propriety from the large bone, which forms the posterior boundary of the abdominal cavity.

The bodies of the vertebrae vary with respect to figure in different fishes, being cylindric in some instances, and angular or compressed in others; they are all, however, distinguished by having the surfaces by which they are conjoined hollowed out to form a semi-elliptical or conical cavity: these cavities are opposed to each other, and thus produce, throughout the whole spine, a chain of cavities, each of which is nearly of a spherical figure, and alternates in succession with the vertebrae; these cavities are furnished with concentric layers of cartilage, or rather a peculiar intervertebral substance, which somewhat resembles ligament, but is highly elastic: these concentric layers complete the form of each cavity, and constitute the bond of union between one vertebra and another. The interior part of the cavities is actually filled by fluid.

The centre of each vertebra, which is very thin, is perforated with a small hole, which is lined by the same substance that invests the cavities; a communication is thereby established between the cavities, the whole length of the spine, which is probably designed to obviate the compression of the fluid in the different cells or cavities during the motions of the spine.

By this species of articulation of the vertebrae with each other several advantages are obtained; strength and lightness are bestowed on the spine, and a great facility of motion, as every vertebra rolls upon a globe composed of an elastic substance, and of fluid. The first vertebra is articulated with the opisthocranum in the same manner as those of the spine are with each other.

The external surface of the vertebrae are very generally marked by a number of depressions or little cavities, in the longitudinal direction of the spine, which give to the circumference of each vertebra very much the appearance of being constructed of short pillars, with regular spaces between them. This structure diminishes very considerably the weight of the spine, without subtracting from its strength.

The spinous processes of the vertebrae are commonly long, slender, sharp-pointed bones; they arise from the superior sides of the bodies of all the vertebrae, and from the inferior sides of the caudal, and some of the last dorsal or abdominal vertebrae. They originate in the lower surface of the caudal vertebrae we believe always as two processes, which coalesce, and form a triangular space, in which the blood-vessels of the tail pass along the spine. They are double at their roots in the pleuroneurides and other fishes, along the superior part of the spine also.

The inferior spinous processes of the last dorsal vertebrae are short, imperfectly formed, and have their extremities applied and flattened to each other, in order to furnish the large bone that forms the boundary of the abdominal cavity, of which more hereafter.

The first vertebra of the tail has its extremity spread out in the figure of a fan, which appears to be composed of a number of offens rays united to each other.

The ribs are sometimes wanting in fishes, and, when they do exist, are usually very small.

The generis **filarius, cyprinus, and chetodon**, however, furnish examples of fishes with strong ribs, which surround the abdominal cavity almost to its top.

In the herring **genus (clupea)**, the **zeus vanner, &c.** they unite in a fort of **flerum**.

In many fishes the ribs divide at their extremities into two branches; it is very common also to meet with a second row of ribs, which arise above the others; these are usually fewer in number than the proper abdominal ribs, and pass between the portions of the lateral muscles.

The **flerum** but rarely exists in this class of animals, as the ribs seldom extend as far as the inferior part of the body.

In the dolph (**zeus fader**) there is a species of **flerum** formed by a number of irregularly shaped offens pieces, which appear to be only connected with each other by ligament, and the common integuments. They are furnished with sharp spines externally, and are hollow next the cavity of the body.

The membrea which correspond in fishes to the anterior and posterior extremities of other animals are the **peloral** and **abdominal fin**.

The **peloral fin** is sustained by a very considerable bone, which, with the corresponding one, surrounds the body immediately behind the aperture of the gills. Cuvier has, from hence, called them the **girdle-formed bones**; he likewise considers them as analogous to the scapula, in which he is justified by their position, and some circumstances in their formation. These bones are articulated with the inferior and posterior part of the cranium; they pass backwards and outwards, as far as the middle line of the body of the fish, during which course they are narrow, flat on the external surface, and have a round ridge along their internal surface. They then make a turn forwards and inwards, and meet each other a short distance behind the os hyoideum. At the place where they turn forwards, they send a thin, sharp process backwards, and soon after they receive, in articular depressions, the ends of two long, slender, three-sided bones, which pass from below upwards, across the muscular parietes of the abdominal cavity. Some anatomists consider these bones as being analogous to the **elaioides**; Cuvier does not allow it, but without laying the grounds of his objection. It is sufficiently plain, however, from their position and connections, that there are no other
other bones, except the clavicles, or the fork-shaped bones of birds, with which they can be compared.

It is the inferior half of the scapula that properly corresponds with the bone which bears that name in other animals; the other portion seems to be a part added in fishes, in order to give firmness to the whole member, by connecting it with the head, and likewise to carry the pectoral fin farther down upon the body. The inferior portion is broad and thin, and furnished with a thin, fleshy process, or rather plate, which runs along each side of the bone, near the anterior edge, which may be compared with the spine that divides the surface of the spine in mammals.

The osseous rays which compose the pectoral fin are connected to the posterior edge of the scapula by means of a number of small bones, that seem to perform the office of a corpus, and with which it should perhaps be considered to correspond. Each oseous ray, towards the extremity in particular, consists of a succession of minute bones, closely united to each other; these might be compared to the joints of the fingers.

The above description of the pectoral member has been taken from the dory (zeus faber); it is necessary, therefore, to mention some varieties of structure that exist in other fishes.

The pectoral fin does not exist in some fishes, as the genera muraena and sebenites.

The bone, which is formed by the union of the two inferior extremities of the scapula, is very acute in those fishes that have the body compressed vertically; but in those with a depressed or flattened body, the scapula turns inward, and meets each other nearly in a straight line.

The number of carpal bones varies; Cuvier states, that there are four large bones of this kind in the wolf fish (anarhichias lupus), the red gunner (trigla eucanu), and in the armed and flying trigle (trigla cataphracta and trigla voletens); four small bones in the genus pleurocetes, and the evening (gadus merlangus); eight small bones, in two rows, are found in the dory (zeus faber); three small cylindric bones in the flurus, and five in the echolonus, porches, &c.

When the first rays of the pectoral fin are spiny, they are composed of single sharp-pointed bones; they are attached immediately to the scapula.

In some of the genera flurus and gasterostons the articulation with the scapula is so contrived, that the fin can at pleasure lay the spine close to the body, or place it erect, and keep it fixed in that position; there is a cylindric tubercle formed on the spine, in the front of which there is a hole. The spine of the fin is articulated with this cylinder by a depression, which has a projecting process before and behind it. When the spine is extended, the anterior process, which has the figure of a hook, enters the above-mentioned hole, and the spine turning a little on its axis, the process is hooked upon the edge of the hole in such a manner, that the spine cannot be inflected until it makes a turn upon its axis in a direction opposite to the former.

The ventral fins which correspond in fishes to the pectoral extremities are sometimes wanting, or situated at different parts of the inferior surface of the body. They do not exit amongst the cartilaginous fishes, in the genera petromyzon and fignathus; and in some species of balistes, ofracion, tetraodon, &c.

The orders of the oseous fishes are determined by naturalists from the absence or position of these fins; thus all the apodal order want the ventral fins. The anguilliformes have them situated under the throat, and before the pectoral fins. In the thoraces they are placed below the pectoral fins, and in the abdominal order of fishes the ventral fins are found under the belly, which is their proper situation, or that which their name implies.

The bones analogous to the pelvis, and which sustain the rays of the ventral fins, are various in their figure and position, with respect to each other. They are more commonly flat, and have the internal edges applied to one another in the jugular and thoracic fishes; but their inner surfaces and external or inferior edges are more or less separated, in order to accommodate the muscles which approximate and retract the rays of the fin.

In the dory (zeus faber), the pelvic bones are triangular plates, slightly concave on the surfaces next each other, and furnished with a spinous edge on both the surfaces; one angle, which is very acute, is directed obliquely inwards and forwards, towards the cavity of the body; the other angle produces a long fleshy process, and the anterior angle is blunt or a little rounded: both the anterior and posterior angles are connected by a ligament to the chain of bones forming the sterneum in this fish. The rays of the fin are articulated to the middle of the inferior surface, and not to the anterior angle, as stated by Cuvier.

We are indebted to this anatomist for some details of the structure of the ventral fins in several fishes.

In the eel (anguilla), and the flur-angler (uranophorus), the pelvic bones are adhered together at their internal edge; their inferior surfaces are opposed to each other, and leave between them an oval space. The angle of their junction projects within the cavity of the abdomen.

In the genera cottus, sebena, chleterus, and pescs the bones of the pelvis are also united at their internal edge; they are flat and long, and their external edges are directed downwards so as to form a fossa.

In some of the sticklebacks (gasterostes) the pelvic bones are separate, extremely long, and receive near their middle a movable spine, which occupies the place of the fin.

The zeus vulgar has these bones small and cylindrical. The pelvic bones are not connected to the inferior points of the scapula in the abdominals, as they are in the jugular and thoracic fishes.

In this order of fishes the bones of the pelvis are also, according to Cuvier, generally unconnected with each other, and are preferred in their situation by ligaments.

In the carps (cyprinus) they are long, and only touch about one-third from their lower end.

The herrings (clupea) they are very small, close together, and form an addition to the little bones that supply the place of the sterneum.

The pelvic bones in the pike (esox lucius) are broad and triangular; they are close together at the anterior extremity, but diverge at the posterior end, which is broader and receives the rays of the fin.

In the anableps these bones are very far apart, and bear upon their external border a very long spine, which extends towards the vertebral column, and is placed in the direction of the ribs.

In the genus flurus the pelvic bones are united to each other; they have the shape of an elongated, round in the middle, and often spinous in front. The rays of the fin are attached to their external and posterior edge.

These bones are subdivided into one piece in the genus heriocaris. The fins are conjointed to the outward edge.

The osseous rays of the ventral fins are similar to those of the pectoral fin, but in general shorter; the ventral fins are capable of being moved forwards or upwards, and of having their rays expanded, and of being brought backwards, closer together, and of having their rays approximated and folded.

The dorso, caudal, and anal fins are members superadded.
to fishes, to afford in the motions of swimming; they vary in number and extent in different species, which peculiarities it is the province of the naturalist to point out. They consist of a number of oblong rays which resemble those of the pectoral and ventral fins. The first rays of the dorsal fin are, however, frequently fleshy spiny bones, and those of the tail are generally longer, exhibit more of a jointed appearance, and are more frequently bifurcated at the extremities than the other fins of the body.

The rays of the caudal fin are furlain upon the posterior edge of the fan-shaped extremity of the last caudal vertebra, with the intervention of some small bones, which resemble the carpal bones of the pectoral fin.

The rays of the dorsal and anal fins are supported upon the extremities of long, slender, spine-shaped bones; the other extremities of these bones alternate with the extremities of the superior and inferior spiny processes of the vertebrae, to which they are attached by ligament.

These additional spiny bones are intended to increase the lateral surfaces of fishes; we therefore find them, as well as the real spiny processes of the vertebrae, long in proportion to the breadth of the body; in the flat fishes (plano-nelte) they are particularly long.

The additional spines, in some instances, as the dog (zeus faber), are united to each other by thin cartilaginous lamina, and furlain similar lamina in a vertical position with respect to the spines, by which means regular flaps are produced on each side for the muscles of the posterior part of the dorsal and the anal fins.

It remains, to complete the account of the skeleton of ossiferous fishes, to describe the bone which forms the boundary of the abdominal cavity; this bone is not unfrequently the strongest in the whole body; it is of an elongated shape, and slightly bent, rounded, and very smooth on the side next the cavity of the abdomen; it appears in many fishes like a large inferior spiny process of the vertebrae, but it is in reality a bone interpolated between some of the spiny processes of the dorsal vertebrae, and some of the additional spines of the anal fin, with both of which it is united by a sort of firm union, which appears like an archyloysis.

This bone is extremely useful in binding together and giving firmness to the pliable fabric of the tail, which otherwise would not be able to sustain the impulsion of the water during the actions of swimming. It likewise affords a smooth and firm boundary to the abdominal cavity.

The skeleton of the flat cartilaginous fishes differs in much from those above described, that it is almost impossible to discover any analogy between many of these parts.

The subjuncts we shall clime as examples of this genus of fishes are the thornback and flate (roja clarvata and roja buia).

The cartilaginous pieces which compose the cranium are so intimately united, that it is difficult to recognize them: futures, however, are discoverable, which mark out pieces that correspond to the temporal, occipital, and parietal bones.

The form of the cranium is nearly that of an oblong figure, somewhat enlarged, and irregular posteriorly. The internal surface corresponds with the external form, except where the organs of hearing are contained, at which places the cavity of the cranium is proportionally diminished.

The cavity of the cranium is also prolonged anteriorly, or, more properly speaking, is continuous with the cavity of the mouth, which renders the disproportion between it and the brain even greater than in other fishes.

The foramina for transmitting the olfactory and optic nerves are at opposite sides of the cranium.

The parts composing the face in the flat chondropterygii are few, and very unlike the bones of the face in other animals.

The cranium, as before observed, is continued anteriorly into a long, slender, hollow cartilage, which forms the central part of the snout.

Where this cartilage commences from the cranium, there is placed on each side of it a hollow cartilage or box, nearly of an oval figure, which contains the organ of succincting.

The cartilages of the snout and organs of succincting might be considered as analogous to the nasal and ethmoidal bones, the vomer, and sphenoid, united together.

Upon the external parts of the bones holding the organs of succincting, there is articulated a small irregular trunca phosphoryed cartilage, which is bent backwards: this appears to supply the place of the malar and zygomatic bones.

Both the jaws are situated under the cranium, and are sustained upon two elongated cartilaginous pieces, which correspond in office, though not in figure, with the articular bones: these pieces are connected by one of their extremities with the lower jaw, close to the articulation; and by the other extremity with the parts of the cranium which correspond to the temporal bones. The jaws are two cartilaginous rims, nearly of the same size at every part; each jaw has a movable articulation at the lympthias, by which means they can be protruded, and the figures of the mouth altered. The jaws are articulated with each other, by a round tubercle of the superior jaw being received into a socket in the inferior jaw.

The tongue is wanting, as before observed, in the ray genera. There is, however, a rim of cartilage extended between the two first branchial arches and under the membrane, lining the lower part of the mouth, which takes the place of the lingual bone, and when the mouth is widely opened forms a projection, which has been mistaken for a tongue in these fishes.

The part corresponding to the intermediate bones which sustain the inferior extremities of the branchiae, are two thin pieces of cartilage, which are united in the middle, at the posterior part have a pointed shape, and terminate before in two horn-like processes.

The cartilages which appear most analogous to the byldes are two branches which arise from the external edges of the thin pieces just described, and two other branches which are attached to the sides of the cervical spine immediately behind the last branchial arches: the branches from the intermediate cartilage ascend backwards and outwards: those from the spine descend in the same direction; they are united to each other on the anterior part of the scapula, to which also they are connected at their point of union.

The branchial arches are very strong in this genus, and the joints have a freer motion than in other fishes, by which the extremities of the arches can be brought closer to each other: a number of cartilaginous rays also arise from the convex side of each arch, which pass between the rows of the membranous lamina, as already mentioned. The inferior extremities of the arches are articulated with the cartilage, which takes the place of the cervical vertebrae, and not with the cranium, as in other fishes.

The spine is articulated with the cranium by two condyles, between which the spinal canal projects a little, and is received into a deficiency of an arched figure formed on the superior and inferior sides of the foramen magnum.

The cervical vertebrae are consolidated into one piece; on the superior and lateral parts of which cartilaginous plates are produced, which correspond to transverse and spiny processes.

The dorso and caudal vertebrae are distinct, as in other fishes.
The former furnish from the superior part of their bodies small, thin, square plates, which are connected to each other by ligament. The last have their lateral surfaces excavated by similar processes on their superior part, and some projections also inferiorly; they, however, gradually decline, and towards the extremity of the tail are feebly to be discerned. In the thoracobac (Tria cheiota), the superior processes fall into, besides the dorsal fin, a row of hook-shaped bones, which have their points turned backwards.

The bodies of all the vertebrae, except the cervical, which form but a single piece, are united by elastic ligaments; the inter-vertebral joints contain a fluid, and each vertebra is perforated in the centre by a small hole, in the same manner as in fishes generally.

A favourable opportunity for examining the nature of the inter-vertebral articulation occurred to Mr. Home: in the dissection of the bogfish Sauries (Sauries maximus). "Four days after the fish was brought on shore, the inter-vertebral substance being cut into, a limpid fluid rushed out with so much velocity that it rose to the height of four feet. At the end of twelve days a portion of the spine was examined, the inter-vertebral joints of which had been preserved entire: upon sawing through two of the vertebrae a fluid was met with, of the consistence of liquid jelly, with clots of different sizes floating in it; so that in eight days a considerable tendency to coagulation had taken place, although the fluid was entirely excluded from the air."

"The cavity between every two vertebrae was found to contain, in the Sauries, about three pints of liquid. When this fluid was evacuated, the elastic ligamentous substance which united together the concave surfaces of the two contiguous vertebrae, brought the ends of the vertebrae within an inch and one-half of each other, in which state the inner layers of the ligaments, which are less firm in their texture than the outer, project into the cavity, and may be mistaken for a part of its natural contents: this portion, when soaked in water, swells out to a considerable size, the water readily infusing itself between the layers of which it is composed."

"The whole thickness of the ligaments is about one inch, the external half of which is compact and elastic; the other appears to possess a very high degree of elasticity."

Mr. Home adds that the gelatinous substance which fills the inter-vertebral joints of other fishes is fluid during life, which fact was verified in the Sauries (Sauries bat). Mr. Bodie found that in the hog and rabbit the central part of the inter-vertebral joints contains a cavity with a smooth internal surface, of the extent of half the diameter of the vertebra, which is filled with a thick gelatinous fluid; and we have observed the same fact in other quadrupeds, from which it would appear that the mode of articulation in the spine of fishes is not absolutely peculiar to them.

Mr. Home describes the structure in the spine of theurgeon (Aipenser fluvior) as being different from that of other fishes.

"There is," he says, "extremely, the common appearance of regular vertebrae; but these prove to be only cartilaginous rings, the edges of which are nearly in contact, and are united together by elastic ligaments, forming a tube the whole length of the spine. This is lined, throughout its internal surface, with a fine, smooth, elastic substance; within this is a soft, flexible substance, in a small degree elastic; in the centre there is a chain of cavities in the form of lozenges, containing a fluid, and communicating with one another by very small spouts. The spine of the lamprey el (Petromyzon marinus) is found to resemble that of theurgeon."

The above structure is not so different from that of the spine of fishes in general, as it would at first seem to be; since we have discovered the communication between the inter-vertebral cavities to exist both in the cartilaginous and bony tribes of fishes.

Cuvier states that there are no ribs in the chondropterygii; but we find on the sides of the bodies of the dorsal vertebrae a number of short-pointed processes, which might be considered as rudiments of these parts.

The pectoral member of the ray genus is peculiar in its form and direction, and is of prodigious magnitude. The pieces which form the rays of the fin are analogous to the feathers; they are connected with the back part of the dorsal spine by means of two thin, flat cartilages. They pass outwards, enlarge, and form two wide foramina on each side, through which the nerves and vessels pass to the fin. The scapula next produces two branches, one of which affords backwards nearly parallel with the spine, and the other goes forwards as far as the anterior part of the head; these branches have several joints in them, by which they can be moved nearer and farther from the body.

The scapula are united on the under part of the fish by a strong cartilaginous bar, which supplies the place both of the sternum and clavicles. The rays of the fin arise from the external side of the branchial, which is slightly concave; they are exceedingly long, particularly in the middle of the fin, and each composed evidently of many joints. It is upon the great number and extent of the rays of the pectoral fin that the peculiar square figure of the flabit chondropterygii depends.

The pectoral fins of the Sauries are constructed upon the same plan as in the genus Sauries, but are much smaller, and are not connected to the spine.

The ventral fins are supported upon the extremities of a transverse piece of cartilage in the chondropterygii, which is situated at the posterior part of the abdomen; it is not attached to the spine, but held in its place by its connection with the muscles.

The external rays of the ventral fin in these fishes are stronger than the others, and are composed of some pieces articulated to each other in succession, which very much resemble the joints of the digit in other animals, and which, therefore, form the analogy which exists between the rays of the fins of fishes in general, and the fingers or toes of the amniotes.

Figs. 1. Plate XII. of the Anatomy of Fishes, exhibits a lateral view of the skeleton of the dog (neus flexor); a is the cranium; b, the cavity between the two orbits; c, the sphenum; d, the part corresponding to the lacrymal bone; e, the piece which appears analogous to the ethmoidal bone; f, the nasal bone; g, the ossicus flatus, which comes from the occiput to join the vomer; h, the bone analogous to the malar, or the palate; i, the superior maxillary bone; k, the intermaxillary bone; l, the inferior jaw; m, the articular bone by which the lower jaw is connected to the head; n, the os hyoideum, on the edge of which are seen the rays of the membrane branchiole; o, the lingual bone; p, the principal bone of the operculum; q, the other bone of the gill-cover; r, the superior pharyngeal bone; s, the branchial arches; t, the inferior pharyngeal bones; u, the cordiform bone. As these last parts are situated internally, they are seen imperfectly; r, the operculum; s, the bone analogous to the clavicle; t, the carpus, on which are arranged the rays of the pectoral fin; u, the chain of bones formed under the integuments, in the manner of a flipper; w, the pelvis, on which are seen the rays of the ventral fin; x, y, z, the cervical, dorsal, and caudal divisions of the spine; from the two flaps of which long, spinous processes are seen to proceed upwards, and to furnish the additional
tional spinosus bones on which the dorsal fins are articulated. From the inferior part of the caudal, and some of the last dorsal vertebrae, spinosus processes are seen to arise, which become connected with the additional spines supporting the anal fin, and of which some are united to the extremity of the bone that bounds the abdominal cavity. The extremity of the tail produces the fan-shaped bone, which bears the caudal fin; y, the true or abdominal ribs; z, some spimnary ribs which are designed to pass amongst the muscles of the spine.

Fig. 2. of the same plate, shows the cavity which exists between the vertebrae of an offcous fish; a, a, two of the vertebrae of the turbat (pleuronektes maximus), divided longitudinally; b, b, ligamentous tubercles by which they are united; c, the internal vertebral cavity.

Fig. 3. of Plate XII. of the Anatomy of Fishes, gives a view of the cavity in one vertebral; a, the body of the bone; b, spinosus processes partly cut away; c, the canal for holding the spinal marrow; d, the concavity of the intervertebral joint; e, the foramen, or rather short canal, by which the inter-vertebral cavities communicate with each other.

Fig. 1. of Plate XIII. of the Anatomy of Fishes, represents the inferior parts of the skeleton of the thornyback (rhgus clavara); a, the cranium; b, the cartilage which forms the middle of the fin; c, c, the oval cavities for containing the organs of smelling; d, d, the branches articulated upon the external part of these cavities; e, e, the two jaws; f, f, the cartilages analogous to the articular bones by which the jaws are connected to the cranium; g, the rim of cartilage that supplies the place of the ligamental bone; h, the intermediate cartilage to which the lower extremities of the branchial arches are united; i, i, the inferior branches which seem to supply the place of the os hyoides; j, j, the superior branches of the same; k, k, the vertebrae; l, l, the cervical portion of the spine, consolidated into one piece; n, the dorsal portion of the spine; o, the caudal division; p, p, short processes from the files of the dorsal vertebrae, that correspond to the ribs; q, the transverse bar that answers for clavicles and sternum; r, r, r, r, the branches of the scapula; the bodies of the scapula, and the connection of these parts with the spine, are in a great measure concealed from view; s, s, s, s, the rays of the pectoral fish; t, the transverse cartilage which bears the ventral fins, laid across the spine in its proper situation; u, u, the rays of the fin which more particularly resemble, in their figure and mode of articulation, the digit of other animals; v, v, the smaller rays of the same fins. The rays of the other fins, having no peculiarity of structure, are indicated by their position.

Fig. 2. of Plate XIII. exhibits a view of the articular surface of one of the dorsal vertebrae of the thornyback; a, the body of the vertebra; b, the canal for lodging the medulla spinalis; c, the spino- nus processes; d, the concavity opposed to that of the adjoining vertebrae; e, the perforation in the centre of the vertebra, by which the inter-articular cavities communicate with each other.

Muciles.

The muciles which move the jaws of fishes are commonly large, and calculated for powerful and extensive action. They are more numerous and complicated in the cartilaginous than the osseous fishes. We shall first describe them in the ray genus.

The principal depressor of the posterior jaw is a single, flat, square muscle, which arises from the transverse bar that is analogous to clavicles, and is inserted into the posterior margin of the jaw. Cuvier also describes two small muciles, one on each side of that just mentioned, which contribute to the depression of the jaw: they arise from the transverse bar and the skin, and are inserted near the commissure of the lips. These three muciles retract the mouth, as well as depress the lower jaw.

Three muciles close the jaws: the first arises from the external part of the base of the cranium; it passes over the superior jaw, and is lost in the aponeurosis which covers the principal muscle, at the external part of the mouth. The second muscle is a thinner flip; it arises from the fore-part of the lower jaw, passes in a circular manner round the angles of the mouth, somewhat like the orbicularis oris; then over the upper jaw, to the superior part of the end of which it is inserted. The third of these muciles brings the jaws forwards on the head, as well as of flutting them. The third muscle is a large round-shaped muscle, which encircles the articulation and the ends of the two jaws: it appears externally like one muscle, but consists internally of three parts; one is inserted into the ring-like processes at the end of the lower jaw; another into the external parts of both jaws, at their joint; and the third passes round the upper jaw, and is inserted by a tendon into the cruci-ligament which goes to the lower jaw.

There are two very long muciles which come from the spine, and pass between the palate and the cranium, in order to be inserted into the superior jaw. These serve to bring the mouth forwards, as both jaws, from their connection with each other and the neighbouring parts, are protruded and retracted together.

A pair of very thick muscles arise from each side of the sternum; their fibres are divided obliquely forwards and outwards, and unite upon a strong tendon, which is inserted into the inferior extremity of the articular cartilage that sustains the jaw. They draw that extremity backwards and inwards and consequently enlarge the angle this cartilage forms anteriorly with the base of the cranium: they carry both jaws downwards, and by bringing their extremities nearer to each other, thrust out or protrude the middle parts of the mouth. These muscles likewise maintain the articular cartilages in the above-mentioned position, and furnish fixed points for the jaws to move upon, when they are projected from the head.

Two other muscles, which are small, commence by tendon from the middle of the articular cartilage; proceed backwards, inwards, and downwards, in order to spread their fleasy fibres on the aponeuroses behind the lower jaw. They assist the preceding muscles in bringing the articular cartilage inwards and downwards.

The muciles of the jaws in the fish (squalus) resemble those of the ray genus.

In the sturgeon (acipenser flavio) the muscles for protruding and retracting the jaws are very simple. The one which brings the mouth forwards comes from behind the eye: it is very strong, and passes backwards to be attached to the articular cartilage. The retractor is a much smaller muscle: it is situated between the cranium and the superior part of the articular cartilage.

The other muciles of the jaws of the sturgeon resemble those of the ray and shark genera.

The muciles of the jaws in the genera belton, tetraodon, diodon, and stenias, are described by Cuvier as having a complicated action. The bones of the face are extremely prolonged in these fishes, in order to form a prominent muzzle, at the extremity of which the two jaws are placed, and perform their movements.

One muscle, which fills the superior part of the fossa on the side of the muzzle, arises from a ligament which complete
pletes the anterior border of the orbit; its flabby fibers, in
passing from behind forwards, terminate in part upon the
posterior border of the descending branch of the superior
jaw, but are chiefly lost on a tendon which surrounds the
extremity of that branch, and proceeds to the lower jaw,
on which it is inserted above the articulation. This muscle
moves the two jaws in opposite directions, and approximates
the one to the other. In drawing backwards and upwards
the extremity of the descending branch of the superior jaw,
it depresses the portion of that jaw which is beyond the
point of support. The same muscle likewise raises the lower
jaw.

A second muscle fills the inferior portion of the fossa that
is on the side of the muzzle, from the surface of which its
fibers arise: they proceed obliquely forwards and inwards to
an aponeurosis, which extends along the internal edge of
the fossa, and of which the extremity goes to be affixed to
the internal surface of the lower jaw. This muscle has the
same action as the first.

The preceding muscle covers a third, which is smaller.
It arises likewise from the surface of the fossa, and sends a
flabby tendon near to the posterior edge of the descending
branch of the superior jaw. This muscle co-operates with
the two others.

The inferior jaw is depressed, in the families, by three
muscles. The first is a single muscle, which is analogous to
the mylo-hyoides: it arises from the side of the hyoides,
between the rays of the operculum, and is inserted into the
inferior border of the lower jaw; the fibers converge, and go
forwards to be inserted into the inferior edge of the lower
jaw. The next two muscles are small: they arise from a
fossa under the orbit; their tendons are inserted into the
posterior edge of a cartilaginous plate, which is connected to
the base of the cranium, behind the articular bone. This
plate is attached to a long cartilaginous filament, which
advances on the side of the articular bone or cartilage, as
far as the inferior and internal part of the lower jaw. In draw-
ing the plate upwards and backwards, these muscles also
bring the filament backwards, and thus depress the lower
jaw.

The moon fish (tetraodon mola) has three muscles, similar
to those last described, and a second cartilaginous plate.
In the genus holyear there is a muscle which serves to
elevate and draw backwards the piece analogous to the
articular bones; it arises from the lower edge of the vomer,
or the vault of the palate, and descends obliquely forwards
to be inserted into the upper edge of that piece.

In other fishes, the lower jaw is depressed by a long
flabby muscle, but which, nevertheless, from its attach-
ments and use, must be considered analogous to the
mylo-hyoides: it arises from both sides of the os hyoides
and rays of the gill-cover, in two broad, thin, flabby slips; these
unite under the throat, and are inserted at the symphyses
of the lower jaw; it spreads the membrane of the gill-cover
when the jaw is fixed.

The lower jaws are elevated by two very strong portions
of muscle, which in a degree overlap and intermix with each
other; they occupy all the space corresponding to the
articular bone, from which, and from the cranium at the
back of the orbit, they arise. The two portions, which
Cuvier considers as but one muscle, are inserted into the
coronal processes of the lower jaw, into the ligament which
passes from one jaw to the other, and in some fishes we
have observed into a ligament which goes forwards to the
inter-maxillary bones: besides, therefore, raising the lower
jaw, these muscles depress the superior maxillary bones,
and depress and retract the inter-maxillary bones, which form
the superior margin of the mouth, or what is called the
upper lip in fishes.

Cuvier describes in the 
*muraena anguilla* two layers
of muscle which lie under the preceding, and are nearly
inserted into the same point of the lower jaw: they arise
from the orbita fossae. He detected similar muscles in the
carp, but did not find them in the 
viper (goyx loris), the
trouth (salmo feris), or the salmone (salmo salar); we have not
observed them in any other fish.

There is a small muscle which is attached to almost
the whole of the internal surface of the side of the lower jaw,
and covers the ventricle which exists in the maxillary bone: it
furnishes a strong tendon, which is fixed internally to the
lower and anterior part of the articular bone; it affords
the other muscles in raising the lower jaw, but if the
mouth be previously opened widely, it serves to have the
power of keeping the lower jaw in the depressed position.

The articular bone is moved by two muscles on each side:
one arises from the cranium at the back and upper
part of the orbit; its fibers pass obliquely downwards
and forwards, and are affixed upon the external surface of
the thin part of the articular bone, near its upper edge:
the effect of its action is to elevate the articular bone
and bring them outwards, by which the capacity of the mouth
is increased, and the jaws retracted. The other muscle
arises from the vomer, membranous septum of the orbit,
and the middle line of the cranium: its fibers descend in a
direct manner to the upper part of the thin portion of the
articular bone. which it has the power of bringing inwards,
and thereby abridges the cavity of the mouth, and protrudes
the jaws.

Cuvier describes two muscles in the carp (cyprinus carpio),
intended to retract the lips in this species, which has the
bones of the face formed for carrying the mouth farther
forwards than other fishes. The first of these muscles is
shorter than the second; it arises partly from the anterior
extremity of the articular bone, and in part from the poste-
rior end of the maxillary bone: it ascends a little obliquely
to be inserted into the most elevated point of the inter-
maxillary bone by a slender round tendon, which crosses
the tendon of the next muscle. The second retractor of the
lip is much larger than the preceding: it is situated
nearly horizontally, in the space comprised between the
inferior edge of the orbit, and the concavity of the arti-
cular bone, from which it arises; it is inserted by a long
flat tendon to the middle and posterior processes of the inter-
maxillary bone, which it draws directly backwards.

From the preceding description it will be perceived,
that in addition to the motions of the jaws, by which the
mouth is shut and opened, they are also insensible to
projection and retraction, and that the cavity of the mouth
is altered with respect to its width or its length in the
performance of these motions. These effects are not only
convenient to fishes in the act of taking their food, but are
necessary also for conveying it into the oesophagus. The
muscles, however, most immediately concerned in de-
stitution, are those which move the branchial arches and
pharyngeal bones, as will appear when these muscles come to
be described.

The tongue of fishes scarcely appears to perform any
motions distinct from the other parts of the mouth.
Cuvier, it is true, has described two muscles on the tongue
of the *conger (muraena conger)*, which are analogous to the
mylo-hyoides; they arise from the extremities of the os hyoides,
and go forwards upon each side of the lingual bone, to
which they are inserted: if these muscles act in conjunction
they depress the tongue, but, if separately, the tongue is
drawn
drawn to either side. Cuvier likewise states that the tongue of the conger is contracted in its breadth by some transverse fibres, which pass from the edges to the middle part; we have not observed any muscles for moving the tongue in those species we have dissected, but we have often seen tendinous fibres pass from the os hyoidei to the sides of the lingual bone.

The muscles intended to move the branchial arches and the pterygoid bones in offium fishes are too numerous and complicated, that we almost despair of giving the reader a clear conception of them. They may be divided into three sets or orders, besides some distinct muscles; the first is composed of a cluster of muscles, which connect the superior ends or abutments of the branchial arches, and the inferior pterygoid bones to the bony sides of the cranium. The second set consists of a few muscles placed over the joints of the inferior ends of the arches, and the inferior pterygoid bones, with the intermediate bones that are connected to the lingual bone; the third set is made by muscles which surround the posterior side of the last branchial arch, the pterygoid bones, and the origin of the esophagus.

In the first set there are seven muscles; all these, except one, are attached from the side of the head, immediately beyond the orbit, at the joint of the articular bone.

The first muscle comes from the common origin already mentioned, and is inserted into the posterior side of the base of the short branch of the first branchial arch; it bends the joint of the arch, and brings the whole arch forwards.

The second arises from the same point, and goes to be attached to the posterior side of the short branch of the second branchial arch. It has the same effect as the preceding.

The third muscle arises from the base of the cranium, between the articulations of the scapula and articular bone, and is inserted into the posterior edge of the short branch of the last branchial arch. It elevates the last arch, and thereby affilts in opening the esophagus.

The fourth comes from the common point of attachment, and terminates upon the footstalk of the three half branchial arches, and the small anterior pterygoid bone; it tends to draw these bones outwards, and thus dilate the opening into the esophagus.

The fifth muscle arises with the others, and proceeds to be affixed to the external edge of the principal pterygoid bone. Its operation is similar to that of the last mentioned muscle.

The sixth arises from the common footstalk of the three last arches, and goes on to the external edge of the short branch of the second arch near its base. It contracts the arches, by binding the joint at the concavity of the arch, and that at the footstalk; it therefore tends to close the gills.

The seventh muscle has the same origin as the preceding; it is a stronger muscle, and is spread equally upon the anterior surfaces of the two last branchial arches; it concurs to produce the effect ascribed to the last mentioned muscle.

The second set of branchial muscles is made up of four pairs, or eight slips on each side; four of these are longer than the others, and situated more obliquely and superficially.

The first arises from the ligament which connects the conjoined processes of the two posterior arches to the lower end of the first intermediate bone; it proceeds obliquely backwards, and is affixed to the inferior end or abutment of the second branchial arch. The next three arise together from the conjoined processes of the two last arches already mentioned. One goes to be implanted into the inferior end of the third branchial arch, the next is inserted into the fourth branchial arch, and the fourth lies in the interior pterygoid bone.

The four other muscles of this set are short, lie in an obliquely transverse direction, and are in a great measure concealed by the preceding muscles; they are extended from the inferior ends of the branchial arches to the adjoining parts of the intermediate bones.

The effect of the action of each of these muscles is the same; they all tend to depress the lower part of the mouth, if the branchial arches be rendered fixed; and if not, they separate the arches from each other, and lower them, thus opening the gills, and widening the aperture of the esophagus.

The circle which is made round the entrance into the esophagus by the last branchial arches and the pterygoid bones of each side, has on its posterior surface a chain of small muscles.

The two first arise from the junction of the footstalks of the inferior pterygoid bones, and are inserted into the most external points of these bones. They approximate the pterygoid bones, and bring them downwards.

The next pair arise from the outside of the termination of the preceding muscles, and are inserted near the middle of the posterior surface of the last arch. They approximate the two last arches by means of their connection with the inferior pterygoid bones.

The third pair of muscles are extended across the joint of the last arches, and consequently, when they act, bring the branches of the arches together.

The fourth muscles arise from the footstalks of the superior pterygoid bones, and are inserted into the points of the inferior abutments of the last arches. They make these abutments approach the superior pterygoid bones, by which the arch is closed.

Besides these four pairs, there are four slips of muscle, which pass from the pterygoid bones of one side to the other. The muscle connecting the superior pterygoid bones is very strong. These complete the circle, and diminish it by approximating these bones.

There are further, a number of muscular fasciculi surrounding the orifice of the esophagus in the manner of a sphincter. These fasciculi are thrown up upon the sides, where they have also nearly a straight direction, by which they have the effect of contracting the joint of the last arch. There are likewise some fibres extended from the muscle that lies between the superior pterygoid bones, to the sphincter of the esophagus.

When all the muscles of this set co-operate, the opening into the esophagus is abridged; or, if the animal wilt it, entirely closed; from the connection between the last arch and the others, they are all brought close together, and the dentilated surfaces of the inside of the arches, and of the pterygoid bones, are made to approach near, as to prevent the escape of the prey which the fish may be in the act of swallowing.

There are four distinct and remarkable muscles on each side, which are materially concerned in the motions of the gills and pharynx.

The first are very thick and massy: they take their origin from the anterior edge of nearly the lower half of the saeula, and are inserted upon the sides of the broad, thin, heart-shaped bone which is situated under the throat of the fish. By means of the connection of this bone with the hyoid
Fish.

Hyoid branches, intermediate bones, &c. Those muscles will open the pharynx, by depressing the tongue and branchial arches. If these parts, however, be kept fixed, they will bring the pectoral member forwards; they will also depress the lower jaw, in consequence of the connection the heart-shaped bone has with that part. Cuvier considers these muscles as analogous to the _flessoHolotii._

The second muscles arise on each side from the anterior edge of the scapula, opposite to the middle of the muscles raising the pectoral fins. They are thin slips; they pass through the substance of the muscles last described, and go to be inserted in the lowest part of the inferior pharyngeal bone. They depress the branchial arches, and thereby widen the pharynx.

The third pair of muscles arise by a small tendon from the anterior part of the scapula, opposite to the articulation of the clavicle with that bone, and proceed for some way before they reach the point of their insertion, which is the lowest part of junction of the inferior pharyngeal bones. They draw the pharyngeal bones downwards and backwards, and thereby contribute, with those last described, to open the pharynx, and render it of a round shape.

The fourth muscles arise from the second vertebra from the head, diverging a little in their course, as they proceed a considerable way forward, and are attached to the inside of the superior pharyngeal bones. They have the power of retracting these bones, and thus co-operate with the other muscles which dilate the entrance into the eosophagus. They likewise turn the superior pharyngeal bones, so as to oppose to each other their rough or denticulated surfaces. These muscles are strong, and remarkable also on account of their length: they arise as far back, in the subscapula (glandus meralangi), as the fifth vertebra from the cranium.

The preceding description of the branchial and pharyngeal muscles contains what we have observed in the _dogus (caus faber)._ The structure of other effuse fishes, in this respect, does not appear to be materially different. In some of them, the bundle of muscles, by which the branchial arches and the pharyngeal bones are supported to the cranium, is composed of a fewer number; and those for contracting the passage into the eosophagus are less distinct and strong. The most remarkable variation is met with in the _carp (cyprinus carpio),_ in which the pharyngeal bones are constructed for breaking and dividing the food. In this fish, the inferior pharyngeal bones are not, as usual, attached to the last branchial arches, but are elevated behind these near to the cranium, to which they are supported by a number of muscles, of which Cuvier has given the following description.

There are first two exceedingly strong muscles attached to the sides of the base of the cranium, behind the adductor of the operculum, and inserted into the superior extremity of these bones. They elevate the bones, and draw them a little outwards.

Two other muscles arise from the external angle of the glenoid cavity, which receives the superior pharyngeal bone, and go to be inserted along with the first muscles. They bring the superior extremity of the pharyngeal bone inwards.

Two strong muscles are affixed by their anterior extremity to the middle part of the pharyngeal bones, and proceed obliquely backwards and inwards to be inserted into the occipital apophysis. They draw the pharyngeal bones backwards.

The pharyngeal bones are supported by a very strong single muscle, which Cuvier, both from considering its structure and use, calls the _digastric adductor._ The two bellies of which it is composed arise from the middle part of each of these bones, and are inserted into a common tendon, placed in the interval of the anterior portion of those bones, and is there connected to the spongy fibres which fill up that interval, affixed by some transverse fibres of the pharynx, which go from one pharyngeal bone to the other. This muscle is able to approximate the bones with much force, and to urge their teeth against the superior plate. The operation of these muscles belongs rather to the functions of mastication and deglutition than to those of the gills.

Two strong muscles arise from the internal surface of the scapula, and are inserted by a very strong tendon to the anterior extremity of the pharyngeal bones. They bring the scapula forwards and inwards; or if it be fixed, they bring the two pharyngeal bones at the same time backwards and downwards.

Two other muscles, attached at one part to the inferior side of the anterior part of the pharyngeal bones, and at the other to the internal surface of the scapula, may likewise approximate the inferior extremities of the scapula from the middle line; but they can more easily separate the pharyngeal bones the one from the other.

Finally, there are two long slender muscles, which are extended from the inferior and anterior extremity of the pharyngeal bones to a process, which corresponds to the intermediate bone of the last arch. These bring the pharyngeal bones forwards.

The branchial muscles in the _frondemorphynx_, and, as it would appear, in all the fishes with _fixed branchia_, are few and simply arranged. The cluster of muscles which connects the branchiæ with the head, and the small muscles which go from the branchial arches to the intermediate bone, do not exist in these fishes.

The flender muscles which go from the clavicle to the archæ, in effuse fishes, are supplied in the _rays_ by two very strong muscles, which arise posteriorly by two thick tendons from the transverse cartilage, and proceed obliquely forwards and inwards, under the middle cartilage of the branchiæ, into which they are inserted. In drawing this cartilage downwards and backwards, they open all the branchial arches.

There are other muscles constructed to open and shut the branchiæ, which are peculiar to the _rays_ and _shark_ kind.

Between the anterior bones of the rami and the rays of the branchiæ, a muscle is found, the fibres of which seem to separate on each side from the middle ray, being directed towards the others, but particularly towards their extremity, so that the effect of their action is to approximate the extremities of the rays, and consequently to separate and open the two ends of the arch. The action of this muscle is limited by several ligaments, which go from the base of the ray, nearest the extremity of the arch, towards the extremity of the succeeding ray.

This arch is closed by another muscle, which is short, thick, and cylindrical. It is situated transversely on the angle that is formed by the two pieces of the arch, where there are three ligaments of some depth, in which the two extremities of the muscle are implanted.

There is further, in these genera, a very strong muscle, which envelopes the gills, covering every part of them except that next the mouth; it has the effect of compressing or approximating the whole at once. The fibres are parallel, and have an oblique direction from before backwards. Five tendinous intercurrences are to be seen, which correspond to the external surface of the muscles already described.
which lie between the laminae and rays of the branchio-
which lie between the laminae and rays of the branchio-
type of muscle has the effect of
between two muscles; the one upon the external, and the
the other upon the internal side. These are analogous to the
mucular fæce of the ray and shark kind.

The operculum of the gills in _officous_ fishes is raised by one
pair of muscles, and brought down upon the branchial apert-
ure by two muscles on each side, and one common to both

The elevator or adductor of the operculum arises from the
external part of the bale of the cranium, at the root or joint
of the articular bone: it is a short, taper muscle, and is in-
ferred into the head of the triangular bone of the gill-cover,
which is joined to the articular bone. This muscle acts
under the disadvantage of being infixed as far as possible
from the edge of the bone that is to be raised: it must,
however, be aided in producing its effects by the elevation
of the articular bone.

The two muscles which flunt the operculum are described
by Cuvier as only one: they arise from the bale of the cra-
nium, almost immediately behind the preceding muscle, and
which they form a thicker mass; they are inserted into the
neck, or anterior part of the superior edge of the triangular
bone.

The common muscle is attached internally to the rays and
offensive plates of each gill-cover, between which the fibres
cross from one side to the other. The effects of this muscle's
motion are the approximation of the rays and the shuttling
down of both operculae.

The rays of the gill-covers are expanded, and the mem-
brane branchiolygrous and spread out, by the mylo-
yoideus muscle which is attached to the offensive rays, and
by a muscle composed of two portions, which Cuvier de-
scribes as being particularly plain in the _tent_ (falmo fario):
one portion arises from the lower edge of the posterior part
of the os hyoideus; the other arises from the internal surface
of the five anterior rays, and is attached to the other rays by
long tendinous filaments. Both portions unite in one ten-
don, which passes under the anterior extremity of the oppo-
site branch of the hyoideus, and is expanded under the lingual
bone.

Besides these muscles, the _moon-fish_ (tetraodon sola) has
the operculum itself composed of several muscles. The
principal one, which forms almost the whole of the operculum,

The very limited motions of the head, upon the spine of
officous fishes, are effected chiefly by the great lateral muscles;

The principal elevator of the head is a long small muscle,
which arises from the base of the shoulder, on the top of the
cartilage which corresponds to the scapula, and the adjoin-
ing transverse procés of the cervical spine: it tends a long
tendon through a pulley on the side of the eye, which is
left in the anterior part of the font.

On the lower part of the head there is a pair of muscles,
similar to those for raising the head: they arise from the
transverse cartilage, analogous to clavicles and flerrum, at
which place the muscle of each side is united; they proceed
forwards on each side of the mouth, and furnish tendons
which pass in the gelatinous substance of the face, at the
anterior extremity of which they terminate. These muscles
deprive the head. Cuvier gives a somewhat different de-
scription than we have given of the foregoing muscle.

A third pair of muscles arise from the spinal column, and
the anterior portion of the arch which furnishes the large
wings, and are inserted into the posterior extremity of the head.

The main muscles, except in the flat chondropterygis, are
the most remarkable in the fish's body, whether we view
them with respect to their bulk or their structure.

These muscles are analogous to those which lie along the
spine of other animals; but, from the form of the skeleton in
fishes, they are situated upon the sides of the body, and have
sequently received the name of _lateral muscles._

The face of the lateral or spinal muscles exceeds, in an ex-
traordinary proportion, that of all the other muscles of a
fish; they make the principal bulk of the animal, as they
constitute, with the fijtuous fabric which fills them, al-
most the whole of the organs of motion.

It is a most impossible to convey a clear idea of the com-
position of these muscles by description alone, it is to ex-
tremely complicated, and to different from the ordinary
structure of the muscles in other animals.

The great spinal muscles of fishes in general consist of
three portions, which, from their situation, deserve to be dif-
tinguished into the _superior_ or dorso-lateral, the _middle_ or _vertebral_,
and the _inferior_ or _undervisal_, portions.

The muscular fibres of which each of these muscles is
composed, are formed into successive _layers or rows_, by
means of the interpolation of thin aponeuroses. These
muscular interpositions merely exhibit, on the external sur-
face of the lateral muscles, the appearance of lines placed
at short and determined distances from each other, and
thus subdividing each portion into a number of regular
compartments. The subdivisions or compartments have dif-
frent forms or directions in each portion, which will be after-
wards pointed out. The short rows of muscle that fill up
the compartments appear, when viewed upon the external
surface, to be all arranged in a longitudinal direction, or to
follow one another in the line of the fish's body; but if ac-
curately examined, they will be found to consist of flakes or
pieces of muscle, which partake of the figure of a wedge and
the bow of a spoon, being thick at one edge and thin at
the other, and concave on one side and convex on the other.
The figure of the flakes is well exhibited by the application
of heat, particularly in the genus _gadus_; in cooking the
 MacBook Air
The interflections of the ventral portions of the lateral muscle describe very faint curves on the fore part of the body, at which place they are, rather indistinct, but towards the tail they form V-shaped lines, which come gradually closer to each other, until at length they compose parallel tendons, in the same manner as the connected vertebral and dorsal portions.

This portion of the lateral muscles, besides being a powerful flexor of the tail, compresses the ventral and branchial cavities, and is therefore analogous to the intercostal and abdominal muscles of other animals.

The preceding description is taken from the 'Dory (zatus falter); a fish which has the lateral muscles particularly distinct and strong. In the other species we have described, we have found the structure to be similar, that the 'dory may be given as a general example of the class.

In some of the flatfish (Pleuronectes) the ventral portion of the lateral muscle appears to be double, or to be composed of two parts which join each other in the line of the angle of the interflections, and therefore correspond to the dorsal and vertebral portions. Mr. Carlisle, in the Croadian Lecture for 1805, describes the ventral portions as being always of two masses, which he calls the ventral and abdominal feathers.

In the 'mackerel (Scomber scombrus), the 'burring (Alypea harengus), and some others, we have observed a layer of muscle of a dark colour, extended along the middle line of the body; if this layer be cut transversely, it exhibits the figure of a compressed triangle. It is lodged in a corresponding vacancy, which is formed along the junction of the other portions of the lateral muscle over the spine of the fish: this long stripe of muscle has probably no peculiar action, as the interflections of the adjoining parts are continued through it in the same direction as in other fishes.

The lateral muscles of the genus 'effusion differ in some circumstances from those of other fishes. As the 'effusions have the body rendered immovable by being inclosed in a hard horny shell or case, these muscles are not connected to the spine, but to the head and the tail only. Their structure also is not so complicated as in other instances, their fibres being principally longitudinal.

The internal surface of the case of the 'effusion is lined with an aponurocytous only.

Cuvier describes an additional pair of muscles that are peculiar to the tail of these fishes; they are of a pyramidal figure; they arise from the inner side of the case, on the lower or abdominal side of the body, and are inserted by small tendons into the inferior part of the side of the last caudal vertebra. They carry the tail to either side, and departs.

The motion of swimming consists almost entirely in the flexion and subsequent extension of the spine of fishes; in the production of both which effects, the lateral muscles are the sole agents, by one line or part acting alternately, or in opposition with another. The peculiar composition and arrangement of these muscles are designed to bring extraordinary power and velocity of action, combined with a limited operation as to extent and duration. The weight of the column of water displaced by every impulse of a fish, during the act of swimming, and the celerity with which some species move through water, not even exceeded by that of the flight of birds, has to rare a mechanism as to prove the power and rapid operation of the spinal muscles, while the limited capacity of flexion of the tail of fishes, and the exhaustion these animals experience when their muscular efforts are protracted, show that the spinal muscles are incapable
FISH.

Pable of an extensive or long continued action. Mr. Carllide has very ingeniously attributed the physiological properties of the lateral muscles to the arrangement of their fibres, and the minute ramifications of their blood-vessels, which do not admit the red particles; and he contrails this structure, and the kind of muscular power consequent upon it, with the organization and functions of the muscles of tardigrade animals. See Phil. Trans. part 1. 1826.

It has been already observed that the spinal muscles of the flat chondropterygii, or the ray genus, are excepted from the description of the general structure of these parts in other fishes. They are formed more upon the plan of the muscles of the tail of certain quadrupeds, than like those of their own class.

Cuvier describes the lateral muscles of the ray genus as being composed of two layers, and each layer consisting of two muscles. As we have not particularly described them, we shall adopt his description.

The superior lateral muscles arise from the middle of the vertebral column above the abdomen, by a flabby head, covered with strong apaneuroves: this portion extends as far as the pelvis, and then detaches itself to form branches, which pass through parallel sheaths, and proceed successively towards the middle line, where they are inserted into the upper part of each of the vertebrae of the tail. Flabby fibres accompany these tendons to some distance, after their separation from the common fascicule.

In the inferior part of the tail the superior lateral muscles receive accessory fibres from each side, but these are simple tendons, which seem only intended to guard against two violent an extension, either to one side or the other.

Each tendon of the superior lateral muscles pulls the vertebrae of the tail, to which it is attached, in the direction of its own action, and the flexion, or general curvature of the tail upwards, is the result of their common contraction.

The inferior lateral muscles arise also from the lumbar vertebrae, like the preceding, but more externally. Their arrangement also is similar, with this difference, that their tendons make a kind of turn, and run under the tail, where they are inserted into each of the vertebrae. They also receive accessory tendons. They produce motions in an opposite direction to those of the superior muscles, that is to say, they bend the tail downwards. Their tendons are more slender than those of the former. They divide into two branches at their extremities, and each bifurcation affords a passage for that of the next vertebra, so that they mutually serve as sheaths; and are all, except the last, both perforating and perforated.

The spinal muscles consist of flake, and are pale, as in the officious fishes, although their form is different in this genus.

The dorsal, anal, and caudal fins are moved by a great number of small muscles. In the interval left between the dorsal portions of the lateral muscles, along the back, there are found some long flender muscles, extended from the neck to the first ray of the dorsal fin, and between the dorsal fins, where there exist more than one, and from the dorsal to the caudal fin. By means of the infection of these muscles into the first ray of each of the fins they tend to raise and spread them.

The number of these muscles varies according to the excellence or number of the dorsal fin. In the gymnotus, and some others which want the dorsal fin, there is only a single pair, which extends from the neck to the caudal fin. In the species which possess one dorsal fin, there are two pairs, and in those that have two dorsal fins there are three pairs.

There are muscles corresponding to the above, placed upon the lower or inter-articular edge of the fins, intended for the expansion of the anal and caudal fins. Cuvier describes two pairs of these in the carp (Cyprinus carpio). The one arises from the junction of the bones which sustain the pectoral fins, and is inserted on each side into the ligamentous suture which unites the two ventral fins; the other arises, of this pair of muscles is composed, are four or five in number, in form resembling beads, and placed at some distance from each other.

The other pair extend from the anal fins to the first rays of the caudal fin. These flender portions are still thinner, and their tendons much longer than those of the former pair.

The other motions of the dorsoal and anal fins are accomplished by means of a number of slender muscles, resembling in their form and position the intercosti of the hand. They lie upon the spines, which are added to the spines procured the dorsal and caudal vertebrae, for the purpose of sustaining the dorsoal and anal fins. There are two sets or series of these muscles, a superficial and a deep-seated; the first arises from an apaneurose which lies the skin, and furnishes fepta to form a sort of sheath to each of these muscles, and which, by adhering along the roots of the additional vertebral spines, makes a degree of sheath also for the free margins of the lateral muscles; these muscles are inserted into the bastes of each of the rudi of the fins. The immediate effect of their action is to bend the rays of the fin laterally, if those of one side only are employed; but, if both sides act, the rays are brought closer to the body; if already inclined that way, but if standing in a right angle with the body, these muscles may serve to sustain them, or keep them fixed in that position.

The second set lie under the preceding muscles, and are enclosed in the same sheath with them; they are each attached to two of all the inter-articular spines bones for almost their whole length, and at their roots to the inter-muscular sponaeurose, already mentioned: their tendons are inserted into the sides of the bastes of each ray, by which means they draw the rays of the fin out of a right line, and thus tend to expand the fins as well as bring them to either side of the body.

Cuvier describes a sort of short oblique muscles for closing the rays of the fin, which we have not seen except on the caudal fins.

The flexion of the caudal fins is effected at the same time with that of the whole tail, by means of the great lateral muscles already described; but the rays of the caudal fin are expanded and contracted by particular muscles for the purpose.

Those that spread the caudal fin are concealed by the lateral muscles; they arise from some of the last vertebrae, spread in a fan-like manner, and are inserted into the roots of the rays; the outermost fascicule come from the three vertebra preceding the last, and terminate upon the five or six of the external or longest rays; those of the intermediate rays arise from the two last vertebrae.

The muscles which serve to approximate the rays of the caudal fin appear like a row of beads or barley-corns, lying obliquely upon the joints of the rays and inter-articular bones, with the broad, thin termination of the last vertebra. These muscles of one side of the tail appear to pass in a different direction from those of the other side, or to decussate each other.

The single fins are evidently intended to increase the lateral
FISH.

The fins of fishes, during the act of swimming, and thereby communicate a greater impulse to the water. They are also useful in turning the fish, and particularly the caudal fin must act like the helm of a ship. Mr. Carville made the experiment of cutting off the different fins of living fishes in succession, with the view of determining their separate offices; he observed, that after the removal of the single fins there was an evident tendency in the fish to turn round, and the pectoral fins were kept constantly extended to obviate that motion.

The single fins may also be considered as instruments of defence to fishes, more especially when the rays of the dorsal fins terminate in sharp spines, which they do in a great number of species, and in those cases the muscles for erecting the rays are particularly strong.

In offious fishes, the great lateral muscles supply the place of the abdominal muscles, as well as those which arise from the spine; but in the ray genus we find some muscles, which correspond a good deal with the abdominal muscles. The inferior parietes of the abdomen in those fishes are composed of some layers of muscles which are attached to the transverse cartilages and the posterior branches of the scapula; and to the pieces composing the pelvis; these fibres take a similar direction to that of the straight and oblique muscles of the belly, and those of each side are distinguished by an aponeurotic line, analogous to the linea alba. They tend to depress the wings, and bring the pelvis forwards and downwards.

The inferior parietes of the abdomen are formed by two thin, broad muscles; one arises from the aponeurosis, under the skin of the back, and is inserted into the back of the posterior branch of the scapula; the other arises from the aponeurosis of the muscles of the dorsal spine, and the back of the pelvis, and is inserted along the middle of the posterior branch of the scapula; these muscles are concerned in the elevation of the wings.

The muscles of the pectoral fin are simple in both the cartilaginous and the offious fishes.

In the offious fishes there is, in some species, a small, short muscle, situated on the internal and back part of the portion of the scapula, where that bone is connected to the cranium. It has the effect of bringing the scapula closer to the head.

There is likewise a small tensor muscle which arises from the front of the clavicle, and is inserted into the posterior flank of the scapula; it brings the scapula backwards, and the clavicle forwards and inwards.

There are two sets of muscles situated upon the broad and thin portion of the scapula for moving the rays of the pectoral fin. The external set consists of three muscles, two of these are partially covered by the other; the two uppermost may be divided into a great number of fasciculi, which send tendons to the bases of the rays of the fin; the most inferior of the external set sends tendons only to some of the most inferior or external rays of the fin. The internal set consists of two muscles much resembling the two first that are placed externally; they send tendons into the roots of the rays on the inside. By all these muscles the rays of the fin are raised from the body and brought closer to it; turned forwards, and the edge presented to the water.

In the genus ray, besides the muscles already mentioned in describing other parts, which act upon the pectoral members, there is a very short muscle which goes from the lat transverse process of the cervical spine to the top of the shoulder; it appears to raise the scapula. There is also a muscle extended along the concave side of the posterior branch of the scapula; its fibres arise from a tendon which is stretched from above the joint to the point of that branch; they are inserted into the edge of the fin. The use of this last appears to be to bring the posterior branch of the scapula nearer the body; this motion is attended with the expansion of the rays of the fin.

The muscles which act immediately upon the rays of the wings in the flat chondropterygi are as numerous as the rays themselves; they altogether compose two great layers of fasciculi, somewhat resembling the muscles of the single fins of offious fishes; one layer is placed upon the superior surface of the wings, the other upon the inferior; they thus cover the whole fin, arising from the external side of the scapula, and extended to almost the very edge of the fin.

Their office is to raise and depress the wings.

The muscles which move the rays of the ventral fin in offious fishes are situated upon the external and internal surfaces of the pelvic bones. On the external surface there are three or more fasciculi, which in approaching the bases of the rays form lesser fasciculi, one of which is inserted into each ray; the external muscles elevate the fin, and from their oblique direction and mode of attachment they also tend to close the rays. There is but one muscle usually on the internal surface of the pelvic bone; with its fellow, it fills up all the space left between the two flat surfaces of the bones of the pelvis. These muscles have the effect of depressing the rays of the ventral fin, and at the same time of expanding them, so as to present a broader surface to the water.

In the chondropterygi the external rays of the ventral fin, more especially the outermost, have their muscles in distinct fasciculi, which are capable of drawing the rays in all directions. These muscles might be compared with those that act upon the lower extremities of mammals: the small rays of the ventral fins have fasciculi closely applied to them in the same manner as those of the pectoral fin in these fishes.

The chief uses of the pectoral and ventral fins are to turn and flip in swimming, and to preserve the position of the fish; therefore we observe, they are always employed when the animal wishes to continue nearly in one place. When the motion of the fish also is very gradual through the water these fins are sometimes the only instrument employed in swimming. From the experiments made by Mr. Carville of cutting off the fins in a living fish, it would appear that the pectoral fins are useful in ascending, and that they serve to keep the head uppermost; when both the pectoral and abdominal fins were removed, he found that the fish had a tendency to roll and could not ascend at all.

Air Bladder.

This singular organ is peculiar to the class of fishes. Anatomists have ascribed various functions to it; we have, however, chosen to place it amongst the instruments of motion, for reasons which will be given hereafter.

The air bag is wanting in several species of fishes, and has been supposed to be absent in some others, in which it really exists. It is not met with in one of the chondropterygi, in the genus lophius, in the men men ray ( traumatic mole); it is supposed to be wanting in the ammodytes telesinus, the gnomatias farav, the callanmias draco, the blennius fraseri, and blennius vestitata. Sc.; in the genera cephal, echeneis, and eusus. It is absent in the flat fishes (pleuracotes), and in the mackerel (scomber scombrus); we have not found it in the sevus (trachurus draco). Bloch appears to have extended the list of fishes in which this organ is absent farther than is right; he denies its existence in the electricel elc (gymnotus electricus), although Mr. Hunter described it in that fish. Redi also stated it to be wanting;
in the uromophus sebae, in which Cuvier has found an air-bag resembling that of the carp (cyprinus carpio).

The air-bag is always situated upon the inferior surface of the dorsoventricle; sometimes, as in the genus gadus, it is adhered firmly and intimately to the spine. At other times, as in the genera salmo, ophis, &c., it tends to proffer to the ribs and the spaces between them.

In the dory (zeus faber) it is connected to the spine by ligaments which arise from the bag, but is not continuous with it.

In the carp (cyprinus) the anterior portion of the bag only is attached to a descending process of the second dorsal vertebra. In the salmon (acipenser huso), the el (murena), the bering (elops), and many other fishes, the bag is unconnected with the spine, and preferred in its proper position by its peritoneal coat, and the duct which communicates with the cefalaphus or stomash.

The structure of the parietes of the air-bladder is extremely curious. It has two proper coats and a peritoneal covering; the internal proper coat is in general a fine delicate membrane, which, in many cases, is not closely adherent at every part to the other coat; it appears to be double, and the innermost layer to be, in some places, looser, and capable of being moved upon the surface of the other.

The external proper coat is in many cases incomplete or wanting in some parts of the air-bag: thus, in the genus gadus there is only the membranous tunic along the upper surface of the bladder, which corresponds to the bodies of the vertebrae; the intimate connection with the external parts of the spine rendering a stronger intermixture in this place unnecessary: this coat also appears to be wanting in the posterior bladder of the carp (cyprinus carpio). It is absent also upon the posterior end of the air-bag in the dory (zeus faber), but in this instance it is supplied by a thick, sili, light-looking tunic, which has considerable strength.

The external proper coat has a most peculiar structure: it is very chiefe in its texture, resembling, when cut through, the ligamentum nuchae of mammalia; it is of a beautiful silvery white colour, and the inner surface glitters like polished metal; from these characters we should wish to give it the name of the argenteum coat: it is tough, but possesses very little elasticity, which it appears to lose entirely upon being stretched. This coat is generally thick, but does not tend to be strong in proportion; it tears with the application of a much lighter force than would be required to rupture a tendon or ligament of the same degree of thickness. Cuvier states its consistence to be so considerable in the salmon as not to shrivel when the bag is emptied of its air; it is also very strong in the genera silurus and gadus; in other instances, as in the pike, hering, etc., carp, &c., it is as thin as a membrane: in the leuciscus (polypterus niloticus) this coat exhibits some oblique fibres, which Cuvier is disposed to consider muscular; it is the argenteum coat which is so intimately united to the external parts of the vertebrae in the cod.

An opinion prevails that it is unwholesome or dangerous to cut the air bag of fishes, which probably arises from the indigestible nature of the external coat.

The cobitis joffils is distinguished by having the parietes of the air-bag composed of bone; the offensive covering appears to supply the place of the external proper coat in this fish, and is likened to the membrane.

The peritoneal coat does not always entirely cover the air-bladder; in some instances, when the latter adheres to the spine, it only passes over the inferior surface of it.

In certain fishes the air-bladder contains a remarkable vascular apparatus; this is always situated on the inner side of the inferior or abdominal parieties of the bladder, it appears to be interposed between the duplicatures of the internal proper coat of the bag, the innermost of which is extremely thin where it covers the surface of the vascular apparatus.

There is great variety in the figure of the vascular organ in the cod (gadus morhua); it is a broad patch, somewhat of a heart-shape, composed of a number of short foliated processes hanging close to each other. In the cobitis (gadus merlangus) these processes are finer, lighter, and not so close together, and look like the vascular furred membrane produced by the deposition of lymph on an inflamed surface.

In the mullet (mugil cephalus) there is a number of granular vascular bodies spread over an oval surface, about two inches long and one inch and a half broad; these are fed by an artery of some size, which, after entering the bag, sends branches to each of these little masses.

In the el and conger (murena anguilla and murena conger) there are two spherical vascular bodies placed at a little distance from each other.

In the dory (zeus faber) there are four vascular bodies, situated nearly at equal distances from each other; they are narrow, rounded upon the surface, and are composed of smaller irregular-shaped masses, which give them a granular appearance; each body is coiled or twisted like a piece of intine, and they are all connected together by the blood-vessels which pass through a hole formed in the lower parieties of the bag for the purpose, and on entering the bag branch off regularly to supply each of the vascular bodies.

In the gadus palatialis, Cuvier states that the inner surface is entirely covered with long and numerous vascular filaments.

Whatever may be the form and arrangement of the vascular bodies, they agree in one circumstance: they receive a great supply of red blood that every point is coloured, the whole appearing of an uniform crimson colour, as if it were dyed. There is no other organ of the animal body, with which we are acquainted, that possesses the same peculiarity of vascularity, except the choroid gland of the eye of fishes; but even this part falls short in the degree of vascularity.

It may be stated in a general way that in those fishes which have a distinct vascular apparatus, there is either a communication between the air-bladder and the stomach or esophagus, or the internal membrane of the bag receives a considerable number of blood-vessels. In some cases, however, when these provisions exist, the inner surface of the air-bladder is abundantly supplied with blood-vessels. In the leuciscus (polypterus niloticus), for instance, the vessels form a immaterial tangle, which colour a great part of the surface of the bag.

It has been commonly fapposed that the vascular bodies, and the vessels distributed upon the inner surface of the bladder, are designed to recreate the air with which it is filled. This fett, which has been called in question by some physiologists, is fully proved by the structure observed in the vascular bodies of elts (murena), and the fee perch (perca labrax). In the former, the vascular bodies exhibit on their surface a fine net-work of vessels containing air; and in the fee perch, besides the usual vascular body on the inner part of the bag, there are two others placed externally on each side, and extended from the base to the point of the cone-shaped bladder of this fish. These arise from these a great number of little air-vessels, which unite into several principal trunks that penetrate the parities of the bladder, and open into its cavity by thirty or forty orifices on each side, arranged in a line.
As the offices of these angular organs are so satisfactorily demonstrated, they might with propriety be called air-glands. The circumstance of the vascular bodies secreting air is a most interesting fact in physiology, and serves to explain the production of gaseous matter from the secreting furnish in other class of animals.

The communication which the air bladder has, in several fishes, with the stomach is one of the most curious circumstances in the history of this organ. It has been supposed, by some anatomists, to be intended to discharge the contents of the bag; but we are more disposed to think that it is designed to admit air, which is formed by the surface of the alimentary canal. In no instance has any fish been observed to expel air by the mouth or anus; and it is retained in the stomach, the specific gravity of the animal would remain the same, and consequently the supposed purpose would not be answered. On the other hand, the secretion of air from the surface of the stomach is a well-ascertained fact, with respect to many other animals, and may be inferred from the analogy to take place also in fishes. Another argument may be drawn from the surface of the air-bag being commonly found life vascular in those instances where this communication exists.

The duct, which serves to convey the air from the alimentary canal into the bladder, has been observed to exist in certain species of the genera acipenser, narina, perca, salmon, elops, cyprinus, cupida, flaurus, and polysternus. It varies with respect to its size and figure, and the places at which it arises and terminates. In the eel (narena anguilla), the conger (nereina conger), and the narina belua, it passes from the anterior part of the stomach to the middle of the bladder, between the two air-glands; it becomes wider as it approaches the bladder. In the pike (eops lucius), the trout (salmo fario), the salmon (salmo fario), and the flurgeon (acipenser flurum), the opening into the bag is situated near its anterior extremity. In these fishes it is short and wide, particularly in the pike and flurgeon; in the latter it is so wide, that a finger will pass through it, and so short, that it appears like a ring rather than a duct. It arises from the eolophagus in the salmon, and from the beginning of the stomach in the flurgeon. It opens into the anterior third of the bag in the narina. The duct is extremely long and small in the carp (cyprinus carpio), and passes from the termination of the eolophagus to the anterior part of the posterior portion of the air-bag. In the eerring (cupida baren- gus) the posterior or funnel-shaped extremity of the stomach gives origin to a slender duct, which enters the air-bag at about one-third from its posterior extremity.

The orifice into the eolophagus is not furnished with any valves to prevent the admission of extraneous substances; but when it is wide, it is encompassed by some muscular fibres, which perform the office of a sphincter. This structure is well seen in the flurgeon and the bichir (polysternus chilotus); in the former, the short duct has a muscular coat of circular fibres; and in the latter, the orifice is surrounded by a sphincter. When the duct is very small, the contraction of the ordinary muscular fibres of the alimentary canal seems to be adequate to the shutting of the orifice.

In whatever manner the orifice of the air-duct be constructed, its opening or closing is unquestionably regulated by the will of the animal.

Having stated the general structure of the air-bag, and the parts connected with it, we shall enumerate the peculiarities of its form which have been observed in different fishes.

The air bladder in some instances consists of two parts or chambers, communicating with each other. In the bichir (polysternus chilotus, Geoffroy), it forms two large cylindrical faces, of which the one is much longer than the other, extending the whole length of the abdomen; they only unite when they communicate with the eelophagus; the tetraodon oblongus ilho has the bag of two portions, but of different figure and magnitude; they lie together, and unite at their anterior extremity. In the gadus holbo the two portions of the bag are of unequal lengths, being parallel to each other, and are joined in their middle. In the carp (cyprinus), and the mohephorus eoker, the bag consists of two faces, the one placed behind the other, and separated by a contract, which leaves a small aperture of communication between them.

The air-bag is single in all other fishes, except the foregoing examples, and exceedingly various in its form, even in species of the same genus. It has the figure of an elongated cone, with the base turned forwards, in the flurgeon (acipenser flurum), the salmon and trout (salmo fario and salmo fario), the pike (eops lucius), the dory (eops lucius), &c.; it is long, conical, and fringed posteriorly in the flaurus eperlanus; short and oval in the narina belua, nar w and more elongated in the common eel, the eanger, and the flurgeon anguilla; it is long and pointed at both ends in the herring (cupida baren- gus). In the eel (gadus morhua), it is pointed posteriorly, touched or divided into a number of lobules along the sides, straight at the anterior part, from the corners of which two veriform processes go off, which are considerably convoluted. Cuvier describes these processes as two ducts, leading into the eelophagus, but they terminate in blind extremities; it is bifurcated anteriorly in the herring (gadus morhua), long and fringed in the hake (gadus merluccius); in the narina morhua it is oval in many of the genus narina. In the anatlepse retiformis it is small anteriorly, and enlarged behind; in the flacija cubicus, it is irregular, slightly notched before, and a little contracted in the middle; the flacija quadriruticata has the same figure, with two processes on the sides. In the genus flaurus the air-bag has the form of a heart, and contains internally a number of transverse lepta, which are incomplete upon the posterior of the eel. In many of the genus dieedus also similar partitions have been observed to exist.

The air bag in some fishes possesses two muscles; they are short thick layers, which pass downwards on each side of the anterior part of the bag. In the dory (eops lucius) they have an oval form, and have no foreign attachments, but belong entirely to the parieties of the bag. In the eel (gadus morhua) there are two muscles on each side, which are affixed to the two first lobules, or faculated portions of the eel bladder, and have their superior extremities inserted into the lips. Cuvier states that these muscles exist in the eelophagus of all fishes, and in the flacija cubicus, in which last species they are extremely thick. He supposes that the use of the muscles is to compress the air-bag, and, by diminishing the bulk of the air it contains, encroach the specific gravity of the fish. They appear, however, to be incompetent to such an effect, as they can only act upon the anterior portion of the bag; they are, therefore, probably destined to urge the air from the fore part of the bluddle, when the animal has occasion to defend in the water.

It is to be regretted that the different experiments, which have been instituted to ascertain the chemical properties of the air contained in this organ, have afforded such contradictory results: scarcely any two of them coincide with each other. Thus, La Cepede has stated that he discovered hydrogen gas in the air-bag of the carp (cyprinus carpio). Pocock found azote gas in that of the eelophagus of the trach (cyprinus carpio). Fischer met with carbonic acid gas. D. Breadth, in examining the air-bag of the flurgeon, &c. (cyprinus carpio),
fish gladius), sometimes found it to contain oxygen, and at others fixed air. Others have stated that the air-bag of the carp, &c. is filled with atmospheric air. Some later experiments on the subject have been communicated to the French National Institute by M. Biot. He ascertained that the contents of this organ varied from pure azote to 87ths of oxygen; but there existed no hydrogen. He stated that fresh-water fishes, which frequently swim near the surface, afforded the least proportion of oxygen; and he thought that this gas was in greater quantity, according to the depth of water from which the fish came.

Biot's experiments are very interesting, as they go some way towards reconciling the contradictory accounts of other physiologists, and may perhaps be considered as explaining the different degrees of purity observed at different times in the air of the bag in the same individual.

Anatomists are as much at variance with respect to the use of the air-bag, as they differ in their accounts of its contents. Needham supposed that the air produced in the blood was deposited in the bladder, and afterwards carried into the stomach, in order to assist digestion. Vieq d'Azyr adopted a similar opinion: he thought the bladder was subservient to digestion, and that it received the finer kinds of food. Fischer imagined this organ an accessory one to the gills, besides forwarding the motion of the animal in its element: he conceived that the fish came to the surface for the purpose of swallowing atmospheric air, which afterwards passed through the pulmonary duct into the bladder, and, when spoiled by remaining in contact with the vascular bodies or blood-veils, was expelled through the same channel.

It is impossible to conceive speculations more absurd or more easily overturned, than the preceding. Each of the above opinions supposes that there is always a communication between the air-bag and the alimentary canal, which, as before stated, is ascertained to exist in but a small number of fishes, but if this obstacle did not exist, both the theories of Needham and Vieq d'Azyr are still extremely improbable. The admixture of air with the alimentary substanies would interrupt, instead of promoting their digestion. It would be utterly impossible for any process similar to respiration to be carried on in a close sac; as the air could not be reconverted, its operation would cease, and to suppose the secretion of oxygen into the air-bag, and the absorption of the carbonic acid gas produced there, is perfectly preposterous; as well might an animal require in a close vesel.

The true and only use of the air-bladder appears to be to diminish the gravity of the fish in relation to its bulk, and thereby enable it to continue buoyant, or ascend in the water with little or no muscular effort; this is the popular notion; and hence the common name of swimming bladder or swim are used; in corroboration of which opinion it may be remarked, that those fishes have the largest air-bags which swim rapidly, and frequently ascend and descend in the water; that when it is want we can always discover some other modification or conditions in the organs of locomotion which are adapted to fulfill the same purposes, and that when such provisions do not exist the fish commonly grows at the bottom of the water. Thus the shark genus is furnished with a long and powerful tail, and the pectoral fins are in general of some f. z. In the mackerel (scomber scombrus) the skeleton and muscular substance are both light, and the tail is particularly strong; the garfish (sea bream), which has a light skeleton, and muscular substance very like the mackerel, has an extremely small air-bag. The flat fishes swim by means of a continual beating or flapping of the water with their broad surfaces, in a manner exactly analogous to flying.

Lafréry, the lamprey (petromyzon), which wants the air-bag and has a tail badly formed for swimming, generally lies buried in the mud at the bottom of the water.

To these observations we shall add some experiments we made upon one occasion on living fishes, the gudgeon and gudgeon (cyprinus rutilus and cyprinus gobio), which, in our opinion, put it beyond all doubt that the air-bladder is an organ of motion. A knife was plunged past the spine into the air-bladder; upon the air rushing out, the fishes descended to the bottom of the vessel of water, and there remained. In order to ascertain whether the inflow of such a wound could have any effect, a similar one was made upon other living fishes, taking care not to penetrate the air-bladder, but they afterwards ascended and descended as usual; an air-bladder was next removed from the body of one fish, and attached to the external part of the body of another fish, which had previously sunk to the bottom in consequence of the air being extracted from its bag by a wound; it now became as unable to descend in the water as it was before to rise, and was detained at the surface in despite of all its efforts to escape to the bottom of the vesel.

Two conclusions are to be drawn from the foregoing experiments: first, that the air-bag is absolutely necessary to the locomotion of those fishes, to which it naturally belongs, and that, in the body of the living fish some change is produced in the bulk, or quantity of the air contained in the bag to enable the fish to descend. Some anatomists have accounted for the diminution of the volume of air in the bag, by supposing it to be carried into the stomach or oesophagus, and thence expelled, but this could only take place in those few fishes which have a duct of communication between those parts.

Others have supposed that the air-bag is diminished by being compressed at the will of the animal, either by the great lateral muscles, or those situated at the anterior part of the bag: it seems, however, very doubtful whether the action of either of these muscles can materially affect the whole bag; but if this were granted, it might be still objected, that in some instances the air-bag is so thin as not to be able to sustain much compression without danger of being ruptured, and that in other instances its parietes are so thick as to resist a moderate degree of compression, and in the cobitis fistilus, it being an oblong sac, is incomprehensible.

Shall we suppose that the gaseous contents of the bag are encroased and diminished, as occasion may require, by secretion and absorption? There appears but one objection to this supposition, which is the rapidity that would be necessary in effecting these changes in the quantity of the air. It may be remarked, however, that air is secreted, under some circumstances, in the human stomach almost instantaneously; the secretion of saliva and the tears is, perhaps, equally rapid: the vascular action which conveys the fluid to the cheeks surges in velocity any of the voluntary motions of animals: it is, therefore, not inconsistent with some of the well known phenomena of the vascular system to suppose that the volume of air in the swimming bladder of fishes may be regulated according to necessity, by the vessel distributed to the parietes of the bag, or, perhaps, from those of the stomach, when these two parts communicate. It would be improper, however, to adopt this opinion upon the mere ground of its being possible: future experiments must determine what really are the means employed by fishes to alter their gravity.

Plate XIV. of the *Anatomy of Fishes* contains the illustrations of the structure of the air-bag. Fig. 1, represents the air-bladder of the dory, (seus fischer) turned inside out, in order to bring into view the internal coat and air glands.
glands, &c: at, the anterior part of the bag, b, the posterior
part: the argentine coat is seen through the internal
membrane, and at b the fishty looking coat which supplies
its place, the inner membrane adheres most loosely at this
part; c, e, f, the four air-glands or vascular bodies, d, the
blood vessel which is distributed to them with the accompa-
nying vein; e, r, the muscles seen through the inner
coat.

Fig. 2. exhibits the air-gland of the cod (Gadus morhua); e, the
surface presented to the cavity of the bag.

Fig. 3. is the air bladder of the cod, (Muraena anguilla)
divided longitudinally, and the parietes spread out; a, the
argentine coat, b, b, the internal membrane with its
blood-vessels; c, c, the two air-glands; on the left side the
inner membrane is raised to uncover the gland, and bring
into view the network of the air vessels upon it at d; c, c,
portion of the duct which goes to the stomach.

Fig. 4. represents a portion of the oesophagus and stomach
of the flounder (Pleuronectus fluviatilis) laid open, with a part of
the air-bag attached to it; a, the oesophagus; b, the stomach;
c, the air-bladder; d, the duct leading from one into the
other; surrounded by an annular muscle; e, the office of the
duct.

Fig. 5. is the double air-bag, with its duct in the carp
(Cyprinus carpio) inflated and dried; a, the anterior portion
of the bag; b, the posterior chamber with thinner parietes;
c, the duct; d, the difference before it terminates in the
alimentary canal, a portion of which is preferred at d.

Fig. 6. exhibits the stomach and air-bag of the eel (Anguilla
boreogena); a, the anterior part of the stomach; b, the
posterior or indistinguishable portion, from the extremity
of which a duct is seen going off to the air-bag c, which is
long and pointed at both ends.

Fig. 7. is a view of the air-bag in the Gilius helmin, cut
equal to show the partitions of the interior, which produce
a cellular appearance.

Electric Organs.

These parts, and the very singular faculty they bestow,
have been observed to exist but in a very small number of
species; there are only five fishes which are at present known
to possess the electric property. The torpedo (Raja torpedus),
the electric eel (Gymnotus electricus), the flounder electricus,
the Indian eel (Trichirias indicus), and the tetrando electricus.

The parts which produce the electric phenomena have
been described by several naturalists in the torpedo and gym-
notus, but most minutely and correctly by the late Mr.
Hunter, and the electric apparatus of the flounder electricus
has been described and delineated within these last years by
M. Geoffroy the French naturalist, but no account has yet
been given, as far as we know, of these organs in the electric
species of Trichirias and Tetrando.

Before entering upon the consideration of the phenomena
exhibited by the electric fishes, we shall give a description of
the organs by which they are produced in the torpedo,
the electric eel, and the flounder electricus; and with respect
to the two first, as the subject is peculiarly interesting, we
shall copy the detailed and accurate account published by
Mr. Hunter in the Philosophical Transactions.

The electric organs of the torpedo are placed on each
side of the cranium and gills, reaching from thence to the
semi circular cartilages of each great fin, and extending lon-
gitudinally from the anterior extremity of the animal, to the
transverse cartilage which divides the thorax from the abdo-
men; and within these limits they occupy the whole space
to the skin of the upper and of the under surfaces.

They are thicker at the edges near the centre of the fish, and
become gradually thinner towards the extremities.

Each electric organ, at its inner longitudinal edge, is
unequally hollowed, being exactly fitted to the irregular
projections of the cranium and gills. The outer longitudi-
nal edge is a convex elliptic curve. The anterior extremity
of each organ makes the section of a small circle; and the
posterior extremity makes nearly a right angle with the inner
edge.

Each organ is attached to the surrounding parts by a
close cellular membrane, and also by short and strong tendi-
nous fibres, which pass directly across, from its outer edge,
to the semi circular cartilages.

They are covered, above and below, by the common
skin of the animal, under which there is a thin fascia spread
over the whole organ. This is composed of fibres, which
run longitudinally, or in the direction of the body of the
animal. These fibres appear to be perforated in innumera-
ble places; which gives the fascia the appearance of being
calculated; its edges all around are closely connected to
the skin, and at last appear to be lost, or to degenerate into
the common cellular membrane of the skin.

Immediately under this is another membrane, exactly
of the same kind, the fibres of which in some measure de-
culate those of the former, y fling from the middle line of
the body outwards and backwards. The inner edge of this
is lost with the first described; the anterior, outer, and
posterior edges are partly attached to the semi circular car-
tilages, and partly lost in the common cellular membrane.

This inner fascia appears to be continued into the elec-
tric organ by so many processes, and thereby makes the
membranous sides or breadth of the columns, which are pre-
cently to be described; and between these processes the fascia
covers the end of each column, making the outer-
most or first partition.

Each organ of the fifth under consideration is about
five inches in length, and at the anterior end three in breadth,
though it is but little more than half as broad at the pos-
terior extremity.

Each consists wholly of perpendicular columns, reaching
from the upper to the under surface of the body, and vary-
ing in their lengths, according to the thickness of the parts
of the body where they are placed, the longest column being
about an inch and an half, the shortest about one-fourth of
an inch in length, and their diameters about two tenths of an
inch.

The figures of the columns are very irregular, varying
according to situation and other circumstances. The greatest
number of them are either irregular hexagons, or
irregular pentagons; but, from the irregularity of some of
them, it happens that a pretty regular quadrangular column
is sometimes formed. Those of the exterior row are either
quadrangular or hexagonal; having one side external, two
lateral, and either one or two internal. In the second row
they are mostly pentagons.

Their coats are very thin, and seem transparent, closely
connected with each other, having a kind of loose net-work
of tendinous fibres, passing transversely and obliquely
between the columns, and uniting them more firmly
together. These are most observable where the large
trunks of the nerve-paths. The columns are also attached
by strong tendinous fibres, passing directly from the one
to the other.

The number of columns in different torpedos of the size
of that now offered to the society, appears to be about
470 in each organ, but the number varies according to the
size of the fish. These columns increase, not only in size,
but...
but in number, during the growth of the animal, new ones forming perhaps every year, on the exterior edges, as there they are much the smallest. This process may be similar to the formation of new teeth, in the human jaw, as it increases.

"Each column is divided by horizontal partitions, placed over each other, at very small distances, and forming numerous interfaces, which appear to contain a fluid. These partitions consist of a very thin membrane, considerably transparent. Their edges appear to be attached to one another, and the whole is attached by a fine cellular membrane to the inside of the columns. They are not totally detached from one another; I have found them adhering, at different places, by a kind of felt, passing from one to another.

"The number of partitions contained in a column of one inch in length, of a torpedo which had been preserved in proof spirits, appeared, upon a careful examination, to be one hundred and thirty; and this number in a given length of column appears to be common to all sizes in the same state of humidity, for by drying they may be greatly altered; whereas it appears probable that the increase in the length of a column, during the growth of the animal, does not enlarge the distance between each partition in proportion to that growth; but that new partitions are formed, and added to the extremity of the column from the facein.

"The partitions are very vacuolar; the arteries are branches from the veins of the gills, which convey the blood that has received the influence of respiration. They pass along with the nerves to the electric organ, and enter with them; then they ramify, in every direction, into innumerable small branches upon the sides of the columns, fending in from the circumference all around upon each partition in all arteries, which ramify and anastomose upon it; and passing also from one partition to another, gradually with the vessels of the adjacent partitions.

"The veins of the electric organ pass out, close to the nerves, and run between the gills, to the auricle of the heart.

"The nerves entered into each electric organ, arise by three very large trunks from the lateral and posterior part of the brain. The first of these, in its passage outwards, turns round a cartilage of the cranium, and sends a few branches to the first gill, and to the anterior part of the head, and then paffes into the organ towards its anterior extremity. The second trunk enters the gills between the first and second openings, and, after furnishing it with small branches, paffes into the organ near its middle. The third trunk, after leaving the skull, divides itself into two branches which pass to the electric organ through the gills; one between the second and third openings, the other between the third and fourth, giving small branches to the gill itself. The nerves having entered the organs, ramify in every direction between the columns, and send in small branches upon each partition where they are fewest."

"The fish shown in Plate XV. of the Anatomy of Fishes, exhibits a view of the upper or back surface of the torpedo, on which the electric organ of each side is uncovered by raising the integuments, in order to show the extensive portion of the body of the fish, which these parts occupy: a, the integuments turned back, displaying on their inside an hexagonal net-work, which was the continuation of the columns into the skin; b, b, b, the ends of the column applied to the integuments. An exactly similar appearance presents itself on raising the skin of the inferior or opposite surface of the body of the fish.

In Plate XVI. of the Anatomy of Fishes, fig. 1, shows the electric organ of the torpedo on the right side, divided horizontally into nearly two equal parts at the place where the nerves enter; the upper half being turned outwards. a a, b b, c c, d d, the corresponding parts of trunks of the nerves as they emerge from the gills, and ramify in the electric organ.

"a a, the first or anterior trunk arising just before the gills.

"b b, the second or middle trunk, arising behind the first gill.

"c c, the anterior branch of the third trunk, arising behind the second gill.

"d d, the posterior branch of the third trunk, arising behind the third gill.

"Fig. 2 of the same plate, exhibits a perpendicular section of the torpedo, a little behind its inspiratory openings.

"a a, the upper surface of the gill.

"b b, the muscles of the back, as divided by the fiction.

"c c, the medulla spinalis.

"d d, the pharynx.

"e e, the right gill, split to expose the course of a trunk of a nerve through it.

"f f, the breathing surface of the right gill.

"g g, the fin.

"h h, the perpendicular columns which compose the electric organ, with a representation of their horizontal positions.

"i i, one of the trunks of the nerves, with its ramifications.

"The ptychognathus electricus may be considered both anatomically and physiologically, as divided into two parts: viz. the common animal part; and a part which is superadded, viz. the peculiar organ. I shall at present consider it only with respect to the last; as the first explains nothing relating to the other, nor any thing relating to the economy of fish in general.

"The first, or common animal part, is so contrived as to exceed what was necessary for itself, in order to give situation, nourishment, and most probably the peculiar property to the second. The last part, or peculiar organ, has an immediate connection with the first, the body affording it a situation; the heart, nourishment; and the brain, nerves, probably its peculiar powers. For the first of these purposes, the body is extended in length, being much longer than would be sufficient for what may be called its progressive motion. For the real body, or that part where the viscera and parts of generation are situated, with respect to the head, as in other fishes, is extremely short; so that, according to the ordinary proportions, this should be a very short fish. Its great length, therefore, seems chiefly intended to afford a surface for the support of the peculiar organ; however, the tail part is likewise adapted to the progressive motion of the whole, and to preserve the specific gravity; for the spine, medulla spinalis, muscles, fin, air-bladder, are continued through its whole length.

"Besides which parts, there is a membrane passing from the spine to that fin which runs along the belly or lower edge of the animal. This membrane is broad at the end next to the head, terminating in a point at the tail. It is a support for the abdominal fin, gives a greater surface of support for the organ, and makes a partition between the organs of the two opposite sides.

"The organs which produce the peculiar effect in the electric fish constitute nearly one-half of that part of the fish in which they are placed, and perhaps make more than one-third of the whole animal. There are two pair of these organs,
organisms, a larger and a smaller; one being placed on each side. The large pair occupy the whole lower or anterior, and also the lateral part of the body, making the thickness of the fore or lower parts of the animal, and run almost through its whole length; \textit{viz.} from the abdomen to near the end of the tail. It is broadest on the sides of the fish at the anterior end, where it inclines more of the lateral parts of the body, becomes narrower towards the end of the tail, occupying less and less of the sides of the fish, till at last it ends almost in a point.

These two organs are separated from one another at the upper part by the muscles of the back, which keep their upper or posterior edges at a considerable distance; below that, and towards the middle, they are separated by the air-bag, and at their lower parts they are separated by the middle partition.

They begin forwards, by a pretty regular edge, almost at right angles with the longitudinal axis of the body, situated on the lower and lateral parts of the abdomen. Their upper edge is a pretty straight line, with small indentations made by the nerves and blood vessels, which pass round it to the skin. At the anterior end they go as far towards the back as the middle line of the animal; but in their approach towards the tail they gradually leave that line, coming nearer to the lower surface of the animal. The general shape of the organ, on an external or side view, is broad at the end next to the head of the animal, becoming gradually narrower towards the tail, and ending there almost in a point. The outer surfaces of the organs are fitted to the shape of the parts with which they come in contact; therefore, in the upper and inner surface it is hollowed to receive the muscles of the back.

There is also a longitudinal depression on its lower edge, where a subfacile lies, which divides it from the small organ, and which gives a kind of fixed point for the lateral muscles of the fish. Its most internal surface is a plane adapted to the partition which divides the two organs from one another. The edge next to the muscles of the back is very thin, but the organ becomes thicker and thicker towards its middle, where it approaches the centre of the animal. It becomes thinner again towards the lower surface, or belly; but that edge is not so thin as the other.

Its union with the parts to which it is attached is in general by a loose, but pretty strong cellular membrane, except at the partition, to which it is joined so close, as to be almost inapplicable.

The small organ lies along the lower edge of the animal nearly to the same extent as the other. Its situation is marked externally by the muscles which move the fin under which it lies. Its anterior end begins nearly in the same line with the large organ, and just where the fin begins, it terminates almost in the end of the tail, where the large organ also terminates.

It is of a triangular figure, adapting itself to the part in which it lies. Its anterior end is the narrowest part; towards the tail it becomes broader; in the middle of the organ it is thickest; and from thence becomes gradually thinner to the tail, where it is very thin.

The two small organs are separated from one another by the middle muscles, and by the bones upon which the bones of the fins are articulated.

The large and the small organ on each side are separated from one another by a membrane, the inner edge of which is attached to the middle partition, and its outer edge is laid on the skin of the animal.

To expose the large organ to view, nothing more is necessary than to remove the skin which adheres to it by a loose cellular membrane. But to expose the small organ it is necessary to remove the long row of small muscles which move the fin.

The structure of these organs is extremely simple and regular, consisting of two parts; \textit{viz.} flat partitions or septa, and cross divisions between them. The outer edge of these septa appear externally in parallel lines nearly in the direction of the longitudinal axis of the body.

These septa are thin membranous, placed nearly parallel to one another. Their lengths are nearly in the direction of the long axis, and their breadth is nearly the semidiameter of the body of the animal. They are of different lengths, some being as long as the whole organ. I shall describe them as beginning principally at the anterior end of the organ, although a few begin along the upper edge, and the whole, passing towards the tail, gradually terminate on the lower surface of the organ; the lowermost at their origin terminating soonest. Their breadths differ in different parts of the organ.

They are in general broadest near the anterior end, answering to the thickest part of the organ, and become gradually narrower towards the tail; however, they are very narrow at their beginnings or anterior ends. Those nearest to the middle of the back are the broadest, owing to their curved or oblique situation upon these muscles, and grow gradually narrower towards the lower part, which is in a great measure owing to their becoming more transverse, and also to the organ becoming thinner at that place.

They have an outer and an inner edge. The outer is attached to the skin of the animal, to the lateral muscles of the fin, and to the membrane which divides the great organ from the small; and the whole of their inner edges are fixed to the middle partition formerly described, also to the air-bladder, and three or four terminate on that surface which inclines the muscles of the back. These septa are at the greatest distance from one another at their exterior edges near the skin, to which they are united; and as they pass from the skin towards their inner attachments they approach one another. Sometimes we find two uniting into one. On that side next to the muscles of the back, they are hollow from edge to edge, answering to the shape of those muscles; but become less and less towards the middle of the organ, and from that, towards the lower part of the organ, they become curved in the other direction. At the anterior part of the large organ, where it is nearly of an equal breadth, they run pretty parallel to one another, and also pretty straight; but where the organ becomes narrower, it may be observed, in some places, that two join or unite into one, especially where a narrow passes across. The termination of this organ at the tail is so very small, that I could not determine whether it consisted of one septum or more.

The distances between these septa will differ in fishes of different sizes. In a fish of two feet four inches in length, I found them \(\frac{7}{10}\) of an inch distant from one another; and the breadth of the whole organ, at the broadest part, about an inch and a quarter, in which space were thirty-four septa.

The small organ has the same kind of septa, in length passing from end to end of the organ, and in breadth passing quite across: they run somewhat serpentine, not exactly in straight lines. Their outer edges terminate on the outer surface of the organ, which is in contact with the inner surface of the external muscles of the fin; and their inner edges are in contact with the centre muscles. They differ very much in breadth from one another; the broadest being equal to one side of the triangle, and the narrowest scarcely broader than the point or edge. They are pretty nearly as

\[3 : 2\]

\[\text{FISH.}\]
equal distances from one another; but much nearer than
those of the larger organ, being only about 1/7th part of an
inch asunder: but they are at a greater distance from one
another towards the tail, in proportion to the increase of
breadth of the organ.

"The organ is about half an inch in breadth, and has
eighteen septa. These septa, in both organs, are very ten-
der in consistence, being easily torn. They appear to an-
swer the same purpose with the columns in the torpedos,
making walls or butments for the subdivisions, and are to
be considered as making so many distinct organs.

"These septa are interfaced transversely by very thin
plates or membranes, whose breadth is the distance between
any two septa, and therefore of different breadths in dif-
ferent parts; broadest at that edge which is next to the
skin; narrowest at that next to the centre of the body, or
to the middle partition which divides the two organs from
one another.

"Their lengths are equal to the breadths of the septa-
between which they are situated. There is a regular series
of them continued from one end of any two septa to the
other. They appear to be so close as to even touch. In
an inch in length there are about 240, which multiplies the
surface in the whole to a vast extent.

"The nerves in this animal may be divided into two
kinds: the first, appropriated to the general purposes of
life; the second, for the management of this peculiar func-
tion, and very probably for its existence. They arise in
general from the brain and medulla spinalis, as in other fish,
but those from the medulla are much larger than in fish of
equal size, and larger than is necessary for the common
operations of life.

"The nerve which arises from the brain, and passes
down the whole length of the animal, (which, I believe, exists
in all fish,) is larger in this than in others of the same size, and
passes nearer to the spine. In the common electric ray it runs in the
muscles of the back, about midway between the skin and
spine. In the coel, it passes immediately under the skin.
From its being larger in this fish than in others of the same
size, one might conjecture that it was intended for supplying the
organ to some degree; but this seems not to be the case,
as I was not able to trace any nerves going from it to join
those from the medulla spinalis, which run to the organ.

"This nerve is as singular an appearance as any in this
class of animals; for surely it must appear extraordinary, that
a nerve should arise from the brain to be lost in common
parts, while there is a medulla spinalis giving nerves to the
same parts. It must still remain one of the inexplicable cir-
cumstances of the nervous system.

"The organ is supplied with nerves from the medulla
spinalis, from which they come out in pairs between all the
vertebrae of the spine. In their passage from the spine, they
give nerves to the muscles of the back, &c. They
head forwards and outwards upon the spine, between it and
the muscle-s, and send out small nerves to the external sur-
face, which join the skin near, to the lateral lines. These
ramify upon the skin, but are principally bent forwards be-
tween it and the organ, into which they send small branches
as they pass along. They seem to be lost in these two parts.
The trunks get upon the air-bladder, or rather dip between it and
the muscles of the back, and continuing their course forwards upon that bar, they dip in between it and the or-
gan, where they divide into smaller branches; then they get
upon the middle partition, on which they continue to
divide into still smaller branches; after which they pass on,
and get upon the small bones and muscles which are the
bases for the under-fin, and at last they are lost on that fin.

After having got between the organ and the above-men-
tioned parts, they are constantly finding small nerves into
the organ; first into the great organ, and then into the
small one; and so into the muscles of the fin, and at last into
the fin itself. These branches, which are sent into the organ
as the trunk passes along, are of small size, that I could not
trace their ramifications in the organs.

"In this fish, as well as in the torpedo, the nerves which
supply the organ are much larger than those bestowed upon
any other part for the purposes of sensation and action; but it
appears to me, that the organ of the torpedo is supplied with
much the larger proportion. If all the nerves which go to
it were united together, they would make a vastly greater
chord than all those which go to the organ of this elcid. Per-
haps when experiments have been made upon this fish, equally
accurate with those made upon the torpedo, the reason for
this difference may be ascertained.

"How far this organ is vascular I cannot positively de-
termine; but from the quantities of small arteries going to
it, I am inclined to believe that it is not difficult in ve-

cels.

"The arteries arise from the large artery which passes
down the spine; they go off in small branches like the inter-

collic of the human subclavian, and pass around the air

bladder, and get upon the partition together with the nerves, and
distribute their branches in the same manner.

"The veins take the same course backwards, and enter
the large vein, which runs parallel with the artery." Phil.

Plate XVII. fig. 1. of the Anatomy of Fishes, exhibits
the whole of the two organs in the Gymnatus electricus on
each side, the skin being removed as far as these organs ex-
tend: a, the lower surface of the head of the animal; b, the
cavity of the belly; c, the anus; d, the fin; e, the back of the
organ where the skin has not been removed; f, the fin
which runs along the lower edge of the fish; g, the
fin turned back; h, h, h, the lateral muscles of the above
fin removed and turned back with the skin, to expose the small
organ; i, part of the muscle left in its place; k, k, the large
organ; m, m, m, the substance which divides the large organ from the small; n, at this place the
above substance is removed.

In Plate XVIII of the Anatomy of Fishes, fig. 1, shews
a section of the whole thickness of the Gymnatus electricus,
near the upper part, a little magnified. The skin is removed
as far back as the poll on the organ, and the other
parts immediately belonging to it, such as the medulla spi-
nalis. There are several pieces or sections taken out of the
organ, which expose every thing that has any relation to it.

At the upper and lower ends of the figure, f, f, the organ
is entire, the skin only being removed; a, a, the body of the
animal near the back, covered by the skin; b, b, the belly-
fin covered also by the skin; c, part of the skin removed
from the organ, and turned back; d, d, the muscles which
move the fin laterally, and which immediately cover the
small organ; e, the middle muscles of the fin, which lay
immediately between the two small organs; f, the outer
surface of the large organ, as it appears when the skin is re-
moved; g, the small organ, as it appears when the lateral
muscles are removed; h, b, the cut ends of the muscles of the
back, which have been removed to expose the deeper
feated parts; b, the cut ends of the large organ, part of
which has also been removed to expose the deeper seated
parts; k, the cut end of the small organ; l, a part of the
large organ, the reft having been removed; m, the cut end of
the above section; n, a section of the small organ; o, o,
the middle partition which divides the two large organs; \( p \), a fatty membrane, which divides the large organ from the small; \( g \), the air-bladder; \( r \), the nerves going to the organ; \( t \), the medulla pinnae; \( i \), the angular nerve.

Fig. 2, of Plate XVIII. of the Anatomy of Fishes, is a transverse section of the electric cell, exposing at one view all the parts of which it is composed: \( a \), the external surface of the skin, \( b \), the under-skin, \( c \), the cut end of the muscles of the back; \( d \), the cavity of the air-bladder; \( s \), the body of the spine; \( f \), the medulla pinnae; \( g \), the large artery and vein; \( h, h \), the cut ends of the two large organs; \( k \), the cut ends of the two small organs; \( l \), the partition between the organs.

The structure of the electric organ is less complicated in the \textit{Sillurus electricus} than in the \textit{torpedo} or \textit{gymnotus}. In this fish, Geoffroy describes it to be extended all round the body of the animal, immediately below the skin: it is formed by a considerable collection of cellular tissue, so thick and compact, that on the first view it might be taken for a stratum of hard; but when closely inspected, it is observed that this organ is composed of real tendinous or aponeurotic fibres interwoven with each other, and which, by their different gradations, form a reticulation, the meshes of which are not distinctly visible without the help of a magnifying glass. The small cells of this reticulation are filled with an albumino-gelatinous matter, exactly resembling that met with in the other electric fishes. All communication is prevented in the inside by a very strong aponeurosis, which extends over the whole electric reticulation, and which adheres to it so closely that it cannot be separated without tearing it. It is further covered by a thick layer of fat, which also contributes to infuse the organ.

The nerves which are distributed to the electric organ of the \textit{Sillurus} differ from those of the \textit{torpedo}, and the electric cell.

They proceed from the brain; and are the same which are found in all fishes, under the lateral line of the body; but these two nerves of the eighth pair in the \textit{Sillurus electricus} have a direction and volume which are peculiar to that species: they descend, approaching each other, on their issuing from the cranium, towards the body of the fish and vertebrae, which they traverse. They first introduce themselves through an orifice, peculiar to each other, and then issue on the opposite side by one aperture: after receding they suddenly separate, and proceed under each of the lateral lines. They are then found lodged between the abdominal muscles, and the aponeurosis, which extends over the electric reticulation. In the last place, they bend beneath the skin large branches, which proceed to the right and left of the principal nerve. These branches are in number twelve to fifteen on each side; they pierce the aponeurosis, which lines the interior surface of the reticular tissue, and are lost in the latter. Bulletin de la Société Philomatique, tom. iii. p. 166; and an extract from Annales du Musée N° 1, in Phil. Mag. vol. xv. p. 125.

In Plate XVI. of the Anatomy of Fishes, fig. 2, represents the \textit{Sillurus electricus}, with the organ exposed, by a large portion of the integuments being raised; \( a \), the aponeurosis, which extends under the whole of the electric organ; \( b \), the thickness of the reticulation; \( c, c \), the nerve of the eighth pair going to the electric apparatus; \( d, d \), abdominal muscles.

The substance which is found to fill the columns of the \textit{torpedo}, the interstices of the \textit{gymnotus}, and the muscles of the \textit{Sillurus}, is a peculiar combination of albumen and gelatine; it is of the same nature with the contents of what Monroe has improperly called the mucous ducts in fishes, and that transparent substance which envelopes the spawn of frogs; it does not diffuse, but becomes more solid when immersed in water, in conformance of the coagulation of its albuminous part; we have submitted it to the action of tannin, with which it combines, and forms an insoluble compound like gelatine.

The phenomena exhibited by electric fishes are of so extraordinary a nature that they have engaged the attention of every physiologist who has had the opportunity of observing them; but although every occasion has been embraced to make experiments upon the subject, much investigation is still required to arrive at the explanation of the electric faculty, and even to determine disputed points of fact. The very rare occurrence of procuring any of these animals alive in this country prevents us from adding any thing to the stock of knowledge already obtained upon the subject, we can therefore only quote the observations and experiments of other physiologists.

The preceding description of the electrical apparatus in three species would seem to prove, that a similar system of organization belongs to all fishes which enjoy the electric property. The effects of this structure are also similar, and differ chiefly with respect to the degree. All the electric fishes are capable of exciting in other animals a feeling resembling that produced from the shock of an electric jar.

The \textit{gymnotus} is endowed with the greatest power of this kind; the \textit{torpedo} next, and the \textit{Sillurus} the least of the three.

The \textit{gymnotus} is said, by Garden, to grow sometimes, in Surinam, 20 feet long, and to be able to give shocks which prove instantaneously fatal to any person receiving them. Mr. Humbolt states, that a \textit{torpedo}, about 14 inches long, communicated shocks which reached above the elbow, and were difficult to bear even by a person accustomed to receive shocks from an electrical machine; whilst, on the other hand, Walh found, in about 200 shocks, that only one was strong enough to pass beyond the elbow. Much of the force of the shock depends upon the natural strength of the animal and its vigour at the moment of the experiment; it is said to have very little electric power in winter; it is always much diminished in consequence of the fish remaining for any time out of the water. The shocks, however, do not appear to be increased in strength by repetition, unless the animal be otherwise exhausted. Thus Ingenhoz observed, 'that when the shocks of the \textit{torpedo} followed each other very fast, they were stronger at half than in the beginning.'

Electric fishes are capable of repeating the shocks very frequently in a short space of time. Mr. Walsh reckoned fifty in a minute and a half given by the \textit{torpedo}; and upon another occasion he calculated, that 100 were delivered in about five minutes.

When the \textit{torpedo} administers a shock it is always observed to depress the eyes and drop the triangular curtain which covers the pupil, and generally to make some movement of the lateral fins. The other electric fishes do not accompany these shocks by any visible muscular effort.

The \textit{torpedo} also differs from the others in sometimes becoming the part which touches it. Mr. Walsh accounts for the production of numbness by impounding the shocks to be very minute, and so closely following each other as not to be distinguishable, which may be effected by a succedaneous discharge of the numerous columns of the organ, in the manner of a running fire of machinery. In this continued effort, as well as the instantaneous shock, the eyes of the \textit{torpedo}, usually prominent, are withdrawn into their sockets; it is from the becoming property of the \textit{torpedo} that it derives its name.

The faculty in these fishes of exciting by the touch, the
sensation of a shock, or of numbes, in other animals, has been naturally and generally referred to the principle of electricity; even the Arabs, (according to Geoffroy) who always distinguished every animal by a generic and specific name, confounding only the extraordinary property of the torpedo and fibres electricus, and comparing it with physical electricity, called both fishes by the same name, radax or radax, which is also employed in the Arabian language to signify the fish.

Most physiologists have considered the electric organs of fishes as resembling exactly the Leyden jar, or rather a battery of them: they have compared the nerves and albumino-relatious substance to the metals, and the aponoeuroses to the glass; thus supposing the electric organ to consist of conducting and non-conducting substances, and that when the equilibrium is restored between them, the shock is produced.

Unquestionably there are many circumstances in which the common electric shock, and that obtained from fishes agree, but there are other points in which they materially differ.

The sensations occasioned by artificial and animal electricity are similar.

The shock from an electric fish is only communicable through what are called conducting substances, and is also intercepted by the non-conductors; thus it may be received through the medium of wire of different metals, wood, water, and the animal substance; while a person touching it with glas, sealing-wax, &c., receives no shock, notwithstanding the fish gives evidence of the discharge by the motion of the eyes, &c.

The shock will be transmitted to a number of persons taking hands; those at the extremities completing the ring by touching the fish. In this manner Walsh has communicated a shock to four or five people at the same moment, who experienced exactly the sensation of a shock from an electric jar, except that it was weaker. Dr. Williamson gave shocks to ten or twelve persons at once by an electric cell.

The effect of the electric fishes differs from common electricity in several circumstances. However strong the shock may be, it never has been seen to produce the least noise or luminous appearance. Most experimentalists also agree, that the shock will not pass through the smallest portion of air; the conducting substances must be in actual contact with each other.

Williamson screwed two pieces of wire in opposite directions into a board, leaving an interval between their points of the 1/6th part of an inch, his assistant and himself held the opposite ends of the wire, and established a communication with the cell by means of their other hands, but no shock passed. On repeating the experiment and screwing the wires so as to bring their points within the distance of the thicknesses of double post paper of each other, the shock was felt by both persons, but till no spark was discernible, which we conceive renders the accuracy of the experiment doubtful.

Dr. Bancroft indeed affirms, that in Guiana the electric eel shocked his hand at the distance of some inches from the water; a result, however, so very different from the observation of all other experimentalists appears more than questionable.

The electricity of fishes has not the effect of attracting floating substances. When a person is immersed, and touches the fish, he receives a shock as at other times, but gives no appearance of excess of electricity, however long he may keep up his communication with the animal. A Leyden phial also, being put into contact with an electric fish, never becomes charged.

The electric organ differs from the Leyden phial, as Volti has very properly observed, by being entirely composed of conducting substances. The aponoeuroses and membranes which form its various surfaces are not of an insulating nature, like glas, rosin, silk, &c. They cannot be exposed to friction, nor dipped and charged in the manner of the small plates of Franklin, or electrophores. Volti, therefore, concludes that the electric organs do not act upon the principle of a Leyden jar, or an electrophore or condenser, but that they entirely resemble the Galvanic pile, in which conducting substances become exciters of electricity, by being placed in a particular relation with respect to each other.

It would appear that the electric phenomena of fishes are produced in a manner differently from every species of physical electricity. The former are not accompanied with any chemical changes, they do not affect our organs of sense, by any display of light, excitation of odour, or explosive sound. Their mode of operation is not regular and uniform, or governed by external influence, but depends upon the life, and even upon the volition of the animal; for all experimentalists agree in stating that the electric fishes regulate the strength and frequency of the shocks at pleasure. There is no appearance of accumulation or diminution of the electric power, except what arises from the will of the animal; the last shocks which occur after fishes admittins being often more strong and frequent than the first.

The nerves seem to be the principal agents in the exercise of the electric faculty, as they are always found larger in the organs than would be required in parts of the same magnitude, for any species of sensation or voluntary motion.

The great error of physiologists has always been to account for the operations of organized beings, upon the principles which regulate the phenomena of inanimate matter. We are led to make this observation from comparing the electric faculty of fishes, with the property of exhibiting light in some animals, and the power of generating heat, which is found in all living bodies; these three functions, although producing different results, appear to be very similar in their nature, and are equally inexplicable by the laws of physical and chemical attractions; the strong effect of which may be found in the want of success, which has followed all the attempts that have hitherto been made to explain them upon these principles.

Of what use is the electric property to those fishes which possess it? Drs. Williamson and Garden state, that it is employed to kill, or at least stupefy other fishes, upon which they prey.

The former relates, amongst his experiments on the electric eel, that some small fishes being thrown into the same water where it was swimming, it immediately killed and swallowed them; but a larger fish being thrown in, it was also killed, although it was too large for the eel to swallow; another fish was thrown into the water at some distance from the eel, it swam up to the fish, but presently turned away, without offering it any violence. After some time it returned, when, seeming to view it for a few seconds, it gave the fish a shock, upon which it instantly turned up its belly and continued motionless; at the same instant Dr. Williamson received a shock in his hand, which had been previously introduced into the water. A third fish was thrown into the water, to which the eel gave such a shock that it turned on its side, but continued to give signs of life; the eel seeming to observe this as it was turning away, immediately returned and struck it quite motionless. The eel never attempted to swallow any of these fish after the first, although he killed many of them.
F I S H.

in great abundance on the coasts of England, and many other places, and is in its greatest perfection in the beginning of the summer, though some times later than others, according to the severity or mildness of the winter. The whole occasion of these fish coming in such quantities is to feed on this plant; and those who would attend to its growing up, would know when to expect the mackerel better than those who lien for thunder for the signal of them. These come at certain seasons to the coasts of Provence and Languedoc, in the same sands that herrings and mackerel do to other places. This seems to be on another occasion; the fish called by the French the emperor, and by the same confounded with the sword-fish, is the great enemy of these fish, and in summer is so plentiful in those seas, that they find no way of saving themselves, but by flying to the shallow waters, where the other cannot easily follow them; hence they frequent the shores. The pilchards caught upon the coasts of Brittany, and making a considerable article of commerce for that province, are yet a stronger proof of the natural means that bring fish in shoals to certain places, than any other. These fish evidently come for food, and that not natural to the place, but prepared for them by the inhabitants.

The people of Brittany purchase from Norway the offal and entrails of all the large fish caught in the northern seas; this is of late years become a regular and considerable article of trade; they cut these to pieces, and sell them in vast quantities over the whole surface of the sea along their coasts, at times when the winds do not blow so as to blow it off. This always brings together the pilchards in vast shoals as the herring and mackerel come in other places; and the fishermen catch them in such quantities, as to be able to supply all the maritime places in the neighbourhood, with them, at a small price. The salmon, a fish bred in rivers, yet going at certain times to the sea, is another of those fish which come up at times in vast shoals. See Salmon.

We may here add that the desire of food urges fish of one species to follow those of another, upon which they prey, through immense tracts of ocean, even from the vicinity of the pole down to the equator. Thus the cod from the banks of Newfoundland purifies the whiting, which is driven before it even to the southern shores of Spain; and the eel, a species of whale, is said, in the same manner, to purify a shoal of herrings, and to swallow great numbers at a mouthful.

In the Philosophical Transactions, No. 463, sect. 1. we have a method of preparing specimens of fish, by drying their skins, as practised by Dr. Gronovius.

F is h, Black. See Perca nigra and Silurus aquatarius.

F is h, Petrified, in Natural History. The remains of scabrous or funny fish in the strata, are not very commonly found, compared with the vast numbers and variety of all fish whose remains are found; but some very perfect specimens do occur in different strata. Dr. Tewson (Phil. of Mineral. p. 165) seems to consider fishes as peculiar to some particular kinds of strata; in which, however, he is evidently mistaken, though often they are found in flinty limestone, in the quarries of L'Aberche and Pappenheim; see W. Martin's Outlines, &c. pp. 206. and 79. Mr. Kirwan (Geol. Eff. pages 243. 245. 245. 255. and 257.) mentions fishes as having been found in different parts of the world in gypsum, in marl, in argillite, in fine-slime, and in argillaceous sand-flone. On the mountains of Castile, great diversity of fishes are found, in a white laminated stone. And in the blue marls, or water limestone strata of England, beautiful specimens of flattened fish are said to be found. at Barton on Soar, in Leicestershire, (the other Barrow near Flete.)

them. When any of the larger fishes that had been shocked, although apparently dead, were removed into water in another vessel, they presently recovered. Phil. Trans. vol. 65. p. 97.

Dr. Garden gives precisely the same account of the electric eel killing or benumbing its prey, and states that it kills, by repeated shocks, fish which are larger than it can swallow.

It seems, therefore, that the electric property is not an useful one to those fishes which possess it; besides being the means of securing their prey, it must also form an excellent defence for them against the larger fishes, which might otherwise devour them. For a more detailed account of the torpedo, and gymnatus electricus, we refer the reader to France. Redi Exper. Nat. 1666. Obserazioni intero alle Torpedini, de Stecch. Lorenzini, 1678.—Kernp. Amen. Fish, Migration of, denotes their departure from some parts of the ocean and their removal to other parts; and also to rivers at certain seasons of the year, for the purpose of depositing their spawn, or of obtaining the means of subsistence.

The migration of certain kinds of fish in shoals and infinite multitudes, to certain coasts at certain times of the year, is a thing of great advantage to mankind, as it gives opportunities of taking them with great ease, and in vast quantities; but the reason of these periodical returns of the several kinds does not seem much understood, though a little observation would probably clear it up. There is a small fish common in many seas, but particularly plentiful on the coasts of Normandy in the months of June, July and August. This is well described by Rondelet, under the name of the sea-caterpillar; and at this time of the year it is so frequent in the place before mentioned, that the whole surface of the water is covered with it as with a scum. This is the season of the year when the herrings come in such prodigious shoals to those coasts. The fishermen complain much of these nally venom, which disturb their fisheries; but they do not consider that it is to these alone that their fisheries are owing; for it is evident that the herrings feed on these creatures greedily, by the vast quantity found in all their stomachs; and it is highly probable, may scarcely be doubted, that the reason of these fish coming up in such numbers is to feed on them; probably, if observation was made, the same would be found to be the case in all the other places where the herrings come in the same sort of plenty. The mackerel come down in the same numbers regularly at certain times of the year, and for the same sort of reason. This fish is an herb-eater, and is particularly fond of that sea-plant called by naturalists the narrow-leaved purple palnated sea-wrack; this grows
Bredon in the same county has quarries of the yellow or magnesia limestone, a circumstance not always adverted to, in speaking of barrow lime, and in other places on its range. Mr. Graydon (Irish Tran. vol. v. p. 315.) supposes the monte bolca limestone to have been suddenly interred by being enveloped in a diffusion of lime, arising from immense maizes of calcareous slime, ejected in a calcined state, by submarine volcanoes. To us it seems more probable that the igneous rocks were destroyed by the original creation of the earth, and which now engulfs them, whose diffusion in the water wherein they lived, occasioned their fall to the bottom and extension on their flat side when dying, in the position in which they now appear on the lamina of the lower limestone before the upper one, which engulfs them, was produced by the precipitation of the lime matter from the fluid that had occasioned their death; and on similar principles, we think it easy to account for all the fossil reliquia, or relics of the primary creation of organized beings, see Ref. 11. under which title, we propose to give the heads of Mr. W. Martin's excellent mode of arranging extraneous fossils, from his work above quoted.

Fish, with regard to commerce, is distinguished into dry, pickled, green, and red. Dry or salt fish, is that which is salted, and dried either by the heat of the sun, or by fire. Such principally are the cod, rockfish, pilchard, anchovy, and pilchard. See Fishpond. Green fish, is that lately salted, and which yet remaining moist; as green cod, &c. Pickled fish, is that boiled and steeped in a pickle made of salt, vinegar, &c. as salmon, cod, herrings, macarel, pilchard, anchovy, and oysters. Red fish, is some fresh fish broiled on the gridiron, then refined in oil of olives, and barrelled up with a proper liquor, as new oil, vinegar, salt, pepper, cloves, and laurel leaves, or other herbs. The best fish thus prepared areurgeon and tunny.

Fish, considered as a food, makes a considerable article in the furniture of the table; and the breeding, feeding, catching, &c. of them, constitute a peculiar art of no small moment in the economy of a gentleman's house and garden. To this relate the ponds, tanks, &c. described in their proper places. See Fishpond, Stew, &c.

Fish, Breeding of, is a practice similar to that of blowing flih, poultry, and pigs, and adopted for the same deceitful purposes. The method of blowing fish, especially cod and whiting, is by placing the end of a quill or tobacco-pipe at the vent, and pricking a hole with a pin under the fish, which is next the gill; thereby making the fish appear to the eye large and full, which, when dried, will be flabby, and little less than skin and bones. But this imposition may be discovered by placing the finger and thumb on each side of the vent, and squeezing it hard; the wind may be perceived to go out, the skin will fall in, and the fish appear lank and of little value.

Fish, Breeding of. See Fishpond.

Fish, Calmation of, is a method first practised by Mr. Tull, in order to prevent the excessive increase of fish in some of his ponds, where the numbers did not permit any of them to grow to an advantageous size. But he afterwards found, that the calmated fish grew much larger than their usual size, were more fat, and always in feation. This operation may be performed both on male and female fish; and the most eligible time for it is when the ovaries of the female have their ova in them, and when the vesels of the male, analogous to these, have their seminal matter in them; because at this time, these vesels are more easily distinguished from the ureters, which convey the urine from the kidneys into the bladder, and are situated near the seminal vesels on each side of the spine; which, without sufficient attention, may be mistaken for the ovaries, especially when these last are empty. The time best proper for this operation, is just after they have spawned, because the fish are then too weak and languid to bear with success, so severe an operation; however, with skill and care, it may be performed almost at any time. When a fish is to be calmarated, it must be held in a wet cloth, with its belly upwards, and tied with a sharp pen-knife, having its point bent backwards, the operator cuts through the integuments of the rim of the belly, taking care not to wound any of the interstiles. As soon as a small aperture is made, he carefully inserts a hooked pen-knife, and with this dilates this aperture from between the two forefins, almost to the anus. He then, with two small blunt silver hooks, five or six inches long, and of this form, by the help of an assistant, holds open the belly of the fish; and with a spoon or spatula, removes carefully the interstiles from one side. When these are removed, you see the ureter, a small vesel, nearly in the direction of the spine, and also the ovary, a larger vesel, lying before it, nearer the integuments of the belly. This last vesel is taken up with a hook of the same kind with those before mentioned, and, after detaching it from the side far enough for the purpose, divided transversely with a pair of sharp scissors, care being taken that the interstiles are not wounded or injured. After the ovaries has been divided, the operator proceeds to divide the other in the same manner; and then the divided interstiles of the belly are fewed with fish, the fish bones being inserted at a small distance from one another. Mr. Tull observes farther, that the spawning time is very various; that trouts are fall about Christmas; perch in February; pikes in March, and carp and tench in May; and that allowance must be made for climates and situation, with regard to the spawning of fish. When the fish are calmarated, they are put into the water where they are intended to continue; and they take their chance in common with other fish, as though they were not calmarated. With tolerable care, few die of the operation. Phil. Tran. vol. xlviii. part n. art. 160.

Fish, Eyes of. See Eyes and Anatomy of Fish.

Fish, Fecundity of, has been taken notice of by various writers, who have furnished inferences of it in some particular species that have been thought surprising. M. Petit is said to have found in the carp 321,144 eggs; and Lewenhoeck, in a cod of middling size 6,374,000. But Mr. Mathews has lately performed the operation of the curious subject with peculiar attention and accuracy, and extended his inquiries to a greater variety of species than any other person. The method which he adopted was that of weighing the whole spawn very exactly; he then took a piece weighing a certain number of grains, and carefully counted the eggs contained in it; and by dividing the number of eggs by the number of grains, he found, nearly, how many eggs there were in each grain. His computation of the number of eggs exceeded no farther than to those when he could distinguish with his naked eye; though by this limitation, he omitted many eggs, discoverable by a microscope, that might justly have been counted. The weights he used were avoidupoises, and he reckoned 437 2/3 grains to an ounce.

The following table exhibits the general result of his enquiries: the first column contains the names of the fish which he examined; the second, their weight; the third, the weight of their spawn; and the fourth their fecundity; and the fifth the time of the year, when each species of fish was examined. He has also added other columns, exhibiting the portion of spawn weighed, and the number of eggs found in a grain, and the result of examining several varieties.
ties of the same species of fish of different weights, which the curious reader may consult. See Phil. Trans. vol. 111. for 1767. art. 32. p. 230.

* N. B. Part of the spawn of this fish was accidentally lost, and therefore this number is considerably too small. Such an amazing increase, if allowed to attain maturity, would overflow nature; and even the ocean itself would not be able to contain, much less to provide for its inhabitants. But this surprising fecundity is widely directed to two important purposes; it preserves the species among innumerable enemies, and it serves to furnish the rod with sufficiently adapted to their nature.

**Fish, Feeding of.** 1. In a stream, thirty or forty carps may be kept from October to March, without feeding; and by fishing with trammels, or flews, in March or April, you may take from your great waters, to recruit the flews; but you must not fail to feed all summer, from March to October again, as constantly as cooped chickens are fed; and it will turn to as good an account.

2. The confinement and regularity of serving the fish conduceth very much to their well eating, and thriving.

**Fish, Care of.** It is best committed to the gardener, who is always at hand, and on the spot.

**Fish, Weights.** Any sort of grain boiled is good to feed with, especially peas and in hot course ground; the grains after breeding, while fresh and sweet, are also very proper; but one bushel of millet, not brewed, will go as far as two of grains; chippings of bread, and parings of a table, steeped in top-droppings of strong beer, or ale, are excellent food for carps. Of these the quantity of two quarts to thirty carps, every day, is sufficient; and to be fed morning and evening, is better than once a day.

**Fish, Feeding of.** There is a sort of food for fish that may be called accidental, and is no less improving than the bell that can be provided; and this is when the pools happen to receive the wash of commons, where many sheep have pastured; the water is thus enriched by the soil, and will feed a much greater number of carps than otherwise it would do; and further, the dung that falls from cattle standing in water in hot weather, is also a very great nourishment to fish. See further on the method of feeding carp, and the advantages resulting from it, under the article Fish-ponds.

**Fish, Feeding of.** The bell feeding place is towards the mouth of the pond, at the depth of about half a yard; for by that means the deep will be kept clean and neat, the meat thrown into the water, without other trouble, will be picked up by the fish, and nothing will be lost; yet there are several devices for giving them food, especially peas; as a square board like a trencher, supported by four strings, one at each corner, with leads at the bottom for fish to play under. When fish are fed in the larger pools or ponds, where their numbers are great, malt boiled, or fresh grain, is the bell food. Thus carp's may be fed and raised like capons, and perch will feed as well; but perch are not for a fish in feeding time.

**Fish, Generation of.** The general opinion of the world as to the generation of fish, is, that the female deposits her spawn in eggs, and that the male after this ejects the sperm or male semen upon it in the water, by means of which they are fecundated. The supposed want of the organs of generation in fish, has given an apparent probability to this; but Linnaeus is very decided against it. He affirms that there can be no possibility of the impregnation of the eggs of any animal out of its body.

To confirm this, the general course of nature, not only in birds, quadrupeds, and insects, but even the vegetable world, has been called in to his assistance, as proving that all impregnation is performed whilst the ova are in the body of the parent, and he supplies the want of the organs of generation by a very strange process, affirming that the males eject their semen always some days before the females deposit their ova or spawn, and that the females swallow this, and have their eggs by that means impregnated by it. He says, that he has often seen three or four females at this time frequently gathered about the male, and greedily snatching up into their mouths the semen he ejects; he mentions sons of the same sex, some perch, and some of the eel species, in which he had been present at this process. Mr. C. also affirms, that he has frequently seen fishes in actual copulation, and that the whole business is generally done before the ova arrive at maturity. Phil. Trans. vol. xlviii. part ii. art. 106. p. 87. See EXPLANATION OF FISH.

**Fish, Generation of.** Fishes have different seasons for depositing their spawn; some, that live in the depths of the ocean, will not choose the winter months; but in general those with which we are acquainted choose the hottest months in summer, and prefer such water as is somewhat warmed by the beams of the sun. They then leave the deeper parts of the ocean, which are the coldest, and fixed round the coasts, or in the upraised sea water rivers, which are warm, as they are comparatively shallow. When they have deposited their buds, they return to their old stations, and have their progeny to fight for themselves. The spawn continues in its eggstate in some fishes longer than in others; and this is preparatory to the animal's life. E. g. in the salmon, the young spend continues in the egg, from the beginning of December till the beginning of April; the carp continues in the egg, or above three weeks; the little white fish from China is produced in 10 days. All these, when exhausted, are not able to he their uninterfered with agility. They rise, sink, and swim much more readily than grown fish, and they can escape into shallow waters when pursued. But with all these advantages,

Fish Bay, in Geography, a bay on the S. coast of Africa. S. lat. 30° 30'. E. long. 22° 3'.—Allo, a bay on the W. coast of Africa. S. lat. 16° 40'.—Allo, a bay on the N. E. coast of the island of St. Matthew, in the Mergui Archipelago.
Fish, Little, a bay on the W. coast of Africa. S. lat 15° 20'.
Fish Creek, a river of Virginia, which runs into the Ohio. N. lat. 30° 31'. W. long. 81° 5'.—Alo, a river of Maryland, which runs into the Chesapeake. N. lat. 33° 38'. W. long. 76° 43'.
Fish River, a river of West Florida, which runs into Mobile bay. N. lat. 30° 30'. W. long. 87° 50'.
Fish River, Great, Rio Pignonia of the Portuguese, a river of Africa, which rises in the country of the Hotten-tots, beyond the Snowy mountains, and, in its long course, collects a multitude of dreamlets, most of which are constantly supplied with water. On each side of its mouth is a rocky and open shore, but the projecting cliffs form a small cove or creek, which was frequented by the Portuguese shortly after their discovery of the Cape; though from the basaltic appearance of the rock upon the bar that evidently covers the entrance of the river, it is difficult to conceive how they could trust their ships in such an exposed situation; in fact, indeed, they were so small as to be able, at high water, to cross the bar, in which case they might lie, at all feasons, in perfect security. Great Fish river is now considered as the eastern boundary of the Cape Colony.

FISHBONE CREEK, a river on the N. side of the isle of Wight, which runs into the sea. N. lat. 52° 44'. W. long. 1° 4'.

FISHER, John, in Biographia, a worthy English Catholic prelate, was born at Beverley in Yorkshire in the year 1450. His father dying when he was very young, he was placed under the instructions of a priest of the collegiate church in his native town. In the year 1474 he was entered a student at Michael House, Cambridge, a college that is now incorporated into Trinity-college. He took his degrees in the year 1488 and 1491. In 1495 he was appointed one of the proctors of the university, and in a few months afterwards he was chosen master of Michael house, and entered into holy orders. He soon became distinguished on account of his great learning; and attained the high office of vice-chancellor of the university. Scarcely had he performed the duties of chancellor two years, when he was selected as chaplain and confessor to Margaret countess of Richmond, the king's mother. He so entirely gained the confidence of this lady that she committed herself and family to his government and direction. By his advice she established a divinity professorship at Oxford and one at Cambridge; and founded Christ's and St. John's colleges in the latter university. In 1501 he was admitted doctor in divinity, and in the following year the lady Margaret's first divinity professor in Cambridge. In 1504 he was raised to the bishopric of Rochester, and was afterwards frequently offered more valuable fees, which he refused, observing, that "though others have larger revenues, I have fewer souls under my care, so that when I shall have to give an account of both, which must be very soon, I would not defire my condition to have been better than it is." Fisher was now chosen chancellor of the university of Cambridge, and was much engaged in superintending the building of Christ's and St. John's college, being the most active agent and executor of the late countess of Richmond. When St. John's college was finished Fisher went to Cambridge, and opened it with due solemnity, and was commissioned to draw up a body of statutes which should establish it as a college in its own right and as a valuable benefactor to the college, and was the means of the appointment of that illustrious man, Erasmus, to lady Margaret's professorship of divinity, and afterwards to the Greek professor's chair. To the innovations proposed by Luther, bishop Fisher was decidedly hostile: he not only endeavoured to prevent the propagation of Lutherism in his own diocese, and in the university of Cambridge, but wrote and preached with the utmost zeal against it. He is generally thought to have had a principal share in the composition of the work ascribed to Henry VIII., and published with his name, in defence of the "seven sacraments," against Luther, though Burnet and others are not disposed to give it to the bishop. Fisher at this period was very high in favour with the king, and so zealous in his opposition to the tenets of Luther, that he formed a design of going to Rome to concert measures with the popes for opposing his progress; but he was diverted from his design by cardinal Wolsey's convocation of a synod of the whole clergy of England for the same purpose. In this assembly he appeared in the character of a zealous advocate for reformations in the manners of the clergy; and some of his speeches on this and other important occasions are preserved in the Biographia Britannica. About the year 1527 the king applied to him for his opinion on the subject of his marriage with Catherine, his brother's widow. This was the rock on which he found red. So long as his sentiments were congenial with those of the monarch he was in the highest esteem; but now he gave a determination which did not correspond with his passions; he declared honestly, and without any reserve, "that there was no reason to question the validity of the marriage, since it was good and lawful from the beginning." The bishop had made up his mind on the business, and nothing could divert him from an avowal of it on all proper occasions, though he probably foresaw that his own ruin would be the consequence of his yielding integrity. When the divorce came to be argued before the two legates, Campeggi and Wolsey, bishop Fisher, who was one of the queen's counselors, was at the court, and professed himself willing to resign his see; but to this the pope would not consent, and Fisher retained his see, and the office of chancellor, until his death.
cil, exerted himself with much zeal in her behalf, presenting the legates with a book which he had written in defence of the marriage. The bishop did not stop here; he opposed the king in some other of his projects, and resiled a motion made for the suppressing of the smaller monasteries, and granting their revenues to the crown. The speech which he delivered on this occasion was received with great applause by those who adhered to the papal church, and with equal disapprobation by the advocates of the reformation. Some expressions which he used so much offended the house of commons, who complained to the king of the reflections which the bishop had cast on the representative people, that the king sent for the prelate, and having heard his defence, dismissed him with an admonition, "to be more temperate in future." In the year 1530 he was twice in imminent danger of his life. His first escape was from poison which a man by the name of Roufe threw into some gruel preparing for the bishop's dinner; his second was from a bullet fired into his library where he usually sat. After this the bishop retired to Rochester, where he spent most of his time. In 1531 the question was agitated as to giving Henry VIII. the title of supreme head of the church of England: the bishop took the negative side of the question, and opposed the project with all his zeal. He next opposed his sovereign by giving credit, or at least listening to the enthusiastic visions of Elizabeth Barton, the pretended holy maid of Kent. This woman, who was only an instrument in the hands of designing persons, carried on her importunities with a view of alienating the affections of the people from the king, and exciting insurrections against his government. The bishop, it was very evident, had no ill design in the part he took; but finding the prophetets, as she was then denominated, was devoted to the interests of the queen; and having heard much of the fancy of her manners, of the visions which she saw, and of the predictions which she uttered, and which were said to be realized, he conceived she was designing by Providence to display and make triumphant the doctrines and authority of the church of Rome, over the principles of Lutheranism, which were rapidly spreading in England. Fisher accordingly listened to her prophecies, and conceded one of them which seemed to affect the king, or at least to strike a blow at his authority. She announced to her adherents, that if Henry should proceed in his divorces, and marry another wife, he would not be king feven months afterwards. This woman was apprehended, and in the hope of pardon confessed the particulars of her importunity, and named all those who had encouraged her delusions. The bishop was urged to make submissions to the king as the only way of allaying his anger; he refused, and in 1534 a bill of attainder was passed against Elizabeth Barton and her accomplices. Bishop Fisher still refused to submit, and was adjudged guilty of misprision of treason, and condemned to forfeit all his goods and chattels to the king, and to be imprisoned during his majesty's pleasure. It is not certain that the act was enforced against him; but when the act was passed to annul the king's marriage with Catherine of Arragou, and to confirm that with Anne Boleyn, and enjoining all to take the oaths accordingly, bishop Fisher, instead of uniting with his brethren, left the capital. Opportunity was, however, given him again and again to consider the oath, till at length he absolutely refused; and was attainted in the parliament which met in 1534, and his bishopric was declared void. The bishop was thrown into the Tower, where he was treated with much severity, and, as it should seem, from some of his letters, fearfully alarmed the common necessaries of life. Here he would probably have been permitted to have ended his days, had not a cardinal's hat been conferred on him by pope Paul III. which so enraged the king, that he swore it should never be permitted to enter his dominions; and if Fisher were determined to wear it, it should be on his shoulders, for he would not leave him a head for the purpose.

From this time his destruction was resolved on, and the tyrant sent the solicitor-general, Rich, whose name is rendered infamous by undertaking the business, to pump out of him his secret opinions with regard to the supremacy, declaring he had the king's authority to say that no ill use whatever should be made of the communication, which he fought merely on account of the high opinion he entertained of his judgment and integrity. "The bishop gave an unreserved decision on the subject, which the solicitor carried to his master; and on the instant a special commission was issued for trying him for high treason. Rich was the chief and indeed the only evidence that could affect the life of the venerable prisoner, and yet a jury, as infamous as the evidence, found him guilty. The bishop pathetically appealed to the court on the occasion, "I pray you, my lords, consider that by all equity, justice, wordly honesty, and courteous dealing, I cannot be directly charged with treason, though I had spoken the words indeed, the same not being spoken maliciously, but in the way of advice and counsel, when it was requested of me by the king himself; and that favour the very words of the statute do give me, being contrary against such as shall maliciously gain the king's supremacy, and none other: wherefore, although by the rigour of the law you may take occasion to condemn me, yet I hope you cannot find law, except you add rigour to that law to call me down, which hereby I hope I have not deserved." To Rich he addressed himself, "Mr. Rich, I cannot but marvel to hear you come in to bear witness against me of these words, knowing in what secret manner you came to me." He then assured the court that he (Rich) had told him, the king wished him to declare, that on the honour of a king, whatever he should say by this his secret messenger, he should reap no peril or danger therefrom, nor should any advantage be taken against him for the same. Still the court gave sentence, and notwithstanding the honour of a king was opposed to it, Henry confirmed the bloody decree, and the worthy prelate was beheaded on Tower Hill on the 22nd of June 1535, at the age of seventy-five. Erasmus represents him as a man of the greatest integrity, of a strict learning, incredible sweetness of temper, and grandeur of soul. By friends and by enemies he was regarded as a pious and charitable man, not only learned himself, but a great encourager of learning. His chief work was a "Commentary on the seven patristical Pfalmus." Biog. Brit.

FISHER, in Zoology. See Mustela Zibellina.

FISHERMAN'S COVE, in Geography, a harbour on the S. coast of Pitt's Archipelago, within Nepanet's bound. N. lat. 53° 18'. E. long. 23° 53'.

FISHERROW, a town of Scotland, in the county of Edinburgh, at the mouth of the Eik, in the parish of Torith, opposite to Musselburgh.

FISHER'S CANAL, a branch of an inlet leading from Fitzhugh's found, on the W. coast of North America, as called by Capt Vancouver in 1793. At the entrance N. lat. 54° 5'. E. long. 232° 5'.

FISHER'S ISLAND, an island in the Atlantic in Long-island, found, near the S. coast of Connecticut. It is about ten miles in length and two in breadth, with a good soil, favourable for rearing sheep and producing wheat and other grain. It is annexed to the township of South-held, in
Suffolk county, on Long Island. N. lat. 41° 12'. W. long. 72°.

FISHERSFIELD, a township of America, in the state of New Hampshire and county of Hillsborough, incorporated in 1763, containing 526 inhabitants; about 16 miles easterly of Charlestown.

FISHERY, a commodious place for fishing; or a place wherein great quantities of fish are caught.

The principal fisheries of Europe for salmon, herring, cod, and mackerel, are along the coasts of England, Scotland, and Ireland; for cod, on the banks of Newfoundland; for whales, about Greenland; for pearls, in the East and West Indies, &c.

FISHERY also denotes the commerce of fish; more especially the catching of them for sale. The fishery makes a principal branch of the British commerce. A great quantity of vessels and seamen are employed therein; and besides what is spent at home, large sums are yearly returned, merely for herring, cod, and pilchards, exported to Spain, Italy, and several parts of the Mediterranean, and the islands of the Archipelago.

Yet are our countrymen reproached, and with a good deal of justice, for their remissness in this branch of trade. The advantageous situation of our coasts might be of immense benefit to us, did we not let our neighbours overreach us therein. The Dutch, French, Hamburghers, &c. have been accustomed to come yearly in large fleets, and not only to take the fish from our own coasts, but fell them to us for our money, when they have done.

Scotland fuffers incredibly on this score; no country in Europe can pretend to rival it in the abundance of the fine fish, wherewith its numerous harbours, loughs, rivers, &c. are flored. In the river Dee, it is said, an hundred and seventy head of salmon is not very extraordinary for a single draft of a net; and the picked salmon sent hence is allowed the best in Europe. The Scottish islands, especially those on the western side, do certainly lie the most commodiously for carrying on the fishing trade to perfection.

King Charles I. directed his attention to the Scottish fisheries in 1633 and 1635, in conjunction with a company of merchants under his royal commission and patronage, and encouraged by his bounty. With this view he ordered Lent to be more strictly observed; prohibited the importation of fish taken by foreigners, and agreed to purchase from the company his naval stores, and the fish for his fleets; but the civil wars soon set this plan aside. The company had built two fishhouses or magazines; one on the small island of Hermitra, on the north side of North Uist, and the other upon a small island in Loch Maile, a celebrated bay of the above-mentioned North Uist. King Charles II. in 1661, made a like attempt; and was joined in it by the duke of York, lord Clarendon, and several other persons of rank and fortune. In prosecution of the design the most salutary laws were enacted by the parliaments of England and Scotland, in virtue of which all materials used in, or depending upon, the fisheries, were exempted from all duties, excises, and other imposts. In England the company was authorized to set up a lottery, and to make a voluntary collection in all parish churches; and other encouraging measures were adopted. Some Dutch families were invited, or permitted, to settle at Stromway; but whilst the plan appeared to be judiciously formed and likely to succeed, the king having a prejuring occasion for money, was perfidious to withdraw what he had employed in the fishery, at which the merchants joined with him, being displeased, did the like themselves. In 1677, a new royal company was established in England, at the head of which were the dukes of York, the earl of Derby, &c. Besides all the privileges which former companies had enjoyed, the king granted this new company a perpetuity, with power to purchase lands, and also 200l. to be paid them annually out of the customs of the port of London, for every dogger or buss they should build and send out, for seven years to come. A fleet of 10,980l. was immediately advanced, and afterwards 1600l. more. This small capital was soon exhausted in purchasing and fitting out busses, and other incidental expenses. The company, however, made a successful beginning, and one of their busses or doggers took and brought home 32,000 cod-fish; other vessels had also a favourable fishery. But most of the busses, having been built in Holland, and manned with Dutchmen, the French, then at war with Holland, took six out of seven vessels, with their cargoes and fishing tackle; and the company, being in debt, sold, in 1680, the remaining vessels, &c. A company of merchants raised a new subcription of 60,000l. under the privileges and immunities of the former charter. But this attempt proved abortive by the king’s death and the troubles of the next reign. Soon after the revolution the business was again resumed on a more extensive scale, the proposed capital being 500,000l.; but this scheme failed. Since the Union, several efforts have been made to retrieve it; and in 1750 there was a corporation settled on that footing by parliament, called “the Society of the Free British Fishery,” for the term of twenty-one years, under the direction of a governor, president, vice-president, council, and other officers, who were empowered to make bye-laws, &c. and to raise a capital of 500,000l., and the Scotch fishery, encouraged by fishing-chambers, erected in several cities, which establishments promised a more permanent duration. See Herring Fishery.

FISHERY, Anchovy. See Anchovy.

FISHERY, Cod. The cod is a fish of passage, pretty large, with a great head, and teeth in the bottom of the throat; its flesh white; its skin brownish on the back, white under the belly, and covered with a few thin, transparent scales.

It is excellent food when fresh; and, if well prepared and salted, will keep a long time. The fish, thus prepared, is commonly eaten among us in Lent, &c. under the denominations of salt-fish, or pickled-fish.

There are two kinds of salt cod; the one called green- or white; and the other dried, or cured; though it is the same fish, only differently prepared.

They are also distinguished by the places from whence they are brought, as well as by the manner of curing, into Aberdeen-fish, Iceland-fish, green-fish, rock-fish, North-sea cod, poor Jack, and barrelled cod.

Green Cod.—The chief fisheries for green cod are in the bay of Canada, on the Great and Little Bank, near the coast of Newfoundland, the isle of St. Peter, or Pierre, and the isle of Sable; and thither vessels are yearly sent from divers parts both of America and Europe.

The vessels used herein are from a hundred to a hundred and fifty tons burden; and these will bring thirty or thirty-five thousand fish a-piece.

The most essential articles in this fishery are the persons who know how to open the fish, to cut off the heads, and to take them; upon this, almost the only occasion of which last the success of the voyage chiefly depends.

Several authors will have it, that the Biscayans, in pursuance of their whale’s, made the first discovery of the Great and Little Banks of cods at Newfoundland, Canada, &c. a hundred years before Columbus’s time; and that it was a Biscayan...
Bifayan Newfoundlander that gave the first intimation thereof to Columbus.

Others say, that the Great Bank was discovered by a native of St. Malo's, named Cartier. England claimed an exclusive right to the North American seas, in virtue of the discovery of those seas by Sebastian Cabot, in the service of King VII., and first to the northward of thirty degrees; and though the discovery is certainly highly valuable; there is not a trading nation in Europe but allows the commerce of cod-fish to be one of the most secure and gainful that is known.

The bell, largest, and fattest cod are those taken on the southern and western sides of the Great Bank, which is a kind of submarine mountain, stretching from N.E. to S.W., one hundred and fifty miles long, and fifty broad, and at the distance of twenty-five leagues from Newfoundland: those on the north side are generally much smaller. The water on the bank is from 22 to 50 fathoms; on the outside from 60 to 80; on the lefier banks much the same. A great fewell and thick fog generally mask the place of this bank. The chain of lesser banks lies between Newfoundland and Cape Cod in New England; as the Green, French, Porpoise, and Saline Banks, and also Browns and St. George's. Besides these banks, the whole coast of Newfoundland, New England, Nova Scotia, and Labrador, is one continued fishery.

The belt season for this fishery is from the beginning of February to the end of April; at which time the cod, which, during the winter had retired to the deepest part of the sea, return to the Bank, and grow very fat.

Those caught from March to June keep well enough; but those taken in July, August, and September, soon spoil. The fishing is sometimes done in a month, or six weeks; and sometimes it holds four or five months. As Lent draws on, if the fishermen have but half their cargo, they strive who shall make homeward the first; the market being then the bell.

Some will thus make a second voyage, before others have got loading for the first. Each fisher only takes one cod at a time; and yet the more experienced will take from three hundred and fifty to four hundred per day; but this is the most; for it is very fatiguing work, both on account of the weight of the fish, and of the extreme cold which reigns on the Bank.

The wages usually allowed the captain and sailors is one third of the cod they bring home found.

They salt the cod on board. The head being cut off, the belly opened, and the guts taken out, the fisher ranges them in the bottom of the vessel, head to tail; and having thus made a layer thereof, a fathom or two square, he covers it with salt; over this he lays another layer of fish, which he covers as before; and thus he dispenses all the fish of that day, taking care never to mix the fish of different days together.

By that time the cod has lain thus to drain three or four days, they are moved into another part of the vessel, and salted after. After this they are no more to be touched, till the vessel has its burden.

Sometimes they put them up in barrels, for the convenience of carriage.

Dry Cod.—In the fishing of dry cod, vessels of all sizes are used; though such are generally choico, as have large holds, because this sort of fish incumbers more than it burdens.

As cod is only to be dried by the sun, the European vessels are obliged to put out in March or April, to have the benefit of the summer for drying. Indeed, we feed vessels for cod in June and July; but those only buy what had been fished and prepared by the inhabitants of Newfoundland, and the neighboring parts; in exchange for which, we carry them meal, brandies, biscuits, pulse, molasses, linen, &c.

The principal fishery for dry cod is along the coast of Phoebus, from Cape Rofe to the Bay des Experts; in which compass there are divers commodious parts for the fish to be dried in.

The fish intended for this use, though of the same kind with the green cod, is yet much smaller; whence it is the fitter to keep, as the salt more easily penetrates it.

The method of fishing is much the same in both; only this latter is the more expensive, as it takes up more time, and employs more hands; and yet scarce half so much fish is spent in this as in the other.

When several fishing vessels meet, and intend to fish in the same port, he whose shallops first touches ground, becomes entitled to the quality and privileges of admiral; he has the choice of his station, and the disposal of all the wood on the coast at his disposal. (10 & 11 W. III. c. 25.)

As fast as the captains arrive, they unrig all their vessels, leaving nothing but the thongs to sustain the mast, and in the mean time the masts are provided with tent on shore, covered with branches of fir, and falls over them; with a scaffold, fifty or sixty feet long, and about one-third in breadth.

While the scaffold is making ready, the crew are fishing; the proceeds of which, as it is described by Mr. Pennant in his "Arctic Zoology," is as follows:

The boats or shallops are 40 feet in the keel, rigged with a main-mast and fore-mast, and log-falls furnished with four oars, three of which row on one side, and the other (which is twice as large) slays the others, by being rowed sideways over the stern, by a man who stands for that purpose, with his face towards the rowers, contriving them, and steering at the same time as he gives way to the boat. Each of the men in this boat is furnished with two lines, one at each side of the boat, each furnished with two hooks; so that sixteen hooks are here constantly employed, which are thought to make a tolerable good day's work of it, if they bring in from five to ten quintals of fish, though they have流感age for, and sometimes bring in thirty. Two hundred quintals are called a faying voyage, but not less. The bait is small fish of all kinds: herring, capelin, lance, tom cod or young cod; the fish of which they fell, and keep for some time, in case of scarcity of the rest; but these are much less eagerly taken by the fish when salted. In case small fish cannot be gotten, they use kip, which are easily taken in small numbers, by laying nets over the holes in the rocks where the water comes to reach the night. If neither small fish nor birds are to be procured, they are forced to use the raws of fish which they catch; but this is the worst but of any.

When the fish are taken they are carried to the flounder, which is built with one end over the water, for the convenience of throwing the offal into the sea, and for their boats being able to come close to discharge their fish. As soon as they come on the flounder, a boy hands them to the header, who hands at the side of a table next the water, and whose business is it to gut the fish and cut off the head, which he does by pricking the back of the head against the side of the table, which is made sharp for that purpose, when both head and guts fall through a hole in the floor into the water. He then throws the fish to the splitter, who stands opposite to him; his business is to split the fish, beginning at the head, and opening it down to the tail.
FISHERY.

tail; at the next end he takes out the larger part of the back-bone, which falls through the floor into the water. He then shakes the filth off the table, which drops into a kind of hand-barrow, which, as soon as it is filled, is carried off to the salt-pile. The header also flings the liver into a separate bucket, for the making of whale oil, used by the curriers, which bears a higher price than whale oil.

In the salt-pile the fish are spread upon one another, with a layer of salt between them. Thus they remain till they have taken salt, and then the salt is washed from them by throwing them off from shore in a kind of float, called a "pound." As soon as this is completed, they are removed to the last operation of drying them; which is done on standing flake, made by a flight whate, just strong enough to support the men who lay on the fish, supported by poles, in some places as high as twenty feet from the ground; here they are exposed, with the open side to the sun; and every night, when it is bad weather, piled up five or six in a heap, with a large one, his back or skinny part uppermost, to be a shelter to the reef from rain, which hardly damages him through his skin, as he lies floating each way to float it off. When they are tolerably dry, which in good weather is in a week's time, they are put in round piles of eight or ten quintals each, covering them on the top with back. In these piles they remain three or four days to sweat; after which they are again spread, and, when dry, put into larger heaps, covered with canvas, and left till they are put on board.

When prepared they are sent to the Mediterranean, where they fetch a good price; but are not exported in England, for which place another kind of fish is prepared, called by them "Mud-fish," which, instead of being split quite open, like their dry-fish, are only opened down to the navel; they are salted and laid in salt, which is washed out of them in the same manner with the others; but instead of being laid out to dry, are barrelled up in a pickle of salt boiled in water.

The train oil is made from the livers; and it is so called to distinguish it from whale or seal oil, which they call fat oil, and is sold at a lower price (being only used for lighting of lamps) than the train oil, which is used by the curriers. It is thus made: they take a half-tub, and, boring a hole through the bottom, press hard down into it a layer of spruce boughs, upon which they place the livers, and expose the whole apparatus as sunny a place as possible. As the livers corrupt, the oil runs from them; and, draining itself clear through the spruce boughs, is caught in a vessel set under the hole in the tub's bottom.

The founds and tongues are salted at the same time with the fish, and barrelled up: the roes or eggs, being salted and barrelled up, serve to cast into the sea to draw fish together, and particularly pilchards.

By the definitive treaty between Great Britain and France in 1763, the French, who are allowed to fish in the gulf of St. Lawrence, are now absolutely deprived of the powerful fortifications of Cape Breton, and of the possession of Canada and all its dependencies; and are entitled to no possessions contiguous to Newfoundland, except the small islands of St. Peter's, or Pierre, and Miquelon, ceded by the article of the said treaty to his most Christian Majesty as a shelter for the French fishermen; and his most Christian Majesty engages not to fortify the said islands, to erect no buildings upon them, but merely for the convenience of the fishery, and to keep upon them a guard only of fifty men for the police. And by the eighteenth article of the said treaty, it is expressly stipulated between Great Britain and Spain, that his Catholic Majesty deftis, as well for himself as for his successor, from all pretensions which he may have formed in favour of the Guipuscoans and other his objects, to the right of fishing in the neighbourhood of Newfound-

The French, by the treaty of 1783, were to enjoy their fisheries on the northern and western coasts; the inhabitants of the United States having the same privileges as before their independence: and the preliminaries of October, 1811, confirm the privileges granted to the French.

By 43 Geo. III. c. 154, a bounty of 31. per quintal shall be paid on the importation of pickled salmon and dry cod from the island of Newfoundland; the master and mate of every ship importing making oath, at the port of importation, that such fish was taken and cured by British subjects carrying on the fishery at Newfoundland or Labrador; and such fish may be exported without repayment of the bounty. For other regulations of this fishery, see 19 & 20 W. III. c. 25; 26 Geo. III. c. 26; 27 Geo. III. c. 19; 29 Geo. III. c. 53.

Of all the migrating fishes, herrings excepted, the cod is the most valuable to mankind. This fish, we may here observe, is found of cold climates, and is supposed to remain chiefly between the latitudes of 66° and 45°. Those that are taken north and south of these latitudes are either few in number, or bad in quality. They are found as far north as Greenland, but they are small and unacclimated. In Europe they chiefly frequent the coasts of Iceland, Norway, the Baltic, the islands and main land of Scotland. After passing these latitudes, they decrease in number. The English fishermen take them on the Dogger-bank, the Well-bank, and the Cromer, lying on the coast of the kingdom, opposite to Norfolk, Lincoln, and Yorkshire. Of these the Dogger-bank is the most extensive and valuable for white fish in general, as we learn from the account transmitted to Mr. Pennant by Mr. Travis, surgeon in Scarborough. The Dogger-bank lies 12 leagues from Flamborough-Head, and 15 miles from Scarborough; the north side of the bank stretches off E.N.E. between 32 and 40 leagues. The fishermen seldom find any cod, fry, or other round fish upon the bank itself, but upon the floating edges and hollows contiguous to it. The shifting sand on the top of the bank affords them no sufficiency; and the shallow agitated water allows them no rest. It is in the hollows between the Dogger and the Well-bank that the cod are taken which supply the London market. The shore along the coast on the one hand, and the edges of the Dogger-bank on the other, like the sides of a decay, give a direction towards our fishing grounds to the shores of cod, and other fish, which migrate annually from the northern ocean into our seas; and the great variety of fishing grounds near Scarborough, extending upwards of 14 leagues from the shore, afford secure retreats and plenty of proper food for all the various kinds of fish, and also suitable places for each kind to deposit their spawn in.

The bell bait for all kinds of fish is fresh herring cut in pieces of proper size; and next to these, the leifer lampreys, small haddock cut in pieces; sand-worms, mussels, and limpets; and, in defect of these, bullock's liver. The hooks are smaller than those used in Iceland and Newfoundland; being 2 inches long in the shank, and near an inch wide between the shank and the point. The line is made of small cordage, and is always tanned before it is used. The bell weather for succeeding in fishing is a half calm, when the waves are just curled, with a silent breeze.

In our seas the cod-fish begin to spawn in January, and deposit their eggs in rough ground among rocks. Some continue in the rock till the beginning of April. Thesefishes
F I S H E R Y.

fishes in general recover sooner after spawning than any other; and, therefore, it is common to take some good ones all the summer. Those of a middling size are most esteemed for the table, and are selected by their plumpness and roundness, especially near the tail; by the depth of the pit behind the head, and by the regular condulated appearance of the sides, as if they were ribbed. The cod, and other fish of this genus, are in highest favour in the winter; but even then, the glutinous parts about the head lose their delicate flavour after the cod hath been 24 hours out of the water. The general weight of these fish on the Dogger-bank is from 14 to 40 pounds.

The Scottish white fishery, comprehending cod, ling, hake, turbot, skate, foals, and flounders, abound so universally around the Scottish shore, that the whole northern seas, from the Dogger-bank in lat. 54° to the northern extremity of Iceland in lat. 67°, and from the coast of Norway eastward to unknown latitudes on the west, may be considered as one great fishery, in which Scotland, as lying in the centre, has manifestly the advantage over all other nations. The white fishery may be supposed to comprehend the eastern coast fishery from Berwick to the Pentland firth, the Shetland or N.E. fishery, and the Hebride or N.W. fishery. The most considerable of the banks in the eastern fishery, called by way of pre-eminence the "Long Fortys," stretches in a parallel line with the easter coast, from the county of Durham to Kinnaird's head, at the entrance of the Moray firth; thus affording an uninterrupted line of fisheries almost from one extreme of the kingdom to the other, and in some parts at a very inconsiderable distance from the shore. The Shetland fisheries are carried on by two different methods; viz. by boats accompanied with decked vessels, and by boats only. Those of the first class go out of sight of land, where, in 90, 100, and 120 fathoms water, they get the largest fish. When they arrive on the fishing grounds, they set their long lines, each line of 56 fathoms having 15 hooks; and these lines are joined to one another, till the number of hooks amounts to from 600 to 1000. In the fishery by boats of 2 tons burden, and 6 men each, they fish in summer at the distance of 7 to 15 leagues from land, and in winter at the distance of 3 leagues. The summer fishery is carried on from the 18 of June to the 18 of August; the boats go out three times a week, and continue 24 hours each time. The large boats carry from 150 to 120 lines; each line being from 54 to 60 fathoms in length, and hung with 15 hooks at 20 feet distance from one another. In winter they use lead lines, when long ones cannot be managed. They bait with a small fish called pollocks, when at sea; and if these cannot be procured, they use cod, turbot, haddock, or any other fish. The Hebride or N.W. fishery extends from the head of the Solway firth to the coast of Iceland, lying at the distance of 400 miles N.W. from the Long island in the Hebrides. The principal bank in the fishery grounds, lying between the Hebrides and the main land, begins near the mouth of Garden in Roft-lane, and is supposed to stretch in a N.W. direction, towards the Butt of the Lewis, and possibly beyond that cape. This abounds in all the varieties of white fish. A chain of small banks stretches along the east side of the Lewis, from 3 to 5 miles off the shore, and is carried on by the natives both in summer and winter. The whole coast of the Shetland is also one continued fishery, and the seas of the South Hebrides present a number of fishing banks, which our limits will not allow us to recite. But the most extraordinary and valuable bank is called by the old natives the "Mother-bank," and lies between Mull on the east, and Barra and South Uist on the west. There is a bank between the islands of Coll and Colland Tirey, in the direction of the small island of Ganna, which lies in the centre. A valuable bank lies between the islands of Mull, Coll, and Ardanaurchan, on the main land of Argyllshire. In the sound of Mull there is a small bank, which stretches from Aros to Scaladale's bay. There is an inconsiderable fishery along the coast of Argyllshire, called the Inner Sound; a bank lies between Loch Tarbat in Jura, and the isle of Colonia, 16 miles long and 1 broad. Another lies in the channel between Jura and Ilay on the west, and the main land of Knapdale on the east. Those which we have enumerated are the principal banks of the Hebrides, on the west side of the Mull of Cantire. On this side of the cape, within the firth of Clyde, there is a good fishing ground around the Craig of Ailsa; from whence a large bank stretches from Ballintire in Arran, and thence, along the coast, to the Mull of Galloway, where it is lost in the Irish channel. Another bank stretches in a N.W. direction towards Sunda island, and from thence towards Knapdale, off the north side of Arran. Such is the immense scene of improvements, with regard to the Scottish white fisheries, that presents itself to those who are anxious to promote the British fisheries. In some respects the Scottish fisheries have the advantage of those of Newfoundland. The banks of Newfoundland lie at the distance of 2500 to 3000 miles from London, Bristol, Liverpool, Dublin, Cork, and Glasgow; and can only be frequented during the months of February, March, April, May, and June: whereas the Scottish fisheries, when the proposed navigations shall be opened, will, upon a medium, be within a week's sailing of these commercial emporiums, which they can annually in seafons when the Newfoundland fisheries cannot be carried on.

The Irish white fisheries are chiefly cod, ling, hake, coal-fish, and haddock. In these fisheries the Irish are very expert, being trained to the business by their fishing on the banks of Newfoundland, as well as the bays of that island; to which fisheries some thousands of Irishmen resort every seafon, and from whence they return with a small pittance to their families. White fish abound on the west coast of Ireland; but no regular fishery has yet been established with success. See more on this subject in Knox's View of the British Empire, &c.

F I S H E R Y, Herring. The herring is a small salt-water fish, with a bluish back, and a white ferrled belly, not unlike a little shad fish; whence it is called in Latin alfa minor. Rondellet calls it haragus.

It is a popular error to believe the herring to be the bale of the Romans. The bale was so particular fish, but a kind of fauce, made of any kind of salt-fish. The modern herring seems to have been unknown to the ancients; it is neither the bale, nor bales, nor manis, nor innonnis, nor the gera, or Pliny. See Rondellet de Piscib. Marin. lib. v. cap. 13, and Vullios de Idalal. See HERRING.

Herrings are chiefly found in the North sea. In those inconsiderable seas, that are covered with ice during a great part of the year, the herrings hid a quiet and safe retreat from all their numerous enemies; there neither man, nor their full more destructive enemy, the sun-fish, or the exhaust, the most voracious of the whole kind, dares to pursue them. It is true, there are fisheries elsewhere, but none so obvious.

They usually make two fishing seasons for herrings: the first in June, July, and August; the second in autumn. The latter of these is the more considerable, on account
FISHERY.

of the fogs, which are very favourable to this kind of
thing.

The herrings usually keep at some distance from the
coast in July and August; and it is at this time only that
the fishers follow them in the open sea. About the end
of August, and until the middle of September, they come into
shallow water, where they remain for some time in the bays
and inlets of the coast; and this is termed the ground draw.

It hath been observed, that the arrival of the herrings on
the coast of Shetland is certain, and almost to a day, on or
before the 22d of June. As they invariably follow a
southern course, after leaving the Shetland islands, they
reach the Hebrides in July, and keep pressing forward till
the beginning of September, when they go into deep
water.

Fresh shoals appear in November, and continue till Ja-

Frenish. They is an instance which, and cai'd
is far July, but before 22d June. As they invariably follow a

The winter rendezvous of the herrings is probably the
icy sea, within the Arctic circle; as this sea swarms with in-
fects in greater abundance than in our warmer latitudes.

From this sea the great colony of these fishes冬天 about
the middle of winter; and this colony is composed of such
numbers as to exceed the power of imagination. But they
have no sooner left their retreats than they have to encounter
with a multitude of enemies. The fowl-fish and eel-fish
devour them in great abundance; and belugas, the porpoise,
the grampus, the flark, cod-fish, haddock, pollock, and
the numerous tribe of dog-fish find them an easy prey,
and defies from making war upon one another. To these
enemies we may add immeasurable flocks of seal-fish that chiefly
inhabit the northern regions towards the pole, which watch
the outlet of their perilous migration, and spread among
them extensive ruin. In this state of danger, the defeeds
emigrants crowd closer together, as if they could thus se-
cure themselves against the attacks of their enemies.
The main body begins to separate, at a certain latitude, into
two great divisions; one of which moves to the west, and
pours down along the coasts of America, as far south as
Carolina, and becomes so numerous in the Chesapeake bay
as to be a nuisance to the shores. The other division
takes a more easterly direction towards Europe, and falls in
with the great island of Iceland about the beginning of
March. Upon their arrival on that coast, their phalanx,
which hath already suffered considerable diminution, is
nevertheless found to be of such extent, depth, and densi-
fity, as to occupy a surface equal to the dimensions of
Great Britain and Ireland; but subdivided into columns of
5 or 6 miles in length, and 3 or 4 in breadth; each line or
column being led, according to the ideas of fifteen men,
by herrings of more than ordinary size. The herrings swim
near the surface, linking occasionally for 10 or 15 minutes.
The fore-runner of those who visit the British kingdoms ap-
ppear off Shetland in April or May, and the grand body
begins to be perceived in June. Their approach is known
to the fishers by a small rippling of the water, the reflection
of their brilliancy, and the number of solan gannets, or gar-
nets, and other aerial perceptors, who are eager to devour
them and who, with the marine attendants, may forever
see the shoals of them into bays and creeks, where many
thousands of them are taken every night from June till Sep-
tember. Although the Shetland islands break and separate
the grand body of the herrings into two divisions, they still
continue their course towards the south. One division pro-
ceeds along the east side of Britain, and pays its tribute to
the Orkneys, the Murray forth, the coasts of Aberdeen,
Angus, and Fife, the great river Forth, the coast of Scar-
borough, and particularly the projecting land at Yarmouth,
the ancient and only mart of herrings in England, where
they appear in October, and are found in considerable quan-
tities till Christmas. The other division pursues its course
from the Shetland islands, along the west side of Britain;
and there are observed to be larger and fatter than those on
the east side. After pursuing the Shetland and the Orkney
isles, they crowd in amazing quantities into the lakes, bays,
and narrow channels of the shores of Sutherland, Ross, and
Inverness; which, with the Hebride islands, especially the
Long island, form the greatest stationary herring fishery in
Britain; that upon the coasts of Shetland excepted. Some-
times this shoal, in its southern progress, edges close upon
the extensive coast of Argyllshire; fills every bay and
creek; and visits, in small detachments, the firth of Clyde,
Lochline, and other lakes within the entrance of that river;
the coast of Arran, and of Galloway, to the head of the
Solway firth. This shoal proceeds from the western shores
of Scotland towards the north of Ireland; where, meeting
with a second interruption, they are again divided into two
brigades. One shoal passes down the Irish channel, visits
the isle of Man, and affords an occasional supply to the east
coast of Ireland, and the west coast of England, as far as
the Bristol channel. The other shoal skirts along the west
coast of Ireland, where, after visiting the lakes of Done-
gal, it gradually disappears, and is finally lost in the im-
meability of the Atlantic. Herrings, it is observed, are not
seen in quantities in any of the southern kingdoms, as Spain,
Portugal, or the south parts of France, on the side of the
Ocean, or in the Mediterranean, or on the coast of Africa.

"Were we inclined," says a well-known writer, "to
consider this partial migration of the herring in a moral
light, we might reflect with veneration and awe on the
mighty power which originally impregnated, on this most
useful body of his creatures, the instinct that directs and points
out their course, that blest and enables these isles,
which cause them at certain and invariable times to quit
the polar seas, and offer themselves to our expecting
feast."—"This impression was given them, that they
might remove for the sake of depositing their spawn in
warmeater, that would-mature and vivify it more affuredly
than those of the frigid zone. It is not from defect of
food that they set themselves in motion, for they come to
us full of fat, and on their return are almost uniformly ob-
erved to be lean and miserable. What their food is near
the pole, we are not yet informed, but in our seas they
feed much on the onions marin, a calausious insect, and
sometimes on their own fry. They are in full roe to the
end of June, and continue in perfection till the beginning
of winter, when they begin to deposit their spawn. Though
we have no particular authority for it, yet, as very few
young herrings are found in our seas during the winter, it
seems most certain that they return to their parental haunts
beneath the ice, to repair the vast destruction of their race
during summer, by men, fowl, and fish."

It has been generally supposed that the Hollanders were
the first who began the herring-fishery, and observed the several seasons of their passage. Their herring fishing is fixed to the year 1165. It is recorded, however, in the first life of Bishop de St. Ouen, that the herring was brought to the inhabitants of the Netherlands as early as the ninth century. This traffic laid the foundation of a commercial alliance between the two countries, which subsisted, to their mutual advantage, during many ages. Although many laws were enacted during the reigns of James III. IV. V. and VI. for recovering the fisheries of the eastern side of the kingdom, which the Dutch had encroached, greatly to the prejudice of the rightful owners; yet it is well known, that since the first establishment of the herring fishery, the Dutch have enjoyed the principal part of it, and it has very much contributed to their advancement and prosperity in former times. Our seas were their "original mines," as they themselves have acknowledged.

In the year 1313 we have an account of the seizure of a ship of Lynn, in the port of Bergen, which had been fishing on the Norwegian coast for herrings. (Rymer's F. vol. iii. p. 400.) And as landings of herrings carried to a distance must have been salted, it is plain that salted herrings, whether wet or else dried, called red herrings, were in those times a merchantable commodity in foreign parts. And in 1338 we have an account of fifty laths of herrings shipped from Portsmouth for the use of the army and fleet of Edward III. in Cafernay, which must have been salted, either wet or dried. (Fed. vol vii. p. 12.) And they were barrelled and salted at the port of Whitby in Yorkshire, in 1394. Fed. vol. vii. p. 778.

But the present method of pickling them was not discovered till the year 1416, though others date it from the year 1397. Willughby, in his History of Fishes, observes, that Will. Buckell's, or Bachalen, a native of Bier Ufflet, near Shays, who died in 1507, rendered his name immortal by the discovery of the secret of curing and pickling herrings, which he might probably have learned from the people of Yarmouth, and other parts of England, where herrings were not only salted and dried for red-herrings, but salted and barrelled up wet, at different times, from the year 1326 to 1350. Willughby says, that the emperor Charles V. coming to the Low Countries, made a journey to Bier Ufflet, with the queen of Hungary, that he might have the opportunity to view the tomb of this first barreler of herrings. It may be allowed, however, that Bachalen, or Benkelen, might have made some improvement in the practice; which his countrymen afterwards contributed to perfect. By their ingenuity and perseverance they reduced the whole business of the fisheries into a regular system, which it would be the interest of other states to follow. They have likewise been widely aided from time to time by their respective provincial legislatures, not only in every privilege and support, but also in a well digested body of laws and regulations, extending to the most minute circumstances, from the commencement of the out-lie to the export of the herrings.

Yarmouth has been long famous for its herring-fair, which was regulated by an act, commonly called the statute of herrings, in the thirty-first year of Edward III.

This politic monarch, with a view of promoting the herring trade, became a purchaser of their fish; and, in 1358, fifty laths of herrings were shipped from Portsmouth for the use of his army and fleet in France. This practice was adopted by his successors down to queen Elizabeth, who also enforced the ecclesiastical laws respecting the observance of Lent in favour of the fisheries. Indeed Yarmouth owed its rise to the fishery, for the place where it now stands was only a sand-bank in the sea, which in process of time became dry land, and drew thither fisher-men from various parts of England, and also from France and the Low Countries, for the purpose of catching herrings. The commencement of this fishery appears, from several concurring circumstances, to have taken place soon after the landing of Cerdic, the Saxon, in 495. (See YARMOUTH.) The Yarmouth herrings maintained their reputation, and the inhabitants were reckoned the best curers in Europe, so that the Dutch were in the number of their foreign customers. The Yarmouth people have greatly the advantage over the Dutch, in being nearer the herring shoals, and less in being plentifully supplied with wood; whereas the Dutch are obliged to smock their herrings with turf or saw. The fishery commences here about the twenty first of September, and continues till the twenty-fifth of November. The fishing grounds are from ten leagues N. of Yarmouth to the South Foreland. Their trunks or vessels carry from thirty to fifty tons, and each is equipped with 90 or 100 nets, which are replaced about the middle of the season by a fresh lot, of the same quantity and dimensions. Each fish is with a bell, for the purpose of being caught by a fort of machine, as soon as they are disengaged from the nets; the bottom of the well being full of holes, through which the blood and water are discharged. There are two apartments called wings, one on each side of the well, into which the men throw the herrings with scoops; a third throws in the salt, while a fourth and fifth throw up the herrings to the furthest part of the wings. By these means they are preferred till each vessel hath got in 10 or 12 laths, when the vessel returns to Yarmouth road, and the fish is removed ashore in small boats, and conveyed to the fish-house. Here they are salted on the floor, in which flate they lie for two days; they are then washed in large vats of fresh water, put on the spits, and dried with many fires of billet-wood. If the herrings are intended for exportation, they are kept in this flate from four to six weeks, when they are packed in casks of 52 gallons; each cask containing 1000 herrings. One half of salt cures three laths of herrings. This ancient fishery is now much on the decline; and the town has suffered much on this account.

The Dutch began their herring-fishery at the twenty-fourth of June, and employed no less than ten or eleven hundred vessels therein. These vessels are a kind of banks, called fijzenes, carrying from forty-five to sixty two, and two or three small cannon.

Before the establishment of the Society of the Free British Fishery, the number of Dutch vessels employed in this fishery was more considerable, and amounted to a hundred or two thousand.

None of them were allowed to fish out of port without a convoy, unless there were enough of them together to make eighteen or twenty pieces of cannon; in which case they were allowed to go in company. Before they left, they made a verbal convention; which had the same force as if it were in writing.

These regulations of the admiralty of Holland were partly followed by the French, and other nations, and partly improved and augmented with new ones; so that no fisher should sell his net within an hundred furlongs of another boat; that while the nets were on board, a light should be kept on the third part of the vessel; that when a bell was by any accident obliged to leave off fishing, the light should be cast into the sea; that when the greater part of a fleet left off fishing, and call anchor, the red should do the same, &c.

By the act for encouraging the British white herring-fish.
ery, in 1750, it is required, that the busses employed in this fishery, entitled to the bounty of 30s. per ton, shall be decked vessels, built in Great Britain, after the commencement of the act; and that each of them shall carry twelve Whinchester busses of salt, for every half of fish which such vessel is capable of holding; and as many more barrels as such a ship is capable of carrying, and two fleets of haired nets, &c. every vessel of some tons shall have one fleet of nets, every thirty yards full on the rope, and seventeen fathoms deep, and others in proportion; and be provided with one other fleet of fifty like nets, on board a jagger or tender, which is to attend the said fishery. Every such busses properly manned and furnished, shall proceed either to Braffey's Sound in Shetland, and he at the rendezvous of the said fishery there, on or before the eleventh day of June, and shall not shoot their net till the thirteenth, and shall continue following the shoal and fishing, as they move southward, to the first of October; or to Campbeltown in Argyle, and be at the rendezvous of the said fisheries on or before the first day of December, unless they shall have sooner completed their loading of fish.

By 26 Geo. III. c. 81, continued by a subsequent act, a bounty of 20s. per ton shall be paid annually to the owner of every decked vessel, not less than fifteen tons burden, manned and navigated according to law, employed in the British whale fishery, subject to certain regulations, and with the alterations made by 42 Geo. III. c. 79. Every busses or vessel to be entitled to the above bounty shall be built in Great Britain, and have on board (in new barrels) twelve busses of salt for every half of fish, which such ship can carry, and also 250 square yards of netting, and not less than five men for the first 15 tons, and one additional man for every additional five tons; and shall clear out from some port in Great Britain between June 18th and November 20th in the same year, and proceed immediately to the said fisheries, and continue fishing three months, unless its cargo be completed. On its return the officer of the customs shall examine the condition and lading of the ship; and after other documents being produced the commissioners of the customs or excise in Scotland, shall cause payment to be made to the owner or owners, or his or their assigns, the sum of 20s. per ton, according to the measurement of such busses or vessels. For every barrel of herrings twice packed and completely cured, which shall, during one year, be landed from any vessel not entitled to the aforesaid bounty per ton, there shall be a bounty of 4s. But if the number of barrels of herrings imported shall, in one year, exceed the proportion of 22 barrels of herrings, packed and cured as aforesaid, for every ten burden of such vessel, then there shall be paid for every barrel exceeding the said proportion a bounty of 1s. only. For all herrings which shall be landed from any boat or vessel not entitled to the bounty of 20s. per ton, and which shall afterwards be properly salted and cured, there shall be paid a bounty of 6d. per barrel. For the encouragement of the fishery, called the Deep Sea fishery, over and beyond the bounties before granted, there shall be paid the following premiums; i.e., for the greatest quantity of herrings caught by the crew of any one vessel, entitled to the aforesaid bounties of 20s. per ton, and 4s. and 1s. per barrel, and imported by such vessel between June 18th and November 31st in any one year, the premium of eighty guineas: for the next greatest quantity sixty guineas; and for the next forty guineas; and for the next twenty guineas. By 56 Geo. III. c. 81, the ears of fish in Great Britain were allowed to take salt, for the purpose of curing fish, but by the 36th of Geo. III. which subjects salt to the excise duties, and enacts new regulations, this act may be considered as virtually repealed, at least as to its principal clauses. There are other provisions included in the laws, 27 Geo. III. c. 15. 33 Geo. III. c. 56, all which provisions and powers contained in preceding acts are revived by 42 Geo. III. c. 79, except as to the bounties, which bounties by this act are as follows: From the 5th of April 1807, one-half of the bounty of 20s. per ton, and one-half of the bounties granted by the preceding acts for every barrel of herrings landed from any raft or vessel, in respect of which a bounty of 20s. per ton is granted by the said acts, shall cease and determine. For other regulations of the herring fishery, see HERRING.

The manner of fishing has nothing particular in it. The nets wherein the fish is drawn should regularly have their meshes an inch square, that none of the fishery may be taken.

The commerce of herring, both white, i.e., pickled, and red, is very considerable; but there are so many different ports, prepared in such different ways, and different places, that it is hard to say any thing precise thereupon.

The white herrings cured by the Dutch used to be in the greatest repute; they were distinguished into four kinds, according to their sizes. The good sorts of this commodity contain in their coat fat, fatty, firm, and those of 42 Geo. III. caught but when in season, chiefly in the month of July; being taken alive out of the nets; being salted the same day it is taken, and with good salt, and well barrelled.

The Irish herrings have been esteemed the next in value after those of Holland; and principally those of Dublin, which are scarce inferior to the best herrings of Rotterdam or Enkhuizen.

It was about the year 1754, that the Irish parliament began to frame such laws, and to grant such aids as the nature of the fisheries suggested. The principal fisheries of this country are in Loch Sull, the Roffes, Killebegs, and Inverbay, on the coast of Donegal; and an inferior kind of herrings is occasionally taken on the coast of Sligo and Mayo, as far southward as Bredhaven. The fishery at Inverray begins in July, and continues till the beginning or sometimes the end of September. The other fisheries commence in November, and end in January. The herrings taken by the British vessels are preferred, on account of their being gutted, and cured in barrels of 32 gallons. The Irish uncutted herrings, on the other hand, are in some parts of the coast fished in holes dug in the earth, till the herrings have an opportunity of falling them to the busses; they are then packed or piled up in the hold of the vessel, and are thus carried to Cork, and other ports, when they are put into barrels of 32 gallons, and exported to the West Indies. Of the winter herrings taken in Loch Sull, 500 will fill a barrel; and of the early herrings, 800. The busses are from 20 to 100 tons burthen, and are under certain parliamentary regulations, respecting netting, and the number of men. The nets are tamed with a mixture of tar and fish oil, in the proportion of five parts of tar and one of oil; and improvements have been made in the method of working the nets.

The Scotch herring is not so well prepared, gutted, filled, or barrelled, as the Dutch; and yet its talle is excellent, that of those caught on the western coast especially; nor is it to be doubted, but that if the Scots were as careful in these circumstances as their neighbours, their herrings would be the best in the world.

The whole coast of Scotland may be considered as one continued
continued fishery, distinguished, however, by the names of the Shetland, or northern fishery, that on the east side of the kingdom from the Pentland firth to Berwick, and the western or Hebridean fishery. The principal town on the Shetland islands is called Lerwick, situated on a narrow channel of the Main-land, called Braith or Braich-bound. Either the Dutch and other foreigners have been accustomed to refer to the fisheries at the appointed feasons, when Lerwick hath had all the appearance of a continued market on fair. The eastern fisheries along the eastern shores of Scotland, though less considerable than those on the coasts of Shetland, might with proper attention be of great national benefit. But though the whole line of coast from Caithness to Berwick is the occasional resort of herrings, in their autumnal voyage southward, yet in this course of 300 miles, (including the Murray firth,) there is not a fixed or stationary fishery, such as that at Yarmouth, Dealeng, and Gottenburgh, where the herrings arrive almost to a certainty, and generally at the same period of time. The shores on the eastern side of Scotland, that have been most generally explored, and that have produced the greatest quantity of herring, are those of the Forth and the Murray firth. The herring fishery in the Forth was conducted formerly by open boats, which amounted to the number of 6 or 800, and many thousand barrels of herrings were annually exported, besides supplying the home demand. The coast fishing on the Murray firth was conducted on the same plan, governed by the fame regulations, and proportionally benefited to that populous, though remote part of the kingdom. It employed from 5 to 700 boats. These fisheries, at present, in a low state, might be extended to any degree; and also the deep water fishery, to the distance of 20 miles from the coast, where the herrings are larger and fatter than those taken in the Forth, or near the shores, and are nearly equal to the herrings taken in deep lochs of the West Highlands. This deep water fishery should be carried on by buffets or decked vessels, from 20 to 80 tons burden, which ought to be at the Shetland islands early in the feafon, and the produce should be speedily carried to the proper markets; whilst the buffets may continue the fishery down the channel till the end of the feafon. In this manner the markets would be confantly supplied, greatly to the benefit of the merchant, the buffers, and the labouring poor, along the whole coast. The Hebridean, or western fishery, was frequented in very early times by the French and Spaniards, who trafficked with the natives for fish; whence we may conclude that the natives were buffers, and that foreigners were the carriers. It is probable that the fishery was then carried on by little open boats, or berlins, such as the Highlanders generally ufe at the present day. This fishery was the thoroughfare, as we may call it, of the great western fish of herrings, in their annual tour from the Shetland islands to Ireland, which, in the opinion of some writers, they environ, and from whence they return by the opposite channel, in the fame manner as the eastern fishers environ Great Britain, and return north by the western channel. This Hebridean fishery, confidering the manner in which it was conducted, may be juftly fied the school of navigation; and on this account, as well as for its produce, deserves British encouragement. As a nursery of Seamen, the boat fishery will exceed that of the buffets with regard to numbers of persons employed; but, on the other hand, it cannot be put into competition with the buffets in respect of nautical knowledge.

The herring fishery in England is inconsiderable; the fish being too dry for the market. However, at Yarmouth and Lowestoff they have in former times taken and cured about 50,000 barrels of red-herrings in a year; and very large quantities are also caught at the mouth of the Thames by the fishing-smacks of London, Folkestone, Dover, Sandwich, &c. for the London markets, and near the sea-coast of Kent and Suffolk for general consumption. Some shoals are also forced, by the great swell of the Atlantic, into the Bristol channel, and particularly into the Bay of Barfplain, where they have been sometimes taken and cured for exportation, in very considerable quantities.

ging and preparing herrings.—1. For white or pickled herrings: as soon as the herrings are taken out of the sea, one of the crew, appointed for this office, cuts them open, and takes out the guts, and every thing but the milts and roes, which are always to be left in the body of the fish. Then washing them in fresh water, they are left the space of twelve or fifteen hours in a tub full of strong brine made of fresh water, and sea-falt.

When they are taken out, they drain them; and when well drained, put them up in barrels; taking care to dispose and range them evenly, in rows, or layers, pressing them well down, and flrewing a layer of salt both at top and bottom.

When the barrel is full, they flop it up very clofe, that no air may get in, nor any brine out; either of which is very prejudicial to the fish.

The Dutch, after opening and gutting the herrings, cure and salt them by blying or rubbing their inside with salt; they are then packed, with handfuls of salt between each row, and flapped up clofe.

2. For red-herrings: the fish being caught, they proceed to wash, gut, and lay them in brine, as for pickled herrings; only they let them lie double the time in brine, viz. twenty-four hours; insomuch as they are to take all their salt here, whereas the other kind takes half its salt in the barrel.

When the herrings are taken out of the brine, they spit them, i.e. firing them by the head on little wooden spits, and thus hang them in a kind of chimney, made for the purpose; and when the chimney is as full as it will hold, which lasts less than ten or twelve thousand flemoh effects, they make a little fire underneath, of bruffh-wood, which yields a deal of smoke, but no flame.

Here the herrings remain till sufficiently smoked and dried; which ordinarily is in twenty-four hours. They are then taken down and barrelled up for keeping.

Their goodness consists in being large, fresh, fat, oily, soft, and pliable, their outside of a yellow, golden colour; their having roes or not, within them, and being well salted and barrelled. See HERRING.

Fishey, Line. This fish abounds near the Scilly isles, and on the Yorkfhire coast. In the latter situation they are in perfection from the 1st of February to the 1st of May, and some till the end of that month. In June they spawn, depositing their eggs in the soft oozy ground of the mouth of the Tees. At that time the males separate from the females, and return to some rocky ground near Flamborough Head, where the fishermen take great numbers without ever finding any of the female or road fish among them. While a ling is in season its liver is very white, and abounds with a fine flavoured oil; but when the fish goes out of season the liver becomes red, like that of a bullock, and affords no oil. When the fish is in perfection, a very large quantity of oil may be melted out of the liver by a fome heat; but if a violent sudden heat be used, for that purpose they yield very little. Great quantities of ling are cured for exportation, as well as for home consumption. When it is set or split for curing, it is stuffed with each other upwards from
the shoulder to the tail; if less than that, it is not reckoned a sizeable fish, and consequently not entitled to the bounty on exportation; such are called drizelles, and are in season all summer. The usual size of a ling is from three to four feet; but some have measured seven feet.

Fishery, Lobster. Lobsters are taken along the British channel, and on the coast of Norway, whence they are brought to London for sale; and also in the frith of Edinburgh, and on the coast of Northumberland.

By 10 & 11 W. III. cap. 25, no lobster is to be taken under eight inches in length, from the peak of the nose to the end of the middle fin of the tail; and by 9 G. II. cap. 33, no lobsters are to be taken or destroyed on the coast of Scotland from the first of June, to the first of September, on pain of 5l.

Fishery, Mackerel. The mackerel is a salt-water fish, without scales. Its body is round and fleshy; terminating almost at a point, at each extreme. Some persons, well skilled in naval architecture, hold its figure the most commodious for swimming of all others, and propose it as a model for the building of ships.

It is ordinarily about a foot long; when in the water it appears yellow, and when out of it a silver white, excepting four streaks, or speckles, of a deep blue, on the back and sides. Its usual weight is about two pounds. During winter a film grows on the eyes of this fish; in the spring they are half blind; and in summer the film is off. See Mackerel.

The mackerel is a summer fish of passage, found in large shoals in divers parts of the ocean, not far north; but especially on the French and English coasts.

The fishing is usually in the months of April, May, and June, and even July, according to the place. They enter the English channel in April, and proceed up to the offshores of Dover, and the mouth of the Thames, as the summer fisheries; so that by June they are on the coasts of Cornwall, Suffolk, Normandy, Picardy, &c. where the fishery is most considerable. An inferior fish is also taken during the harvest months. They are an excellent food, fresh, but their taste and flavor are much impaired a few hours after they are taken; and not to be despised when well prepared, pickled, and put up in barrels; a method of preserving them chiefly used in Cornwall.

Naturalists have observed, that the water wherein mackerel have been boiled, often yields a light, after stirring it a little. See Fish, and luminous stuff of the Sea.

The fish is taken in two ways; either with a line, or nets: the latter is the more considerable, and is usually performed in the night time. The rules observed in the fishing for mackerel are much the same as those already mentioned in the fishery of herrings.

There are two ways of picking them: the first is, by opening and gutting them, and filling the belly with salt, crammed in as hard as possible with a stick; which done, they range them in flara or rows, at the bottom of the vessel, drawing falt between the layers.

In the second way, they put them immediately into tubs full of brine, made of fresh water and salt; and leave them to steep, till they have imbued salt enough to make them keep; after which they are taken out, and barrelled up, taking care to press them close down.

Mackerel are not cured or exported as merchandise, except a few by the Yarmouth and Lowestoff merchants, but are generally consumed at home; especially in the city of London, and the sea-ports between the Thames and Yarmouth, east, and the Land's End of Cornwall, west. By that 35 Geo. III. c. 54. the curers of mackerel in Great Britain may import any quantity of foreign salt, or take any quantity of British salt, from any salt-works and salt-pits, and remove coast-wise the salt so imported, or taken for the purpose of curing mackerel (or any cod, ling, hake, or salmon, being taken in the mackerel fishery) for home consumption, duty free, except the customs due on importation, in as full a manner as the herring and pilchard fishery are enabled to do for home consumption. For every barrel of white mackerel, twice packed, and completely cured, containing 32 gallons, which shall be exported from Great Britain into any parts beyond seas, (except into any part of the Mediterranean) a bounty of 2s. 6d. shall be paid; and for every barrel of mackerel which shall be landed from any boats or vessels, and which shall be properly salted and cured, shall be paid a bounty of 4d.

Fishery, Oyster. It principally carried on at Colchester, in Essex; Prertherham and Milton, in Kent; the Isle of Wight; the Swales of the Medway; and Tenby, on the coast of Wales. From Prertherham, and adjacent parts, the Dutch have sometimes loaded a hundred large hogs with oysters in a year. They are also taken in great quantities near Portsmouth, and in all the creeks and rivers between Southampton and Chichester; many of which are carried about by sea to London and to Colchester, to be fed in the pits about Wavenhoe, and other places. By 31 G. III. c. 51. if any person shall within any net, trawl, dredge, or any other engine, take or catch any oyster or oyster brood, within the limits of any oyster fishery in this kingdom, or use any such engine for the purpose of catching oysters or oyster brood, though none be taken; or drag upon the ground of any such fishery with any net or other engine; every such person, except the owner, lessee, or occupier of the said fishery, or person lawfully entitled to catch oysters therein, shall be deemed guilty of a misdemeanor, and may be indicted at the assizes or quarter sessions for the county or division; and every such offender being convicted by verdict before the justices in sessions, or on his own confession, may be punished by fine and imprisonment, or either of them, as the court may think proper; such fine not to exceed 2l., or be less than 40s.; and such imprisonment not to be for more than three months, nor less than one month. Offenders may be apprehended by warrant of any justices, who may commit them to the common gaol or other prison, until the next assizes or quarter sessions, unless they enter into recognizance with two sureties in 20l. each to appear and answer to such indictment, &c. See Oyster.

Fishery, Pearl. See Pearl fishery.

Fishery, Pilchard. The pilchard is a small salt-water fish, bigger than the anchovy, but less than the herring, which in other respects it resembles. Its head is yellow; its belly white; and its back a green. It is excellent when fresh, or lightly salted. See Pilchard.

There are several reasons for fishing the pilchard; which, like the herring and anchovy, is a fish of passage from the northern latitudes; and its arrival is indicated by similar signs with those of the herring. They are prepared and fished much as the anchovy is; with this difference, that the head is cut off at the latter: but the pilchard is distinguishable from the anchovy, even though its head were off likewise: the pilchard having a very flat back, and the anchovy a round one.

The chief pilchard fisheries are along the coasts of Dalmatia, to the south of the island Ziza; on the coast of Bretagne, from Belle island as far as Breizh; and along the coasts of Cornwall and Devonshire, when they appear about the middle of July, and range between Fowey harbour and the
the Scilly islands about September; some few occasionally returning after Christmas.

It is a saying of the Cornish men, with regard to the pilchard, that it is the least fish in size, most in number, and greatest in gain, of any they take out of the sea. This observation is amply confirmed by Dr. Borlase's account of this fishery; for besides the great number of persons employed by it, the poor are fed with the offals of the captures, the land with the refuse of the fish and flesh, the merchant finds the gains of commission and commerce, and the fisherman the gains of the fish. The usual produce of the number of hogsheads exported each year, for ten years, from 1747 to 1757, inclusive, from the four ports of Fowey, Falmouth, Penzance, and St. Ives, amounted to 29,793 hogsheads. Every hogshead for ten years last past, together with the bounty allowed for each hogshead exported, and the oil made out of each, has amounted, one year with another, at an average, to the price of 19,135, and 30; so that the cash paid for pilchards exported has, at a medium, annually amounted to the sum of 49,532/. 10s. The number taken at one shooting out of the nets is amazingly great. In 1757, there were at one time inincled in St. Ives's bay 7000 hogsheads, each hogshead containing 35,000 o fish; in all 240,000,000.

That on the coasts of Dalmatia is so plentiful, that it not only furnishes all Greece, but a great part of Italy. That fish the coast of Bretagne has employed yearly above three hundred thousands, and most of the feamen of the country.

The fish caught on our own coasts, though bigger, are not so much valued as those on the coasts of France; owing principally to their not being so thoroughly cured.

The season is from June to September.

The pilchards, like the herrings, naturally follow the light, and will gather about a boat that bears a light in the night time; which contributes much to the facility of the fishery.

On the coasts of France they make life of the roes of cod-fish as a bait; which thrown into the sea makes them ride from the bottom, and run into the nets placed for that purpose.

On our coasts there are perfons, called in Cornwall buxte, poled ashore, who, fypping by the colour of the water where the fhools are, make ligns to the boats, to get among them, to call their nets.

When taken, the fish are brought to a warehouse on shore, where they are laid up in broad piles, supported by backs and sides.

As they pile them, they salt them with bay-leaf; in which they lie soaking twenty or thirty days, and discharge a great quantity of blood, with dirty pickle, and bittern; which latter draws much of the oil from the fish, to the great loss of the owners. When taken out of the pile, there remains a quantity of salt, blood, scales, &c. at bottom, which, with fresh salt, makes for another pile.

They now proceed to wash them in sea-water to clear off the dirt and blood; and, when dry, they put them up in barrels, and press them hard down to squeeze out the oil, which issues away at a hole in the bottom of the casks; and in this state they are fit for sale or use.

Fishery, Salmon. The salmon is a northern fish, occupying the European seas, the latitudes lying between France and Greenland, being unknown in the Mediterranean sea, and other warm climates, and, according to some, breeds in the sea; but the opinion of others seems better warranted, that it breeds in the clear fresh parts of rivers, remote from their mouths. They commonly spawn in November; and when they have found a place fit for the purpose, the male and female unite in forming a proper receptacle for it in the sand or gravel, about the depth of eighteen inches; in this the female deposits her spawn, and the male his milt, which they cover carefully, as it is laid, with their tails; for after spawning, they are observed to have no skin on that part. The spawn lies buried till the spring. The milter and spawn, having performed their office, betake themselves to the sea; and if their route is prevented by rivers, or the like, they become sick, lean, and are then called fitter, pine away, and die in two years time. If they spawn in the mean time, the produce is a diminutive salmon, called fry, which will never arrive at the natural bulk; it being the fish that makes them grow big, and the rivers fat. The female is distinguished from the male, in that its nose is longer, and more hooked, its scales not so bright, and its body speckled over with dark brown spots, its belly flatter, and its flesh not so red; more dry, and less delicious to the taste. In spawning time, when they repair from the sea up to the rivers, scarce any thing can stop their progress. Many have seen them leap up cataracts and precipices many yards high. They will ascend rivers 500 miles from the sea, and force themselves against the most rapid streams. They are frequently taken in the Rhine as high as Basile in Switzerland; they gain the sources of the Laperland rivers notwithstanding their strong torrents; and mount the perpendicular fall across the Liuffi, at Leispil, 7 miles above Falmouth, though nearly 50 feet in height. As soon as they come to the bottom of the cascade, they make a violent, and often meeting the obstruction, and retire some paces back; then they review the danger that affails them, ferry it without motion, advance, and again retreat; till at last, fome of the salmon become over all their force, they take a leap from the bottom, with the body quite straight, and with a strong tremulous motion; and they most frequently clear every obstruction. It sometimes happens, however, that they want strength to make the leap, in which case they are entangled in their defence by baskets placed on purpose, from which they cannot escape. The shooting of salmon, in their leap, is sometimes practised for amusement. See SALMON.

When the salmon first enter the fresh water, they have a number of infects, the hero, falmones of Linnæus, adhering to them, especially above the gills, which are sanguine that the fish is in high feaon: these die and drop off soon after the salmon have left the sea. About the latter end of March the spawn begins to exclude the young, which gradually increase to the length of four or five inches, and are then termed smelts or smoute; and about the beginning of May the Twed, &c. is full of them, but they are soon hurried away to the sea. About the middle of June, the earlies of the fry begin to drop, as it were, into the river again from the sea, being about twelve, fourteen, or sixteen inches, and they gradually increase in number and size till about the end of July (at Berwick the fish in this stage is called gille); when they again begin to increase in size, some being, in August, thirty, twenty-eight, or nine pounds in weight.

The chief salmon fisheries are along the coasts of England, Scotland, and Ireland. The fishing usually begins about the first of January, and ends by the last of September. It is performed with nets, in the places where the rivers empty themselves into the sea, and along the sea coasts thereabout. The fish are keen to crowd thither frequently in shoals from all parts in search of the fresh water; they go fish for them higher up in the rivers; sometimes with nets, and sometimes with a kind of locks, or weirs, made for the purpose, with iron grates therein, so disposed, as that...
that the fish, in going up the river, open them with their head; but are no sooner entered than the gate claps to. Thus the salmon are included as in a retort, where it is easy to take them. In some places they fish for salmon in the night time, by the light of torches, or kindled straw. The fishermen watch when the fish draws towards the light, wherein he bears a single lead, and strikes him with a spear or lid. In some parts of Scotland it is said, they ride a fishing up the rivers, and, when they spy them in the shallow parts, shoot them with fire-arms.

Salmon form, in several countries, a great article of commerce; being cured in different ways, by salting, pickling, and drying. There are stationary fisheries in Iceland, Norway, and the Baltic; but those at Coleraine in Ireland, at Berwick in Great Britain, and in some of the rivers of Scotland, are the most considerable. The capture in the Tweed near Berwick, about the month of July, is prodigious; a boat load, and sometimes near two, are taken in a tide; and it is common to take from fifty to a hundred fish at one haul. At this time the cooper in Berwick begin to file both salmon and gilfe in pipes, and other large vessels, and then barreling them to send abroad. The salmon barrel holds above forty-two gallons, wine measure. Most of the salmon taken before April is sent fresh to London; and that which they fail to send is boiled, pickled, and kitted. Fresh salmon has also been seen in London at the latter end of September; but then the fish are full of large roes, very tender, and are esteemed neither palatable nor wholesome. In the month of July a score of fresh salmon, of eighteen pounds ten ounces and a half, has been sold at Berwick for eighteen pence; but the more common price is between fifteen-pence and two shillings and six-pence. The season for fishing in the Tweed begins the thirtieth of November, though the fishermen work very little till after Christmas, and ends on Michaelmas day. There are on this river forty-one considerable fisheries, besides others of less value, which formerly rented for near 54,000 per annum.

Scotland possesses also great numbers of fine fisheries on both sides of that kingdom. The salmon are cured in the same manner as at Berwick; and a great quantity is sent to London in the spring; but after that time the adventurer begins to barrell and export them to foreign countries; though the demand for them is much abated of late years. They have also in Scotland a great deal of salmon, salted in the old-fashioned way; rich, after soaking in brine for a compulsive time, is well preserved, and is not injured in smoke; this is called upper, is chiefly made for home consumption, and, if properly cured and prepared, is reckoned very delicious food. The great fisheries are those of the Tweed, the Forth, the Tay, the Dee, the Don, the Spey, the Findhorn, the Nith, the Braile, and thence northward to Dungibay head, the coast of the Pentland firth, the coast from Cape Wrath to the Mull of Cantire, all the Hebride islands, and the coasts of Ayrshire, Galloway, and the Solway firth, where the rivers, bays, or lakes are open. The season of fishing at Aberdeen is from the 30th of November to the 8th of September; but few fish come into the rivers before the 15th of January, from which time to the middle of May, the salmon are boiled and killed for the London market, and sent off almost every week, by swift falling blogs, called smacks, retained for the purpose. Those that are caught through the summer are salted for foreign exportation. No salmon is allowed to be barrelled and cured, except by the town's cooper, who are required to put the initial letters of their names on their barrels; nor can they be shipped for exportation till the letters A. B. D. have been burned on each barrel, by an officer appointed for that purpose. No fish that hath been bit by seals, none under a certain fixed weight, nor any that have been damaged in the carriage from the river, are to be put into a barrel, without having the word rebate burned on the end of the cask. The barrels are of a fixed size, containing about 250 pounds of fish, so carefully packed that they do not differ a pound of fish from one another. After they are packed from the nets in which they have been salted, great care is taken to keep them brim full of pickle, till the bungs are fixed down, a day or two before they are shipped. By this attention the Aberdeen salmon hath acquired such a character abroad, that it generally fetches the highest price, and no questions are asked respecting the quality.

The north of Ireland abounds with this fish; the most considerable fishery is at Cranna, about a mile and a half from Coleraine, rented, in 1754, for 620l. a year. It is situated on the river Bann, where they fish with nets eighteen foor yards long, and are continually drawing night and day through the whole seafon, which lasts about four months; eight hundred and forty fish have been taken at a single draught. There is also a weir on the river, which takes the fish that escape the nets. In 1760, three hundred and twenty tons were taken in the Cranna fishery. The salmon are cured in this manner: they are first split, and the guts and gills, and many of the bones, are taken out, and then rubbed with fine salt; and after lying in pickle in large tuns for six weeks, are packed up with layers of coarse brown Spanish salt in casks, fix of which make a ton. These are exported to Leghorn and Venice, &c. at the price of twelve or thirteen pounds a ton. Pennant's Brit. Zool. v. iii. p. 284. 294. See a further account of this fishery under Coleraine.

The 4th & 5th Anne, cap. 21, was made for the increase and preservation of salmon in rivers in the counties of Southampton and Wilts, requiring that no salmon be taken between the first of August and the twelfth of November, or under size, &c. And by 1 Geo. I. cap. 18, salmon taken in the rivers Severn, Dee, Wye, Were, Onye, &c. are to be eighteen inches long, at least; and the nets shall not be less than 15 inches in the mesh; nor shall any salmon be sent to London out of the said rivers under six pounds weight; or the persons catching them shall forfeit £5. This statute contains several other regulations. And by 30 Geo. II. cap. 28, no salmon is to be caught in the rivers Thames and Medway between the eleventh of November and twenty-fourth of August, or to be of less weight than six pounds.

Salmon is also fished for in rivers, after the manner of trout, with a line and hook. He bites bet in the afternoon, about three, in May, June, July, and August; the water being clear, and a little breeze of wind stirring; especially if the wind and stream set contrary ways. The salmon is caught like a trout, with worm, fly, and minnow; and especially the garden-worm, if well secured, and kept twenty days in moss. The salmon never stays long in a place, but is continually shifting to be as near the springhead as possible, and swimming generally in the deepest and broadest parts of the rivers, near the ground. Put two or three garden-worms well secured on your hook at once, as if you were baiting for trout; and be sure to give him time to gorge his bait, before you strike. Some use a wire ring on the top of the rod, through which the line may be let run to any length at pleasure, by a reel near the land.

Fishery, Scot, &c. The fishery for seals is very productive.
The skin of the seal is tanned and made into shoes, commonly called dogskin shoes; it also serves for the bottoms of chairs, and for various other purposes. The oil is used in chambers, and falls at a much higher price than that of the cod-fish, which is burned in street-lamps. The greatest seal fishery is on the coast of Labrador in North America. The boats used in the cod-fishery of Newfoundland are about 50 feet in length, decked at both ends; they have two masts, and a short bow-sprit; they are built of fir or spruce, and will fail, as the seamen say, in the wind's eye. In the winter season, when the Newfoundland cod-fishery is finished, these boats, with 50 to 70 men in each, repair to the frozen shores of Labrador, where the winds and tides often drive immense floats of ice into the bays, and on these floats a great number of seals. As the boats belong to different merchants, the float of ice is marked out in equal portions, and each boat's crew is strictly limited to the part assigned them. Having settled these regulations, they attack the seals in their respective departments. The first man of the party advances towards a seal, which he strikes immediately above the nose with a club; then attacks another and kills it; and marches forward to a third, which he also kills. Thus advancing, the whole field of ice becomes a scene of blood, strewed with dead seals. When the first seal is killed, the next person in rank tears off the skin, which he leaves on the spot, and advances to the second, and so on. A third person takes a layer of fat, with which the seal is covered next the skin, which he leaves on the spot, and immediately follows the two others. Thus the killer, the layer of skin and of fat, with the remaining crew, will sometimes clear to the value of 500£. within the interval of 24 hours. When this happens, they return with what they call a full cargo, which abundantly reimburses their employers. The seal-fishing in Scotland is in some respects similar. The Scottish seals are open through the whole year, and the seals, being of the amphibious kind, frequent the coves and openings of the rocks upon the shore, where they bring up their young. The Hebrides, and the northern shores of the main land, are the principal resort of the seals. On the western coast of North Uist, a part of the Long Island, lies the rock Conamail, about a quarter of a mile in circumference, which is still famous for the yearly fishing of seals there the end of October. This rock belongs to the farmers of the adjacent lands; one of whom furnishes a boat, to whom a particular share is due on that account, besides his proportion as a tenant. The minnister, rector, and subordinate officers have their shares by virtue of their respective offices. The farmers man their boats with a competent number of persons; and when the crew are landed, a signal is given for a general attack, the pairs being surrounded, and they beat down the seals with their flaves. The seals on this occasion make towards the sea with full speed, and often force their passage over the necks of the routs, although always aim at the foreheads of the seals, giving many blows before they are killed; and sometimes the seals lay hold of the seals with their teeth, and carry them away to the sea. These are in the boat shot at them as they run to sea, but few are caught that way. Some of the largest seals lose their lives by endeavouring to fave their young, which they tumble before them towards the sea, and in this act they are cruelly knocked on the head with sticks or flaves. Three hundred seals, it is said, have been killed at one time in this place. They are attacked in October, because in the beginning of this month they bring forth their young on the west side of these islands; but their on the east side are of a smaller nature, and bring forth their young in the middle of June.

The seals eat no fish till they first take off the skin; they take hold of the skin between their teeth, and pluck the skin off each side with their sharp-pointed nails. The natives say that the seals are regularly coupled, and reft at each other in a most extraordinary rate. It is said that the seals make their mutual addresses by salutations; and the female puts away its young as soon as it is able to provide for itself, in doing which it recovers many fewble blows. In the skin of the females there is a hole, within which the teats are secure from injury, as it creeps along the rocks and flones; and on this account nature has formed the point of the tongue cloven, in order to enable the young to suck. The natives find the seals with the ashes of burnt sea-ware, and say they are good food. The vulgar eat them commonly in the spring, and use a long pointed stick instead of a fork, to prevent the strong smell which their hands would otherwise retain for several hours afterwards. This four-footed creature is reckoned one of the twiflet in the sea; and it is likewise said, that in cold weather it will leap to the height of a pike above water; that the skin of it is white in summer, and darker in winter; and that its hair stands up with the wind, and falls again at the ebb. The natives cut the skin in long pieces, and use them as ropes to fix the plough to their horses when they till the ground.

The bairning sharks are supposed to be migratory fishes from the Arctic circle; they frequent the coast of Norway, the Orkney and Hebride isles, the forth of Clyde, the bay of Ballyhannin in Ireland, and the west coast of Wales, particularly Carnarvonshire and Anglesey. They appear in the forth of Clyde, near the isle of Arran, in small schools of seven or eight, but more generally in pairs, some time in June, and remain till the end of July, when they disappear. Although they are in size from 10 to 20 feet in length, they are so tame and stupid, that they will suffer themselves to be fwatered in the water. They lie on the surface, sometimes on their bellies, and sometimes on their backs, as if they were asleep. When the harpooner strikes his weapon into them, which he does as near the gills as possible, and they perceive themselves wounded, they fling up their tail and plunge headlong into the bottom, following the rope round them in their agonies, and attempting to disengage the harpoon by rolling on the ground. As soon as they find that their efforts are ineffectual, they swim away with such rapidity and violence, that a vessel of 70 tons has been towed away by them against a fresh gale. They sometimes run off with 200 fathoms of line, and with two harpoons in the body; and will contend for 24 hours before they are subdued. When they are killed, the liver, which is the only useful part, is taken out and melted in kettles provided for that purpose. A large fish, particularly the female, will yield eight barrels of oil, two of useless sediment, and afford a profit of 20/. The oil is of the most valuable kind, being pure and sweet, extremely proper for lamps, and much valued by tanners. It is also used by the fishermen for curing burns, bruises, and rheumatic complaints.

The catching of fish is a kind of defensive fishery. These animals, though scarcely exceeding the size of a large cod, are equally destructive to nets, and to all the species of fish which they can overcome. They had become so offensive on the coasts of Newfoundland and Labrador, that the enraged fishermen made war upon them as a common enemy, and with such success, that they have almost extinguished the whole species of the American shores. They abound on the coast of Shetland, particularly the Hebrides, where they
are taken in considerable numbers. Being split and dried, they are conveyed by the women through different parts of the country, and sold or exchanged for necessaries; these forming a petty inland commerce.

Fishery. Sturgeon. The sturgeon is a large sea-fish, which at its season runs up the rivers; having a sharp-pointed snout, a flat belly, and bluefish back. Sturgeons, as well as whales, are reckoned among the number of royal fishes.

There are sturgeons of all sizes; and we even read of some twenty feet long; but the middle size are reckoned the best; though some prefer the smaller. See Sturgeon.

It is of the roe or eggs of this fish that the caviar, or caviar, so much prized by the Italians, &c. is prepared. See Caviar.

Sturgeon, when fresh, eats deliciously. To make it keep, they salt or pickle it in large pieces, and put them up in casks, from twenty-five to fifty pounds.

The greatest sturgeon fishery in the world is in the mouth of the Volga, in the Caspian sea; where the Muscovites find employment for a great number of men. We have also had a considerable supply of sturgeon from North America, which rivals that of the Baltic.

They are not caught in nets, but in a kind of enclosure, formed by huge flakes, disposed in triangles, representing the letter Z several times repeated. These kinds of fishers are open on the side towards the sea, and close on the other; by which means the fish, ascending in its season up the river, embarrasses itself in these narrow angular retreats; and not being able to turn itself, to go back again, on account of its bulk, is easily struck, and killed with a fort of harping-iron. They are also taken during summer, in the lakes Frischehaff and Courischeaff, near Pillau, in large nets, made of small cord; the adjacent shores are formed into districts, and farmed out to companies of fishermen; some of which are rented for five thousand guilders, or 500 f. per annum.

The chief object of this fishery is the roe or spawn, which is a commodity so much used in Muscovy as butter in Holland; and there are some sturgeons that furnish each four hundred pounds thereof. It is only the lefser and younger sturgeon that they pickle for eating.

Fishery. Turbot. The method of taking turbot and other fish by the people of Scarborough is this: when they go out to fish for turbot, each person is provided with three lines; each man’s lines are fairly coiled upon a flat oblong piece of wicker-work. The hooks being baited and placed very regularly in the centre of the coil, each line is furnished with 14 score of hooks, at the distance of six feet two inches from each other. The hooks are fastened to the lines upon heads of twisted horse-hair, 27 inches in length. When fishing, there are always three men in each cable, and conveniently nine of these lines are fastened together, and used as one line, extending in length nearly three miles, and furnished with 2520 hooks. An anchor and buoy are fixed at the end of each man’s line; in all four anchors, which are commonly perforated stones, and four buoys are made of leather or cork. The lines are always laid across the current, and remain upon the ground about six hours. The cable is 20 feet 6 inches long, and five feet in extreme breadth; it is about one ton burden, rowed with three pair of oars, and admirably constructed for the purpose of encountering a mountainous sea. When the wind suits, they hoist a sail.

Fishery. Whale, or Greenland Fishery. This huge fish, we have elsewhere observed, chiefly caught in the North sea. The largest are found about Spitzbergen, some of them being there two hundred feet in length. Those on the coasts of America are about ninety, or a hundred; and those on the coast of Guyenne, and the Mediterranean, are the smallest of all.

The first persons that seem to have been employed in the whale fishery were the Norwegians, probably soon after their discovery of Greenland, about the year 837; for we find that king Alfred received information from Outher, a Norwegian, in 887 or 890, that the Norwegians were employed in this fishery. He tells the king, that he failed along the Norway coast, as far north as the whale hunters commonly used to travel; but it seems that all knowledge of this painful employ was lost, at least in this country, for almost seven centuries. The Biscaymers were also concerned in it, for the sake not only of the oil, but also of the whale-bone, before the English; for though their north-east discoveries in 1553 had pointed out the way to the whale-fishery at Spitzbergen, they were so ignorant of the business in 1557, as to be under a necessity of procuring information and assistance from Biscay for this purpose. The first mention that occurs in the English history of whale-fins, or whale-bone, is in 1592, when eight hundred fins, part of the cargo of some Biscay ships, that had been wrecked three years before, were brought to England from the bay of St. Laurence in America by an English ship; previous to which time, the ladies’ fans, as Mr. Anderson observes, must have been made of split or some other tough and plaint wood; the whale fishery being carried on for the sake of the oil long before the discovery of the use of the whale-bone, which was first brought to England, with the blubber or oil, in 1617. The English, having been accustomed to the Northern seas, by their repeated trials for a north-west and north-east passage to China, in 1592 commenced their fishery for whales at or near Spitzbergen, where those animals were found in greater numbers than anywhere else. But the first English voyage for the purpose of killing whales was undertaken by the Russian company in 1611, who sent two ships thither, with six Biscaymers, expert in the business; the ships were lost, though their men and boats, &c. were saved by a ship of Hull, then at Spitzbergen. In 1618, the East India adventurers joined flock with the Russian company for pursuing the whale fishery, and fitted out thirteen ships, but the voyage proved unsuccessful. The manner of managing the whale-fishing, both by the English and Dutch, was then quite different from the present mode; the whales, having never been disturbed, returned to the bays near the shore, so that their blubber was easily landed at Spitzbergen, where they erected coarkeries, i.e. cottages, &c. for boiling their oil; and there they kept it distilling from year to year, and only brought home the purifed oil and the whale-bone. The English, having been the first in that fishery, kept possession of the bell bays; the Hollanders, coming later, were obliged to find bays farther to the north; the Danes, who came later into this trade than the Dutch, got in between the English and Dutch; the Englishhers came after the Danes, and after them came the French, and also the Biscaymers, the most ancient whale-fishers in Europe, except the Norwegians, and pursued the same method. But, since these times, the whales are less frequent in the bays, and are commonly among the openings of the ice farther from the land; so that the blubber is now cut from the whales after they are killed, in the manner described in the sequel of this article, and brought home to be boiled and purified, and the whale-fins are also to be cleaned at home.
F I S H E R Y.

home. This latter method of fishing, being dangerous to
flipping, discouraged our English adventurers who traded
in a company: so that they soon after, viz. in 1619,
relinquished the fishery. Some private adventurers pro-
secuted the trade with various success in 1621, 1622, and
1623, when they were molested by the Dutch, who were
then superior in number of ships, and had the prince of
Orange's commission; for in 1622 the Dutch, for preventing
of disturbance in their whale fishery, had erected an ex-
clusive company, who, by their own power, might protect
it; however, the fishery was laid open, in 1643, to all the
inhabitants of the seven provinces. As to the claims which
different European nations have alleged in favour of a
monopoly of the whale fishery at Spitzbergen, it has been
urged by the English that they were the first discoverers,
y'r Hugh Willughby, in 1533; by the Dutch, who
deny his having been so far north as Spitzbergen, and main-
tain their having first discovered it in 1596; by the Danes,
that Spitzbergen is a part of Old Greenland, possess'd in
time by them. But all nations have now wisely
given up their exclusive pretentions, and that part of the
world remains now alike free to all nations for this fishery.
In 1646, king Charles I. confirmed by his proclamation
the Greenland whale fishery solely to the Russia company,
who soon relinquished it. In 1672 an attempt was made
for reviving this fishery, when an act was passed for the
encouragement of it; and this act was continued in 1690,
but without any great effect. A corporation was es-
ablished by act of parliament, in 1693, for carrying on this
fishery, called the Greenland Company.

In 1725, the English South-sea company revived this
trade: but, after great losses, were obliged to discontinue
it, in 1733. At this time a bounty of 20s. per ton was
granted by parliament to British ships of two hundred
tons and upwards, fitted out for the whole fishery, which
bounty was not only continued, in 1740, but an additional
bounty of 10s. per ton was granted during the war with
Spain, in which we were then engaged; and in 1749 a
further bounty, or allowance of 20s., over and above that
of 1733, was granted to all British whale-fishing ships,
and extended to ships of the British American colonies;
and in 1755 this bounty was extended to ships under two
hundred tons burthen: and, as a further encouragement to
this fishery, foreign proprietors, having three years in it,
were naturalized on certain conditions. See Hackluyt's
Coll. Voyages, and Anderson's History of Commerce.

But, notwithstanding the great importance and numerous
advantages of this trade to England, and the encourage-
ment which the legislature has given it, the Dutch carried
it on with much greater success than the English; and it
became one of the principal branches of their flourishing
trade. The chief merchants of the several provinces al-
so associated themselves into a body for carrying it on, and set
every year a great fleet of vessels to the North seas for
that purpose. They attempted to make their first establish-
ments in Greenland; but not succeeding, they have since
fixed their fishery about the western coast of Spitzbergen,
from the latitude of 76 deg. 40 min. to 80 deg. and from
east to west about eighty-nine leagues.

To give some idea of the manner and importance of this
trade, we shall here follow the discipline for a long time
observed in the whale fishery, the method of fishing:
the cargo and equipage of a vessel; and the produce
thereof.
The discipline is adjusted by a landing regulation, consist-
ing of twelve articles; the principal of which are:

That in case a fishing-vehicle be shipwrecked and the cap-
tain and crew saved, the next vessel they meet shall take
them in; and the second vessel take half of them from
the first; but that no vessel shall be obliged to take any
of the loading of a vessel shipwrecked; that as to the effects
of a shipwrecked vessel, which are absolutely relinquished,
and which another captain shall find, and take up, upon
his arrival in Holland, he shall account for one half of
them to the proprietors of the shipwrecked vessel, clear of
all expenses; that if the crew defect a shipwrecked vessel
they shall have no claim to any of the effects saved, but
the whole shall go to the proprietor; but if they be pre-
sent when the effects are saved, and assist therein, they
shall have one-fourth thereof; that if a perfon kill a fish
on the ice, it shall be reputed his own, so long as he
leaves any perfon with it; but the minute he leaves it,
it becomes the due of the first captain that comes that way;
but that, if a fish be tied to an anchor, or a rope fastened
to the flore, it shall remain to its first proprietor, though
he leave it alone; that if any perfon be wounded or hame
in the service, the commissioners of the fishery undertake to
procure him a reasonable satisfaction; to which the whole
fleet shall contribute.

Besides this general regulation, to the observance of
which all the captains, pilots, and masters of vessels, were
obliged to swear, before they put to sea, there was also a
particular one for each ship's crew, which they were all
sworn to execute, in presence of one of the commissioners,
who went aboard every ship, to receive the oath.

This regulation was a kind of charter-party, importing,
that they would attend prayers morning and evening, on pain
of an amercement, at the discretion of the captain; that
they would not get drunk, nor draw their knives, on forfei-
ture of half of their wages; nor fight, on forfeiture of the
whole; that no one should lay wages on the good or ill
success of the fishing, nor buy or sell on those conditions,
in case they took one or more fish, on penalty of twenty-five
florins; that they would be contented with the provisions
allowed them; and that they would never light fire, candle,
or match, by night or day, without the captain's leave, on
the like penalty.

After the reading of this regulation, the crew were all
called to receive the customary gratuity before their set-
ting out, with an allowance of another sum at their return in
proportion to the success of the fishing.

The captain, on this occasion, received from an hundred
to an hundred and fifty florins; the pilot from forty to sixty;
each harpooner from forty to fifty florins; the other officers
from twenty to thirty florins; the elder sailors twenty;
and the younger twelve.

The fleets, which consisted mostly of vessels from two to
three hundred tons, and from thirty-six men to forty-two,
usually set sail about the beginning of April, and took its
course by the isles of Iceland, from 60 to 61 degrees of la-
itude; after which, leaving them to the west, it steered
northward, through 73, 74, and 75 deg. of latitude, where
they began to find the ice.

It was among these huge heaps of ice, wherewith the
whole quarter is filled, that they first began to try the
whales; and there most of the vessels fixed their shore for
the fishing. But as the fish were larger and fatter the farther
north they went, some captains would venture as far as 80
or 82 deg. of north lat. Each vessel of three hundred tons
had fix shallows; and each shallow had fix harpooners,
with fire-steel to row it. To every shallow there were
seven lines, of three inches circumference; five of them
in the hind part of the vessel, and two before. The said
lines together made six hundred fathoms, and, with the

Vol. XIV.
addition of the other two, eight hundred and eighty. If the whale dived deeper, or ran farther underneath the ice than this float, the line must be cut, left the shallop should be drawn after it.

In the English whale-fishery every ship has fix or seven boats; each of which has one harpooner, one harp-eeer, one manger of the line, and four feather to row it. In each boat there are two or three harpoons, several lances, and six lines fastened together, each line being a hundred and twenty fathom long. To each harpin iron is fastened a strong fick, about six feet long, and a soft pliable line, about six fathom long, called the long-gourd, which is fastened to the lines in the boat. When more line is wanted, the lines of a second boat are fastened to those of the first.

The harpooner, upon sight of the fish, from one end of the shallop where he is placed, flings the harp-iron with all his might against his back; and, if he be so happy as to make it penetrate the skin and fat into the flesh, he lets go a string fastened to the harping-iron, at the end whereof is a dy-gourd, which swimming on the water, discovers whereabouts the whale is; for the minute he is struck he plunges to the bottom, commonly swimming against the wind.

If the whale return to breathe in the air, the harpooner takes occasion to give him a fresh wound, till, fainting by the loss of blood, the men have an opportunity of approaching him, and thrusting a long streaky lance under his gills into his breast, and through the interline, soon dispatch him; and when the carcasse begins to float, they cut holes in the fins and tail; and, tying a rope in these holes, they tow him to the vessel, where he is fastened along the larboard side of the ship, floating upon his back almost level with the sea. They then begin to take the blubber or fat, and the fins, as they are called, or whale-bone.

In order to this, several men stand upon the ship, with a kind of iron carkers, or spars, to prevent their slipping; and cut off the tail, which is hoisted upon deck, and then cut out square pieces of blubber, weighing two or three thousand pounds, which are hoisted on board with the carcan, where each piece is again cut into smaller pieces, each of two or three hundred pounds weight; and these are thrown into the hold, and left to drain for three or four days. When all the blubber is cut from the belly of the fish, it is turned upon one side, by means of a piece of blubber left in the middle, called the cant, or turning-piece; and then they cut out this side in large pieces, called bookies, as before, and also the whale-bones with the gums, which are preferred entire, and hoisted on deck, where the blades are cut and separated, and left till they have time to clean and scrape them. The fish is next turned on its back and the blubber cut out from the back and crown bone; and last of all they cut the blubber from the other side as before. They then cut out the two large jaw-bones, situate in the under-lips, which are hoisted on deck, cleaned and fastened to the throuds, and tubs are placed under them to receive the oil which they discharge; this oil belongs to the captain, and likewise the tail and fins. The carcasse is left to float, and supplies food for Greenland birds, called mallemucks, &c. In three or four days they hoist the pieces of blubber out of the hold, chop them, and put small pieces through the hung-holes into their casks.

A whale, the longest blade of whose mouth is nine or ten feet, generally fills thirty butts with blubber; but one of the largest fish will fill seventy butts and more. A good large whale is valued at about 1000l. flering. A full ship of three hundred tons is worth, clear of all expense, at least 5000l. There is a premium assign'd to every person in the ship for every whale; the captain has three guineas; the mate, one; each harpooner, one; the foreman, one; carpenter, one; cook and boat-eeers, half a guinea each; a common man, a crown; and each boy, half a crown. The captain and harpooneers have no wages; but the captain is allowed twenty-five pounds, and the harpooneers, nine guineas each. In a successful voyage they have fix fillings for every ton of oil boiled in Greenlan-dock; but the rest of the ship's company have monthly wages, besides the fish-money, but no oil-money.

Nothing now remains, but to sail homewards, where the fat is to be boiled, and melted down into train-oil.

The whale-fishery of the Caroline islands is more easy and agreeable than that of all other places, and, befide the great profit, affords a pleasant spectacle to multitudes of people on the shores.

There are ten or twelve of these illes disposed in form of a circle, so that they make a sort of port, in which the sea is perpetually calm and pleasant.

When a whale appears in this gulf, the people all get into their canoes, and rowing toward the sea, keep between the creature and its retreat, and drive him forwards towards the illes at the bottom of the port. They drive him in this manner before them into the shallows, where they plunge into the water themselves, and some get ropes and chains about him, while others dart him with their flairs. Their agility and adrell are wonderful in this. The creature can never get away when they have once got him fastened, but is soon killed, and get to the shore.

**FISHERY.**

_Whale._ To state the produce, we make choice of the fishery of 1697, as being one of the greatest and most fortunate that ever was known; to which we shall add that of the year 1725.

In the year 1697, there were a hundred and eighty-nine vessels of divers nations; whereas a hundred and twenty-one were Dutch, forty-seven Hamburghers, two Swedifh, four Danith, twelve of Bremen, two of Embden, and one of Liebeck; who caught in all 1686 fish.

In the year 1725, there were two hundred and twenty-six vessels; whereas of one hundred and forty-four were Dutch, twelve English, forty-three Hamburghers, twenty-three of Bremen, two of Berghen, two of Flensburg. Their captures were 349 fish.

The Dutch captures in 1697, 41544 puncheons of produced - 
Blubber. 

The Hamburghers - 16414
The Swedifh - 540
The Danith - 1740
The Bremen - 3790
The Embden - 68

The English captures in 1725, produced 1000 puncheons of blubber, and 20 tons of whale-bone.

Now, estimating the puncheon of blubber at thirty florins Dutch, or 26 15s. Englisb, the current price in the year 1697, the total produce of the year's fishing amounts to 175631l. 10s. flering. As to fins, or whale-bones, letting them at two thousand weight per whale, and adding to them at 4l. 4r. they will yield 165312l. which, added to the former sum, amounts to 340943l. 10s.

Mr.
Mr. Anderson, in his History of Commerce, vol. ii. p. 370, observes, from an account of the Dutch whale-fishing for forty-six years, ending anno 1721, that in this time they had employed 5886 ships, and caught 32977 whales, which valued one with another at 500L, give an amount for the whole value of above 16 millions sterling, gained out of the sea mostly by the labour of the people, deducting the expense of the wear and tear of shipping, the earks, and the provisions.

The whale-fishery begins in May, and continues through the months of June and July; but whether the ships have good or bad success, they must come away and get clear of the ice by the end of August; so that in the month of September at farthest they may be expected home; but the more fortunate ships may return in June or July.

The statute 26 Geo. III. c. 41. prescribes the conditions on which ships going on the Greenland whale-fishery shall obtain licences from the commissioners of the customes. A certificate shall be produced, signed by an officer of the customes, after due examination of each ship, stating that the ship is legally qualified for the voyage, by being navigated by a master and three-fourths British subjects, and having on board a competent number of men, boats, lines, provisions, &c. Every ship of the burden of 200 tons, designed for this fishery, shall have on board 40 fishing lines of 120 fathom each, 40 harpoon rods, 4 boats with 7 men at the head, including a harpooner, a keenerman, and a line manager, to each boat, besides the master and larder, and 6 months provision at the head for such a number of men; and every ship of larger burden, an increase of 6 men, one boat, 10 fathom lines, and 10 harpoon rods more, for every 50 tons above the said 200 tons, together with provisions in proportion; and every ship shall have apprentices indentured for 3 years, in the proportion of one at the head for every 35 tons burden, and one fresh or green man for every 50 tons burden. On the return of such ship, her condition shall be certified by the proper officer of the customes, together with a variety of particulars relating to her voyage, cargo, &c. &c.; and the commissioners at the port where such ship shall arrive shall assign a bounty or premium of 30s. per ton, according to the admeasurement of such ship duly certified. This bounty shall be restricted to such ship as shall have sailed from the port whence she cleared on or before the 10th of April in each year, and shall have continued in the Greenland seas, Davis's straits, or seas adjacent, endeavouring to catch whales, and not have departed thence before the 15th of August next following, unless such ship, if 500 tons, be laden with 35 tons of oil, or blubber in proportion, and 1 ton of whale-flins in like proportion to the tonnage, or be forced by accident to depart from these seas. Each ship entitled to the bounty must have kept a log-book. The owners may infringe the bounty, in case of the loss of the ship. Whale-flins, oil or blubber of whales, seal oil or seal skins, or any other produce of seals or fish caught in the seas of Greenland, or Davis's straits, or parts adjacent, may be imported duty free. No harpooner, line-manager, or boat-steerer, belonging to any ship in this trade, shall be liable to be imprisoned from this service. The Greenland seas, Davis's straits, and seas adjacent, shall be deemed and extend to the latitude of 50° 30' N., and no farther. The flat 29 Geo. III. c. 52. c. 53. contains some additional regulations. This act is continued by 41 Geo. III. c. 97.

Southern Whale Fishery. The statutes 32 Geo. III. c. 92. and 42 Geo. III. c. 18, assign premiums to 16 ships employed in this fishery, under certain prescribed restrictions: 12 of which shall be fitted and cleared out between January 1st and December 31st, 1802, and between January 1st and December 31st in each of the three succeeding years, shall sail to the southward of the equator, there carry on the fishery, and return to some port of Great Britain before December 1st in the year subsequent to that of their being cleared out; to 4 of these which shall arrive first within the time limited, with the greatest quantity of oil or head-matter, being not less in the whole than 20 tons in each, shall be allowed 300L each; and 200L. to each of the 4 ships which shall next arrive with the next greatest quantity of oil or head-matter; and 100L. to each of the 4 vessels which shall next arrive with the greatest quantity of oil, &c. not less than 20 tons. To 4 other such ships, which shall proceed to the westward of 30° of latitude, and shall carry on the said fishery, and shall return, before the 31st of December in the second year after their clearing out, to some port of Great Britain, there shall be allowed 400L. each, having not less than 20 tons of oil or head-matter, as aforesaid. The stat. 35 Geo. III. c. 92. requires such ships to be navigated by persons, of whom the master and at least three-fourths of the mariners are his majesty's subjects. Or if such ship clear out from any port of Great Britain, such ship may be navigated by persons being protestants, and who, not being subjects of his majesty, have been before employed in carrying on the said fishery, and on clearing out have taken the oath of fidelity and allegiance to his majesty, and another oath that it is their intention to establish themselves and their families in Great Britain, &c. No premium shall be paid to any ship that has not an apprentices indentured for three years for every 50 tons burden; nor unless such ship shall have regularly kept a log-book on board. The commissioners of the customes in England and Scotland are to pay the premiums, which are to be claimed within two months. Ships concerned in this fishery may sail and pass for that purpose to the eastward of the Cape of Good Hope, and to the westward of Cape Horn, or through the straits of Magellan; but such ships shall be obliged to take out a licence for each respective voyage from the East India company, &c. &c. Every ship intending to navigate any sea comprised within the boundaries of the exclusive trade of the South Sea company, described by an act of the 9th of queen Anne, must take a licence for the voyage from the said company. By statute 42 Geo. III. c. 18. any ship fitting and clearing out, and licensed according to the preceding acts, failing to the eastward of the Cape of Good Hope, and having passed beyond 123° of E. longitude, may pass to the northward as far as 21° of N. latitude, but no further to the northward, until such ship shall have failed or passed to the eastward of 180° E. longitude from London.

Fishery, Writings. These fish frequent the English seas in large schools, particularly during the spring, keeping at the distance of half a mile to three miles from the shore. They are taken in abundance by the line, and afford excellent diversion. They are the most delicate and wholesome of any of the genus, but do not grow to a large size near the coast, where the utmost length is 10 or 12 inches. In the deep water on the edge of the Dogger-bank, they have been found to weigh from four to eight pounds.

Fishery, Free, in Law. The exclusive right of fishing in a public river, is a royal franchise (see Franchise); and is considered as such in all countries where the feudal law has prevailed. (Sedl. More Clavibus, l. 24. Dutrefne, v. 523. Le cig. de Jur. Feud. p. 175.) By appropriating the taking of such grants, and thus the appropriating of that which it seems unnatural to restrain, the use of running water, was prohibited for the future by king John's great charter;
and the rivers that were fenced in his time were directed to be laid open, as well as the forels to be disaffixed. This opening was extended by the fecond and third charters of Henry III. to those also that were fenced under Richard I.; so that a branch of free fishery ought now to be at least as old as the reign of Henry II. This differs from a *federal* fishery; because he that has a federal fishery must also be (or at least derive his right from) the owner of the soil, which in a free fishery is not requisite. (M. 17 Edw. IV. 6, p. 18 Edw. IV. 4. T. 10 Hen. VII. 24. 26. Salk. 63.) It differs also from a common of piscary, in that the free fishery is an exclusive right, while the common of piscary is not so; and, therefore, in a free fishery, a man has a property in the fish before they are caught; in a common of piscary, not till afterwards. (F. N. B. 88. Salk. 67.) Some, indeed, have considered a live fishery not as a royal franchise, but merely as a private grant of a liberty to fish in the federal fishery of the grantor. (2 Sid. 8.)

But to consider such right as originally a flower of the prerogative, till restrained by *magna curta*, and derived by royal grant (previous to the reign of Richard I.) to such as now claim it by prescription, and to distinguish it (as judge Blackstone does) from a federal and a common of fisheries, may remove some difficulties (says the leamed Judge) in respect to this matter, with which our books are embarrassed. For it must be acknowledged, that the rights and dilusions of the three species of fisheries are very much confounded in our law-books: and that there are not wanting respectable authorities (see Hargrave's Notes on Co. Litt. 122.) which maintain, that a federal fishery may exist distinct from the property of the soil, and that a free fishery implies no exclusive right, but is synonymous with common of piscary. Blackft. Com. vol. ii.

**Fisherries, British Society for Encouragement of.** By flat. 35 Geo. III. c. 100. the governor, deputy-governor, and directors of the British society for extending the fisheries, and improving the fca coasts of this kingdom, incorporated by 26 Geo. III. c. 106. are empowered to give the following premiums and loans to persons at the society's Pettett's; viz. Col. a year, in premiums or rewards, to fober and induftrious persons reeding at any of these settlements, who are molt expert in fishing, curing of fish, preparing of foap or oil from fish, making of nets, &c.; and also to lend at legal interet a sum not exceeding 500l. for the purpose of purchasing, building, or equipping boats or other vessels for the fisheries; and also such further sums on loans to such persons as may build houses or tenements at any of the settlements of the society, the sum so lent not exceeding one-third of the value of such buildings, payable by instalments in the course of five years; and also such sums in loans, not exceeding 200l., on proper security to be repaid in one year, to such persons as may undertake to provide flowers of oitmeal or malt, or other necessaries, at either of the said settlements, the sum not to exceed two-thirds of the value of the commodity; and also such sums of money, not exceeding 200l., in loans to such persons as may eitlabish a manufactory of fafl-cloth or corage, &c. such sums to be repaid in three years, and not to exceed two-thirds of the value of the material provided.

**Fishery, aboard a Ship.** Are pieces of timber, convex on one side, and concave on the other, used to strengthen the masts and yards, when they begin to fail, through an extraordinary weight of sail, or after damage in battle, or tempestuous weather. They both nail the fish on with iron spikes, and also avoid them as they call it, that is, wind ropes hard about them. There is also a tackle called the block, in which is the runner of the fish-hook; by which means the fluke of the anchor is haled up to the ship's bow, or chain-ware. (See Blocks.) Perhaps this tackle was called a fish, from that which the ancients called a dolphin, which was a pointed and vastly heavy piece of iron, which they used to heave up by a tackle to a good height, and then, when they came near enough to the enemy's ship, let it fall at once, to break or pierce a hole through the bottom of the enemy's vessel, to sink her.

**Fish-gig.** An instrument used to strike fish at sea, particularly dolphins. It consists of a staff, three or four barbed prongs, and a line fastened to the end, on which the prongs are fixed; to the other end is fitted a piece of lead, which serves to give additional force to the stroke when the weapon flies, and to turn the points upward after the fish is penetrated.

**Fish-garth, according to Skinner, signifies an engine to take fish; but it should rather seem to denote the dam or weir in a river, where these engines are laid and used.**

**Fish gill.** See Ichthyocolla and gill.**

**Fishing, the act or art of catching fish.** Right of fishing and the property of fish belong to the lord of the manor, when he hath the soil on both sides of a river; but where a river ebbs and flows, and is an arm of the sea, they are common to all; and he who claims a privilege to himself must prove it. In the Severn, the soil belongs to the owners of the land on each side; and the soil of the River Thames is in the king, &c. but the fishing is common to all. There are several statutes for preventing the defraction of the fry of fish; and persons using nets for that purpose, or taking salmon or trout out of season, or any fish under certain lengths, are liable to forfeit money, and justices of peace and lords of leets have power to put the acts in force. See 1 Eliz. cap. 17. 3 Jac. I. cap. 12. 30 Geo. II. cap. 21. See Salmon Fishery, and Stealing of Fish.

Fishing is distinguished with regard to its instrument into that performed with the net, for fish that go in shoals; and that with the hook, for solitary fish; which latter is properly called angling.

Fishing, again, is distinguished with regard to its object into that performed in salt water, and that in fresh. The fish practised for whales, herring, cod, salmon, pike, and all other fresh-fish. The latter practised for pike, trout, eels, perch, dace, chubb, &c.

The instruments principally used in angling or fishing with the hook, are the rod, line, hook, and fly.

The points on which the art of fishing chiefly turns are the proper season, place, bait, and manner of application. What relates to each thereof, we shall here give the reader in the several kinds of fishing chiefly practised among us.

In March, April, and September, the warmest days are the best for fishing, and the bait must be deep; for the fish in these cool months lie near the bottom. In fly-fishing, it is always observed, that the fish will rise after a small flower of rain, that has just beat down the flies upon the water without muddying it. March, April, May, and June, are the best months for fly fishing, and the best hours are about nine in the morning, and three or four in the afternoon; in a still warm evening they will eat as long as the day light lasts, at these seasons when the gales are few and plentifully about in the air.

In the extremity of heat, when the earth is parched with drought, there is but little sport to be expected in fishing in any water. In cold weather, when there is a white hoary frost in the morning, the fish will not bite kindly all
all day, except in the evening, if that should prove serene and warm.

Too much wind is never convenient for fishing, though a little is rather advantageous than otherwise. It is bad fishing about sheep-shearing time, in waters where the sheep are washed; for the fish glut themselves in such a manner with what is washed from these creatures, that they will not take any bait till that feaon is over.

North and east winds are enemies to fishing; and it is not right to fish soon after the time of the fish spawning, for they are then sick, and have no great appetite, so that they do not bite readily. All fish have a natural fore-knowledge of a shower of rain, and when clouds are coming on that will fall in rain, they will not bite; the expert angler, who is used to this, often escapes being wet to the skin by it.

The subterranean or under-ground fishing of the lake Ribebklajmim has been much talked of by those who have written of the Zirchütter See, of which it is a part; but on the whole it amounts to no more than this. The waters of this lake emptying themselves through subterranean passages into another lake below, the whole body of the water, with the fish in it, is first received into a large opening, which conveys it into a fort of subterranean bason, in the bottom of which there are many holes, and through these the water is let out, but the fish left behind. The people of the place who know this, defend through the large hole into this subterranean bason with torches in their hands, and as the waters run off, they seize upon the fish wherever they can catch them. This sort of fishing is attended with one inconvenience; for the people being obliged to stand up to the middle or less in the water, the horse-leeches, which are extremely plentiful there, seize upon their legs and other parts, and are only to be got off by some perfons making water upon the part; the heat and nauseous stale of the urine always making them let go their hold.

Phil. Trans. N° 91.

For a curious method of fishing in China, see CHINA.

Fishing, White-lake. See Bait.

The season for taking white-bait is only from the first of August to the first of October. 30 Geo. II. cap. 21.

Fishing, Barbel. See Barbus.

No barbel is to be taken in the Thames or Medway under twelve inches in fize, from the eye to the end of the tail, and only between the twenty-fourth of August and the twenty-first of March. 30 Geo. II. cap. 21.

Fishing, Carp. The carp is generally held the queen of fresh-water fish. It is exceeding lubile, and of all others, the eel only excepted, lives longest out of water. Mr. Ray affirms us, that in Holland they have a speedy way of fattening them, by hanging them up in a net in a cellar, and feeding them with white bread and milk. The fish is wrapped up in a quantity of wet moss, spread on a piece of net, and then gathered into a puerse in such a manner, however, as to allow him room to breathe. The net is then plunged into water, and hung up to the ceiling of a cellar: the dipping must at first be repeated every three or four hours, but afterwards it need only be plunged into water once in about fix or seven hours. Bread soaked in milk is first given him in small quantities: in a short time the fish will bear more, and grow fat by this treatment. Many have been kept in this way, breathing nothing but air, for several days successively. (Phil. Trans. vol. ixi. part 1. p. 510.)

They breed several times in the year; for which reason we seldom meet with male or female without either milt or spawn. Their natural place is some full water; in running waters they rarely, if ever, breed. To make them fat and large, it is a good way, when the pond is low, in April, to take all the sides thereof with an iron rake, and low hay feeds thereon. By autumn there will be a crop of grases, which coming to be overflowed as the pond rises, will be a fine feeding-place for them. See Fish-Ponds.

Great patience is requisite in angling for carp, on account of their incredible policy. They always choose to lie in the deepest places; they seldom bite in cold weather; and in hot, a man cannot be too early or too late for them. When they do bite, there is no fear of the hold. The tackle must be very strong, and it will be proper to bait the place beforehand, where it is to he tied for, with a coarse paffe. It may be also proper to bring the carp to the place intended for angling, by throwing in cow-dung and blood, or bran and blood mixed together, or some chicken guts cut small. The baits are the red-worm, in March; the ead, in June; and the grases-hopper, in July, August, and September. Proper pases may also be prepared for them; as honey and sugar, wrought together with flour, and thrown in pieces into the water some hours before you begin to angle. Honey and white crumbs of bread mixed together also make a good passe. The following passe is much recommended; take common wheat flour and veal, or any other young meat, of each equal quantities; beat them together in a mortar till the meal is thoroughly dissolved or broke to pieces; then add half the quantity of honey; beat it well together again, and add more flour till the whole is of a proper consistence. This has the advantage of a pafe, and of an animal bait, and hangs well upon the hook, so that it seldom falls of success.

The bell season for catching such as are intended for sale is autumn.

Fishing, Club. The chevin or club is a fresh-water fish with a large head. It spawns in March, and is very strong, though inactive, yielding in a very little time after it is flurk; and the larger it is the quieter. His bait is any kind of worm or fly, particularly the large yellow moth; also grains, cheeves, the pith in the bone of an ox’s back, &c. He affects a large bait, and variety of them at the same hook. Early in the morning angle for him with nailles; but, in the heat of the day, choose some other bait; and in the afternoon, fish for him at ground or fly. See Club.

No club is to be taken under nine inches from the eye to the end of the tail, and only between August 24th and March 21th, in the river Thames and waters of Medway. 30 Geo. II. cap. 21.

Fishing, Dace or Darr. See Dace.

No dace are to be taken in the Thames or Medway under six inches from the eye to the end of the tail in size, and only between August 24th and March 21th. 30 Geo. II. cap. 21.

Fishing, Eel. See Eel.

The silver-eel may be caught with divers baits, particularly powdered beef, garden-worms or lob, narrow, hens guts, fish, garbage, &c. But as they hide themselves in winter in the mud, without fluring out for six months, and in the summer, they take no delight to be abroad in the day, the most proper time to take them is in the night, by fastening a line to the bank side with a hook in the water: or one line may be thrown at large, with a good time of hooks baited, and plumped with a float, to discover where the line lies in the morning. A small hook does well here for a bait, the hook being laid in his mouth. For other methods of catching eels, see boreing, BULINT, ESL, fE, and Snigiling.

No lumps or rods for eels are to be laid in the Thames and Medway.
FISHING.

Medway but from April 21st to October 20th; but they may be hooked for all the year. 30 Geo. II. cap. 21.

FISHING, Flounder. The flounder is a flat sea or river fish, caught in April, May, June, and July, in any time of the day, in a swift stream, and sometimes also in a still deep. The bell bait is red worms, wafts, and gentles.

Flounders may be taken in the rivers Thames and Medway at any time of the year; but their size must not be less than six inches from the eye to the end of the tail. 30 Geo. II. cap. 21.

FISHING, Gudgeon. The gudgeon is a small fish of a very delicious taste. It spawns three or four times in the summer-fish, and feeds in streams and on gravel, flying all kinds of flies; but insensibly taken with a small red worm, fishing near the ground; and being a leather-mouthed fish, will not easily get off the hook when struck. The gudgeon may either be taken with a float, the hook being on the ground, or by hand, with a running line on the ground, without cork or float. He will bite well at wafts, gentles, and cadworms; and one may even fish for him with two or three hooks at the same time, which makes good sport.

When you angle for gudgeons, fix up the float or gravel with a long pole, which will make them gather to the place and bite the faster.

The season for gudgeon fishing in the Thames and Medway is from August 24th to March 21st. 30 Geo. II. cap. 21.

FISHING, Perch or Poll. The perch or perch is hook-backed, not unlike a boby, armed with sharp prickers, and his lid's with dry thick scales; he is voracious, and will venture on his own kind even with greater courage than the pike. He seldom grows much above a foot long. He spawns in February or March, and bites best when the spring is far spent. The proper baits are the bradling, minnow, and small frog: as also the lob worm, bob, oak worm, gentle, waft, and cad-bait. The minnow yields the bell sport, which is to be alive, and fluck on the hook through the upper lip or back-fin, and kept swimming about the water. If the frog be used, he is to be fastened to the hook by the skin of his leg. When the fish bites, as he is prone of the leather-mouthed kind, he must have time to pound his bait. The bell place to fish for him is in the turning of the water eddy in a good gravel bottom.

No perch is to be taken in the Thames or Medway under six inches from the eye to the end of the tail, and only between August 24th and March 21st. 30 Geo. II. cap. 21.

FISHING, Pike. The pike is reputed the tyrant of the fresh waters. By the common content of naturals, he is the longest-lived of all fishes. The longer he is found, the courser is his flesh; and so aye merly. This fish never swims in shallows, but always single, being very rapacious, and praying even on his own kind. The pike spawns in February and March. The bell fort is in rivers; the worst in mere and ponds. His ordinary food is frogs, and what fish he can lay hold on.

There are two ways of fishing for the pike: by the ledger bait and the sliding-bait. 1. The ledger-bait is that fixed in one certain place, and which the angler may leave behind him. Of this kind the bell is some living bait, as a dace, roach, gudgeon, or a living frog. To apply it, if a fish, flick the hook through his upper lip; then fastening it to a strong line twelve or fourteen yards long, tie the other end of the line to some stake in the ground, or bough of a tree, near the pike's usual haunt, letting the line pass over the fork of a stick placed for the purpose, suspending the hook, and about a yard of line in the water, but so as that when the pike bites, the fork may give way, and let him have line enough to go to his hold and paunch. If the bell be a frog, the arming wire is to be put in at his mouth and out at his vent, and one of his legs to be hitched or tied over the upper joint of the wire. 2. The walking-bait is that which the fisher calls in, and conducts with a rod, &c. This is perforated by a troll, with a winch for winding it up. At the top of the line is to be placed a ring for the line to be run through. The line, for two yards and a quarter next the hook, to be of flax double, and armed with wire the length of seven inches. On the flank of the hook is to be fastened a smooth piece of lead, so as to sink the fish-bait, which is to be a gudgeon with its head downwards. Thus disposed, the bait is to be cast up and down; and if you feel the fish at the hook, give him length enough to run away with the bait, and paunch it; then strike him with a smart jerk. To fish with a dead bait, use a yellow frog, dace, or roach, anointed in gum of ivy, dissolved in oil of spike, and call it where thepike frequents. After it has lain a little while at the bottom, draw it to the top, and so up the stream, and you will quickly perceive a pike in earnest pursuit thereof. This fish bites best about three in the afternoon in clear water, with a gentle gale, from the middle of summer to the end of autumn; but in winter all day long, and in the spring he bites better early in the morning, and late at night. Another method of fishing for pike, see under Hoxing.

No pike or jack is to be taken in the Thames or Medway under twelve inches from the eye to the end of the tail, and only between August 24th and March 21st. 30 Geo. II. cap. 21.

FISHING, Roach. The roach or roachet is no delicate fish. Those in rivers are more valued than those in ponds, though the latter are much the larger. They spawns about the middle of May.

To angle for this fish in April, cads or worms are proper baits; flats are small white snails or shies in summer. The bait is always to be under water, for this fish will not bite at top. Others use May-fly in that season with good succs. In summer, a pell or mulch be used, made of the crumb of white bread moulded with a little water, laboured with the hands into a tough paste, and coloured not very deep, with red lead. In winter, gentles and the bell bait. Sprouted malt, the young braid of wafts, and bees dipt is blood, and the thick blood of sheep half dried, are notums in this fort of fishing.

In the neighbourhood of London they have a peculiar method of fishing for roach; they take a strong cord, at the end of which is fastened a three pound weight; and a foot above the lead a packthread of twelve feet is made fast to the cord; and to the packthread, at proper distances, they add twelve strong links of hair with roach hooks at them, baited with a white snail or periwillie. Tie on holding the cord in their hands, the biting of the fish draws the packthread, and this the cord, which gives them notice what to do. By this means they sometimes draw up half a dozen, and very commonly two or three at a draught. By 30 Geo. II. cap. 21, no roach is to be taken in the Thames or Medway under six inches from the eye to the end of the tail, and only between August 24th and March 21st.

FISHING, Smelt. See Smelt.

By 30 Geo. II. cap. 21, no smelt is to be taken in the Thames or Medway less than five inches from the eye to the end of the tail, or at any time, except from January 25th.
FISHING.

25th to June 16; and those that are caught in other waters
must be of the above size. 33 Geo. II.

FISHING, Seal. See Seal.

FISHING, Tackle. The tackle is a fine fresh water fish,
having very small scales, but large, smooth fins, with a red
circle about the eyes; and a little lump hanging at each
corner of the mouth. It takes more delight among weeds
in ponds than in clear rivers, and covets to feed in foul water.
His time is said to have a healing quality for wounded
fish; upon which he is commonly called the fisher
physician. When the carp, pike, &c. are hurt, it is
said they find relief by rubbing themselves against the
net.

The season for catching this fish is in June, July, and
August very early and late, or even all night, in the shall
part of rivers. This bait is a large red worm, at which he
bites very eagerly, especially if first dipped in tar. He
also delights in all sorts of同志 made up of strong-
scented oils, or with tar; or a paste of brown bread and
honey; nor does he refuse the eel-worm, lob-worm,
flag-worm, green gentles, cod-bait, or soft boiled bread-
grain.

When a number of tench are to be taken out of a muddy
pond, the method is to take a large casing net, well leaded,
and with the meshes from the crown to a full yard and a
half, not too small; for then, if the pond be deep, the fish
will strike away before the net gets to the bottom. The
place where the net is to be thrown into must be cleared of
weeds, &c. with a rake. A bait is next to be prepared
for drawing the fish together; for this purpose put a quar-
ter of a peck of wheat into three quarts of water, lend
it to an oven, and let it be well soaked; then add to it five
points of blood, and as much bran as is necessary to give it
the consistence of a paste; mix with it some clay, and add
a quart of lob-worms chopped to pieces. Let the whole
be wrought up into a stiff paste, and rolled into balls of the
size of a hen's egg, and throw these into the pond in the
place where the net is to be cast. Let these, and some grains,
be occasionally thrown in, and the place be thus baited for
several days. When the fish may be supposed to be well
acquainted with the place, let a good baiting be given in the
morning, and in the close of the evening let the casing-net
be carefully thrown in. When the net is sunk, the mud all
about it is to be stirred with a long pole with a fork at the end;
the net to be half an hour, and the mud to be thus
stirred all the time; by this means the tench will be raised,
and will be taken in pulling out the net; but if the net were
to be thrown in and taken out in the common way, there
would hardly be one fish taken; for the suffocation of both
tench and carp, when they are frightened, is to plunge their
heads up to the eyes in the mud, and thus placed with their
tails erect, the net must draw over them, without the possi-
bility of entangling them.

FISHING, Trout. The trout is a delicious fresh water fish,
speckled with red and yellow, coming in and going out of
seasom with the back, and spawning in the cold months of
October and November, whereas all the other species spawn
in hot summer weather. There are divers kinds of this fish,
all valuable; but the best are the red and yellow trout; and
of these the female, distinguished by a lfs head and deeper
body, is preferred. They are known to be in season by the
bright colour of their spots, and by their large and thick
back; which last may serve also as a rule for other fish.
Through the whole winter they are sick, lean, and unwhole-
some, and frequently lousy. As the spring comes on, de-
serting the shall, deep waters, they repair to the gravelly
ground, against which which they continue to rub till they get rid
of their lie, which are a kind of worms with large heads.
From that time they delight to be in the sharp streams, and
such as are swift, where they lie in wait for minnows and
May-flies. At the latter end of May they are in their prime.
The usual baits whereby the trout is caught are the worms,
minnow, and fly, either natural or artificial. The proper
worms are the branding, lob-worm, squirrel-tail worm,
which has a streak round the back, a red head, and a broad
tail, earth worm, dung-worm, and maggot or gentle, espe-
cially the three fish; the branding is commonly found in
an old dunghill, or under cow-dung, or else among tanner's
bark; the others are found in the earth, and under large
stones, or stumps of trees; but whatever worms are used,
they are the better for keeping, which is to be done in an
carthen pot, with moss, frequently changed. To take the
trout with a ground bait, the angler should have a light
tapered rod, with a tender hazel top; and may angle with a
single hair of three links, the one tied to the other, for
the bottom of the line, and a line of three-hair links for the
upper part: with this sort of tackle, if the sportsman has
room enough, he will take the largest trout in any river. The
angler must always keep out of sight, and the point of the rod
must be down the stream. The season for fishing for the
trout for the ground bait begins in March, and the morn-
ings and evenings are the best time of the day; but in cloudy
weather the sport may be followed all day long. There
must be a plummet at ten inches from the hook, which the
angler must feel always touching the ground; and this must
be heavier as the stream is fowter. When the minnow is
used, change the whiteh, and that of middling size; slip
the hook through his mouth, and the point and head out at
the tail, so as it may be almost slung on the hook. Then
try, against the stream, whether it will turn. The tackle
in this case may be stronger, for the trout will setze this bait
as soon as it comes in flight; the upper part of the line may
be of three silk and three hairs, and the lower of two of
each; and the hook may be moderately large. In place
of a minnow, a small loach, or stickle-back, may serve the
turn; or, for want of either, an artificial one may be made
of cloth by the life, which is found every whit as good a
bait as the natural one.

The most agreeable manner of fishing for trout is with
the fly: the rod in this case must be light and pliable, and
the line long and fine; if one hair be strong enough, as it
may be made by proper skill in the angler, there will be
more fish caught than when a thicker line is used; and the
fly-fisher should have the wind in his back, and the sun
before him. See Angling.

By Eliz. cap. 21, no trout is to be taken under eight
inches in length; and by Stat. 44 Anne, cap. 21, sea-trout
is not to be taken in particular rivers, creeks, or arms of
the sea between June 30th and Nov. 11th. By 30 Geo. II.
cap. 21, no trout is to be taken in the Thames or Medway
between November 11th and August 24th, or to be of less
weight than one pound.

FISHING-flies. See the preceding articles, and Angling.

FISHING-flies, a bait used in angling for divers kinds of
fish. The fly is either natural or artificial.

Natural flies are innumerable: the most usual on this
occasion are the dunfly, the stone or May-fly, the red-fly,
the moon-fly, the tawny-fly, the vine-fly, the black-fly, the
d作者本人, the flag-fly: also caterpillars, canker-flies, bear-flies, &c. all which appear sooner or later,
according to the forwardness or backwardness of the
spring. To know the particular fly the fish most covets,
when you come in the morning to the river's side, beat the
bushes with your rod, and take up what variety you can of
all
FISHING.

all sorts of flies; try them all, and you will quickly find which are in most esteem; but that fish will sometimes change their fly; but it is only when they have sometimes flitted themselves therewith.

There are two ways to fish with natural flies, either on the surface of the water, or a little underneath it.

In angling for chub, roach, or dace, move not your natural fly twilly, when you fee the fish make at it; but rather let it glide freely towards him with the stream; but if it be in a still and slow water, draw the fly slowly sideways by him which will make him eagerly pursu it.

The artificial fly is most successfully used in blustering weather, when the waters are too troubled by the winds that the natural fly cannot be seen, nor rest upon them.

Of this artificial fly there are reckoned ten principal sorts:

1. The dun-fly, in March, made of dun wool, and the feathers of a partridge wing. 2. A dun-fly, made of black wool, and the feathers of a black drake; the body made of the drift, and the wings of the latter. 4. The snow-fly, in April, the body made of black wool, dyed yellow under the wings and tail. 4. The ruddy-fly, in the beginning of May; the body made of red wool, and bound about with black silk, with the feathers of a black capon, which hang dangling on his sides next his tail. 5. The yellow or greehol fly, in June; the body made of black wool, with a yellow fih on either side, and the wings taken off the wings of a buzzard, bound with black broken hemp. 6. The moon-flv; the body made of dunfih wool, and the wings with the blackish mail of a drake. 7. Tawny-fly, till the middle of June; the body made of tawny wool, the wings made contrary one against the other, of the whitish mail of a white drake. 8. The waf-fly, in July; the body made of black wool, call about with yellow silk, and the wings of drakes' feathers. 9. The telc-fly, in the middle of July; the body made of greehol wool, call about with the feathers of a peacock's tail, and the wings made of buzzards' wings. 10. The drake-fly, in August; the body made of black wool, call about with black silk, his wings of the mail of a black drake, with a black head.

The best rules for artificial fly-fishing are,

1. To fish in a river somewhat disturbed with rain, or in a cloudy day, when the waters are moved by a gentle breeze; the south wind is best; and if the wind blow high, yet not so but that you may conveniently guide your tackle, the fish will rise in plain deeps; but if the wind be small, the bell anging is in swift streams.

2. Keep as far from the water-fish as may be; fish down the stream, with the sun on your face, and touch not the water with your line.

3. Angle always in clear rivers with a small fly and slender wings, but in muddy places use larger.

4. When after rain the water becomes brownish, use an orange fly; in a clear day, a light-coloured fly; a dark fly for dark waters, &c.

5. Let the line be twice as long as the rod, unless the river be encumbered with trees.

6. For every sort of fly have several of the same, differing in colour to suit with the different complexions of several waters and weathers.

7. Have a nimble eye and active hand, to strike presently with the rising of the fish, or else he will be apt to throw out the hook.

8. Let the fly fall first into the water, and not the line, which will scare the fish.

9. In slow rivers or still places, call the fly cross over the river, and let it fish a little in the water, and draw in gently back with the current.

Salmon flies should be made with their wings standing out beside the other, whether two or four. That fish delight in the gaudiest colours that can be; chiefly in the wings, which must be long, as well as the tail.

Fishing-flasts are little appendages to the line, serving to keep the hook and bait suspended at the proper depth, to discover when the fish has hold of them, &c.

Of these there are divers kinds, some made of Muscovy duck quills, which are the best for slow waters; but for strong streams, found cork, without flaws or holes, bored through with an hot iron, into which is put a quill of a fit proportion, is preferable; pare the cork to a pyramidal form, and grind it smooth.

Fishing-bobs, a little engine of steel-wire, of a proper form to catch and retain fish.

The fishing-hook, in general, ought to be long in the shank, somewhat thick in the circumference, the point even and straight: 1. the bending be in the shank. For setting the hook on, use strong, but small silk, laying the hair on the inside of your hook; for if it be on the outside, the silk will fret and cut it asunder.

There are several sizes of these fishing-hooks, some big, some little; and of these some have peculiar names, as,

1. Single-hooks. 2. Double-hooks, which have two bendings, one contrary to the other. 3. Snappers or gorgers, which are hooks to whip the artificial fly upon, or to bait with the natural fly. 4. Springers or spring-hooks, a kind of double hooks, with a spring which flies open, being struck into any fish, and so keeps its mouth open.

Fishing-line. See Angling Line.

Fishing-nets. See Net.

Fishing-rods, a long, slender rod or wand, to which the line is fallened for angling.

Of these there are several sorts, as,

1. A troller or trolling-rod, which has a ring at the end of the rod for the line to go through when it runs off a reel. 2. A whisper or whipping-rod, a top-rod that is weak in the middle, and top-heavy, but all slender and fine. 3. A dopper, which is a strong rod, and very light. 4. A snapper, or snaper-rod, that is, a strong pole, peculiarly used for the pike. 5. A bottom-rod, being the same as the dopper, but somewhat more pliable. 6. A niggling or poking-flick, a forked stick, having a short iron line, with a needle, baited with a lob-worm; this is only for eels in their holes.

Fishing-rods are made of different materials and strength, according to the purposes for which they are used: in fishing with m. x than one hair, and with a silk-worm gut, red seal is reckoned the best, with hickory top, and the length of the whole rod should be about four yards; but for a small fly and single hair, the length of three yards will be sufficient, with the top of yellow hickery, and about nine inches of whalebone, near as long as the rod, which should be of white deal. The rods or buts of rods are generally of ground hazel, ash, or willow, about two or three feet long; and every joint should gradually taper to the top. Hazel tops are preferred, though some use the Bamboo cane, and say it exceeds the best hazel.

For ground angling, especially in muddy waters, the cane or reed is preferred for a flocck; with a hazel top, consisting of one, two, or three pieces, and a small piece of round, smooth, taper whalebone, which is whipped to the hazel with strong silk, rubbed with shoemakers wax; the whole length of the rod being five yards or five and a half yards. The best method of piercing hazel and bone is first to whip the end of the hazel with thread, and to bore it with a square
a square piece of iron of a proper size; and then make the thick end of the bone, first dipped in pitch to go into it; after which let it be scraped, filed, and neatly whipped. However, the neatest rod may be thus made: get a thick white deal or fir-board, free from knots, and seven or eight feet long; let this be divided by a joiner into several breadths, and with his planes let him smooth them round, smooth, and taper. To one of these fasten an haze rod, fix or seven feet long, which may consist of two or three pieces; to the top of which fix a piece of yew, about two feet long, made round, taper, and smooth, and to the yew a piece of small, round, smooth whalebone, five or six inches long. The fir may be coloured by warming it at the fire, and with a feather dipped in aqua-fortis, stroking it over and chasing it into the wood, which will make it of a pure cinnamon colour.

It is found useful to have rings or eyes made of fine wire, and placed upon the rod from one end to the other, in such a manner that when the eye is laid to one you may see through all the reel: through these rings the line is made to run, which will thus be kept in a due posture; and you must have a wire or wheel affixed to the rod about a foot above the end, by which, whenever it is proper, you may give range to the fish. See Angling.

Fishing-tack, or those used in the several fisheries at sea, or on the coasts, are the buoys, coles, cock, dogger, driver, cod-boat, fly-boat, fluyt, hooker, Peter-boat, smack, fland boat, trawler, trinker, &c.

Fishing Bay, in Geography, a bay of America, in Maryland, lying on the east side of Chelapeake bay, partly in Dorchester and Somerset counties, the entrance of which is between Goldsborough and Devil’s islands. This bay receives several rivers from each of the above-mentioned counties as the chief of which are Wicomico and Nanaimoke, and also Tranquaquing and Blackwater creeks.—Also, a bay on the south side of lake Ontario, about 37 miles E. of Fort Niagara.

Fishing Creek, a township of America, in Pennsylvania, situated on Susquehanna river.—Also, a river of Virginia, which runs into the Ohio. N. lat. 39° 55'. W. long. 80° 57'.—Also, a river of Kentucky, which runs into Cumberland river, N. lat. 36° 40'. W. long. 84° 19'.—Also, a river of Pennsylvania, which runs into the Susquehanna. N. lat. 40° 19'. W. long. 76° 56'.—Also, a river of New Jersey, which runs into Delaware bay. N. lat. 39° 5'. W. long. 74° 54'.

Fishing-town Point, a cape on the east coast of Borneo, S. lat. 1° 38'. E. long. 116° 30'.

Fiskilil, a port town of America, in Dorchester county, New York, five miles E. of Hudson river or Fishkill, containing about 30 houties, a church for episcopans, and another for Low Dutch. The town is very extensive, and contains six churches, and 6168 inhabitants, of whom 524 are slaves; 66 miles N. of the city of New York.

Fiskill landing is a part of the above town on the river, where is a post-office.

Fiskill, or Creek, is the small river on which the above-mentioned town stands, and from which it derives its name. It discharges itself into Hudson river, nearly opposite to New Windsor.—Also, the name of a small stream which runs S.W. into Oneida lake.—Also, a stream which rises from Saratoga lake, and runs six miles easterly to the Hudson. Its mouth is opposite to Batten-kill, two miles above Saratoga town, memorable on account of general Burgoyne’s army having laid down their arms as prisoners on its north side, during the conflict between Great Britain and America.

Vol. XIV.

Fislelin, one of the smaller Shetland isles, five miles S. from the island of Yell. N. lat. 60° 13'. W. long. 1° 23'.

Fisll Pond, reservoirs of water for the breeding, feeding, and preserving of fish.

The quality of the pond, water, &c. proper for this end is scarce determinable by any certain symptom or rule: for some very promising ponds do not prove serviceable that way. One of the best indications of a breeding pond is, when there is a good store of rubbish and grazing about it, with gravelly fiddoal, such as horse-ponds usually have; and when a water takes thus to breeding, with a few milers and spawners, that is, males and females, two or three of each, a whole country may be stocked in a short time.

Eels and perch are of very good use to keep down the flock of fish; for they prey much upon the spawn and fry of bred fish, and will probably destroy the superfluity of them.

As for pike, perch, tench, roach, &c. they are desired in breeding almost in any waters, and very numerously; only eels never breed in standing waters that are without springs; and in such are neither found, nor increase, but by putting in; yet where springs are they are never wanting, though not put in. And, which is most strange of all, many say there is not in an eel the least token of propagation, either by milk or spawn; so that law they are produced is a question very mysterious. See Eel.

For fish-ponds, it is agreed, those grounds are best which are full of springs and are to be moist; the one breeds them well, and the other preserves them from being taken. The situation of the pond is also to be considered, and the nature of the currents that fall into it; likewise, that it be refreshe with a little brook, or with the rain-water that falls from the adjacent hilly ground. Add, that these ponds which receive the fall and run of horses, and other cattle, breed the largest and fattest fish.

Fish-ponds are not only a thing of convenience to great families, but may be made a very profitable article with the farmer under due management. Watery and boggy land is often fit for no other use, and these are then a great improvement of it. Ponds made in dry grounds in the flat bottoms between hills, will also serve not only to supply the cattle with water, but the profit of the fish that may be bred in them is greater than many are aware of, and comes without any labour or expense.

In making the pond, observe that the head be at the lowest part of the ground; and that the trench of the flood-gate or sluice have a good swift fall, that it may not be long in emptying on occasion.

The best way of making the head is by driving three or four rows of stakes about six feet long, and at about four feet distance from one another, the whole length of the pond head: the first row of these is to be driven in four feet deep, that they may be very firm and secure; and if the bottom be not good, but be of a loam bottom, some line is to be added, which will harden into a great lot of roots. The earth dug out of the pond is to be laid between these stakes and rammed hard down. Other rows of stakes must be added behind and over these, and the pipe is filled up till the whole is as high and as thick as it is required. The face of it must be made even and firm, and there must be a wash kit to carry on the upper part of water in floods, &c.

If the pond carry six feet of water, it is enough; but it must be made eight feet deep, to receive the trusses and runs that may fall into it.

It would also be advantageous to have fence on the sides for the fish to run themselves in, and are their spawn in;
beside, in other places, certain holes, hollow banks, shelves, roots of trees, islands, &c. to serve as their retiring-places. Consider farther, whether your pond be a breeder; if so, never expect any large carp from thence, the greatness of the number of spawn overstocking the pond.

Carp and tench will live and thrive very well together in the same pond. Where pike are kept, there should be roach, or some other quick breeding fish, to supply them with food.

Some think that pike and tench may be kept in the same pond. They imagine that pike will not feed upon tench; but they are mistaken, for the pike is fonder of this than of almost any other fish. Ponds with clear gravelly and sandy bottoms are usually the best for breeding of fish, and foul water with muddy bottoms is the best for them to fatten in. Carp have been known to grow in one year from five to eighteen inches long in ponds where the water of the common fewers of any town have run into it.

The ordinary growth of a carp is not above two or three inches in that time, so that all the excess is to be attributed to the fatsness of the water of the fewers.

The carp, which was first brought into England by Leonard Mafeal, about the year 1514, is the most valuable of all kinds of fish for the stocking of ponds, because of its quick growth and great increase. If the breeding and feeding of this fish were more understood and practiced, the advantages would be very great, and fish-ponds become as valuable an article as gardens. The gentleman who has land in his own hands may, beside furnishing his own table, and supplying his friends, raise a great deal of money, and very considerably improve his land at the same time, so as to make it yield more this way than by any other employment whatever. The sale of carp makes a part of the revenue of the nobility and gentry in Prussia, Pomerania, Brandenburg, Saxony, Bohemia, Mecklenburg, and Holstein.

For this purpose particular attention should be paid to the soil, water, and situation of the carp-ponds: the best kinds of ponds are those which are surrounded by the finest plantations and corn-field of a rich black mould, having soft springs on the spot, or running water that is neither too cold, nor impregnated with acid, calcareous, felsitic, or other mineral particles. The water, indeed, may be softened by exposing it to the air and sun in a reservoir, or by forming an open channel for it at some distance from the pond. They should likewise be sheltered against the contrary and northerly winds, and be fully exposed to the influence of the sun.

It is found by experience most convenient to have three kinds of ponds for carp; viz. the spawning pond, the nurting and the main pond. The first sort of pond must be well cleared of all other kinds of fish, especially those of the rapacious kind, such as the pike, perch, eel, and trout, and also of all weeds, of lizards, and the water-beetles. It should be supplied with soft water, and be exposed to the sun and air. A pond of one acre requires three or four male carp, and five or eight female ones, and in the same proportion for each additional acre. The heat of breeding are those of five, six, or seven years old, in good health, with full scales, fine full eyes, and a long body, and without any blemish or wound. The pond should be stocked on a fine calm day, towards the latter end of March or in April. Carp spawn in May, June, or July, according to the warmth of the weather: and for this purpose they swim to a fresh, warm, sheltered place, where they gently rub their bodies against the muddy ground, gravel, or other, and by this pressure the spawn issues out. At the spawning season all kinds of fish should be kept from the ponds. The young fry, hatched from the spawn by the general influence of the sun, are left in this pond through the summer, and even the next winter, if the pond is deep enough to prevent their suffocation under the ice in a severe winter; otherwise the breeders and fry are put into separate ponds, more convenient for the wintering.

Ponds of the second kind are the nurseries; the young should be removed into the nurseries in March or April, on a fine calm day; a pond of an acre will admit a thousand or twelve hundred of this fry. When they are first put in, they should be well watched and driven from the sides of the pond, lest they become the prey of rapacious birds. In two summers they will grow so much as to weigh four, five, sometimes six pounds, and to be fishy and well tailed.

The main ponds are the last sort; into these are put carp, that measurfe a foot, head and tail inclusive. Every square of fifteen feet is sufficient for one carp; their growth depends upon the room, and the quantity of food allowed them. The best f wcs for ridding the main ponds are spring and autumn: carp continues to grow for a long time, and to a very considerable size and weight. Mr. Forster mentions one which he had seen in Prussia above a yard long, and of twenty-five pounds weight, and two or three hundred between two and three feet long, and which, as he was told, were of between fifty and sixty years standing.

Goethe mentions an instance of one that was one hundred years old; these were tame, and came to the shore in order to be fed, and swallowed with ease a piece of white bread of the size of a halfpenny roll. Ponds should be well supplied with water during the winter, and when they are covered with ice, holes should be opened every day for the admission of fresh air, through want of which carp frequently perish. See Carp Fishing, and Breeding of Fish.

For the general management of fish-ponds reserve some great waters for the head-quarters of the fish, whence you may take, or wherein you may put any quantity thereof; and take care to have lews, and other auxiliary waters, so that you may convey any part of the stock from one to the other, and lose no time in the growth of the fish, but employ the water as you do your land, to the best advantage. View the grounds, and find out some fall between the hills as nearly flat as may be, so as to leave a proper current for the water: if there be any difficulty in judging of such, take an opportunity, after some sudden rain, or the breaking up of a great snow in winter, and you will plainly see which way the ground calls, for the water will take the trench-fall, and run accordingly.

The condition of the place must determine the quantity of ground to be covered with water. For example, we may propose in all fifteen acres in three ponds; or eight acres in two, and no less; and these ponds should be placed one above another, so as the point of the lower may almost reach the head of bank of the upper; which contrivance is no less beautiful than advantageous.

The head or bank, which, by slopping the current, is to raise the water, and to make a pond, must be built with the clay and earth taken out of the pan or hollow day in the lowest ground above the bank: the shape of the pan is to be an half oval, whereof the flat is to come to the bank, and the longer diameter to run square from it. All fish-ponds should be drawn once in three or four years, and the fish fished; if it be a breeding-pond, the smaller fish should be taken out to flower other ponds with; and in feeding ponds all the fish should be kept as nearly as may be of a size, for the larger and smaller never all thrive well together.

Flounders will both thrive and breed in any pond, especially
specially in a clay pond, and will be much larger than in
rivers.

Bittern, herons, otters, water-rats, and gulls, are all
great destroyers of fish, and the ponds should be kept as clear
as possible of them; but the greatest of all destruction in
fish-ponds is occasioned by frosts.

To remedy this, some propose to break the ice and lay in
pipes, straw, and other things, to give air to the fish; but
all these fail when the ponds are foul; but when they are
clean, the fish seldom suffer any harm, be the frost ever so
long, though no holes be broke in the ice. The length of
foul water seems to be the occasion of the death of the fish,
in this case of its being locked up by frosts, and not the
want of air. The cleaning of ponds frequently is of great
use as well on this as on many other occasions; and it is
done at no expense, because the mud, serving as manure to
the lands, more than pays the expense of taking it out.

When the ground is boggy, and carts cannot come up
to the mud, it is best to cut the ponds long and narrow
in form of mounds, that it may be thrown out at one tos by
the labourers in clearing them; for if it require two toles,
the difference will be just the double price of labour.

In many situations where fish-ponds can be readily formed,
it may not unfrequently be advisable to have recourse to
them in the view of profit from the fish, and their conve-
ience in family use. It is not easy to ascertain what quan-
tity of produce, or profit, might be derived from ponds of
this description under different circumstances, as very few
experiments have yet been detailed from which conclusions
can be drawn. It would lead to much interesting informa-
tion on the subject, if the annual increase in the weight of
different sorts of fish, in different branches of their growth,
and under different circumstances of soil and water, were
correctly determined.

It has been stated by Mr. Lowden of Berkshire, in the
"Annals of Agriculture," that a pond of the extent of
three acres and a half, drawn, after three year's flocking
with flores of one year old, afforded 195 pounds weight of
carp, and 240 pounds weight of tench; which in the whole
was 425 pounds, which sold for twenty pounds ten shillings,
or nearly 2l. 6s. 6d. the acre per annum. And that the
same pond, when flocked with tench only, on being drawn
three years afterwards, produced about twenty-six pounds.
Therefore, supposing that, in a pond which supports two
thousand four hundred fish, half a pound be gained an-
ually, it will be 1000 pounds weight, which, at 6l. the
pond, will afford thirty pounds, and for fifteen acres, forty
shillings the acre; and when at 9l. the pond the three pounds
the acre.

As there is little trouble in this sort of farm management,
such profits should not be disregarded or overlooked in par-
icular situations. In the district noticed above, it is stated
that the usual price, when sold by the pound, is one shilling
for tench, and ten-pence for carp. And that this is the
best manner of disposing of them that can be adopted.
But when they are sold by the number, as per hundred, &c.
they are mostly measured from the eye to the tail, and dis-
posed of in this manner.

In what relates to the proper flocking and managing of
ponds for the raising of fish, in the intention of deriving
advantage from the sale of fish much skill remains to be
accomplished before the greatest possible profit can be ob-
tained.

In different situations the methods of flocking are ex-
tremely different. It is the practice in Berkshire to flock
with carp and tench in the proportion of one hundred to
the acre, while in Suffolk they flock in the quantity of
seventy five brace to the acre. Stocking in too large a pro-
portion may be injurious to the profit, as fish require the
food to be abundant in most cases.

The forts of pond-fish most profitable to farming pro-
prieters, are probably those of carp, tench, perch, and occa-
sonally eels. But in thickly stocked ponds, the two last
forts should not be both admitted at the same time, as they
devour young fry very largely. Where ponds are large,
carp and tench answer well together; but in those of the
smaller kind, the former is apt to deprive the latter of its
food, in consequence of being too much more powerful.
Carp seldom affords much profit in small ponds, but tench
succeed well in those of almost any dimensions. Carp,
perch, and eels, sometimes answer pretty well together,
and likewise tench with eels. Where the ponds are but small,
the best practice is perhaps to keep the carp and tench se-
parate.

Carp frequently injure themselves by breeding, but this is
not often the case with tench.

The situations in which fish-ponds can be made, in the in-
tention of farm-profit, are principally in the dips, hollows,
and other parts of ground where the quality of the land is
very bad, but where there is the convenience of plenty of
water proper for the purpose.

In a national point of view, ponds of this sort can hardly
yet be considered of much importance, but they should not
be neglected by those who are engaged in the improvement
of landed property.

Though fish-ponds are numerous in many districts of the
kingdom, it is perhaps only in the counties of Suffolk and
Sussex that any thing like a system has been established for
raising fish with the intention of profit; but in those coun-
ties fish-ponds have long been formed for letting to dealers
in pond-fish, and flocking in order to the disposal of the
produce as an article of farm-flock, like that of any other
kind. It is not, however, improbable but that as the na-
ture and management of pond-fish become more perfectly
understood, such a practice may be considerably ex-

FISH-TOWN, in Geography, a town of Africa, at the
mouth of the river Calhuri.

FISKEROE, an isle or peninsula on the Laponic
shore, part of which belongs to Russian Lapland.

FISKO, a small island of Sweden, between the head
of Aland and the coast of Finland. N. lat. 60° 26'. E.
long. 25° 45'.

FISMES, a town of France, in the department of the
Marne, and chief place of a canton in the district of
Rheims, situated on the Velle; 17 miles N. W. of Rheims.
N. lat. 49° 18'. E. long. 4° 46'. The place contains 2126.
and the canton 11,152 inhabitants, on a territory of 1824 kilometres, and in 23 communes.

FISSATO, a sea-port town of Africa, in the country of Tripoli; 90 miles N.W. of Tripoli. N. lat. 33° 50'. E. long. 12.

FISSENIA, in Ancient Geography, a town of Asa, in Mesopotamia, seated on the Baxil or Royal river, towards Babylon.

FISSIDENS, in Botany, from fissur, cleaven, and dens, a tooth, an Hedwigian genus of moss, distinguished by its author, from his own Dictaum, only by the male flowers being axillary on the same plant with the female ones; a difference which, though corroborated by the habit in moss ears, is small, we think too difficult to be of any practical use. See DICTIONARY.

FISSLIA, from the fissile or easily cleaven corolla. Jul. 26. Wildb. Sp. Pl. v. 1. 194. Linnæus t. 28. An evergreen tree of the fice de Bourbon, where it is called fse de perspekt, because the smaller kinds of parrots are found of the fruit. The leaves are alternate, on short stalks, elliptico-lanceolate, entire, bluntish, thick and coriaceous, smooth, with one rib and a few flight veins. Stirpes none. Flowers axillary, somewhat racemose, occasionally solitary, on long smooth stalks, resembling those of an orange but smaller. Fruit a small drup, encompassed with the enlarged, cup-shaped, entire, permanent calyx.

This is the Olac fissaturnum of Valh's Enum. v. 2. 33. "Leaves ovate-oblong or lanceolate, slightly veiny. Branches round." See Olac, to which genus it is with indubitable propriety referred by Valh, though they are placed in two very different natural orders by Jussieu, who knew Olac but imperfectly. What he terms barren filaments in the leaf, Linæus, less authentically perhaps, takes for neculars.

FISSLUM-FOLIUM, a leaf that is cleaven, or divided vertically more or less deeply. See LEAF.

FISSURA, in Anatomy, a name given to several openings, particularly in the bones of the head; as the superior orbital fissure of the sphenoidal bone, the inferior-sphenomaxillary fissure formed between the sphenoid and superior maxillary bones, &c.

FISSURA Magna Sylvii, a division in the substance of the brain, separating the anterior from the middle lobe; See Brain.

FISSURE, a term in Surgery. All practitioners and authors have, from the earliest times, understood by the word fissure, a solution of continuity in a bone, having the appearance of a hair. Hence the expression rima capitularis, capitallar fissura, which, in short, is nothing more than a very fine, minute crack in a bone.

The old surgeons used to believe, that this sort of fracture took place both in the flat and the long cylindrical bones; and it was M. J. L. Petit, who first brought into doubt the opinion, in as far as it related to bones of the latter class. The subject was noticed by this writer, in his "Traité des Maladies des Os." In this work, he represents fractures, said to occur exactly in the direction of the length of the bones, as only imaginary. His reason for this sentiment is, that there is no force capable of breaking a bone in this way, which would not much more easily occasion a fracture of the transverse kind.

The signs of a fissure, as stated by Fabricius ab Aquapendente, are very equivocal and fallacious; he observes: "quod fios caecum longitudinum fractum fit, primó adept membra crassitatis ultra naturalem flatum, dieinde dolor, tum membra inequalitas." But all these symptoms, when they make their appearance, ought rather to be ascribed to the effects of the contusion, than to any other circumstance. It is also evident, on reading Fabricius ab Aquapendente, that he meant by a longitudinal fracture, what is now called, an oblique one. Indeed as M. J. L. Petit notices, Fabricius would never have advised extension to be made for a fracture which was exactly in the direction of the length of a bone, since this practice is obviously not applicable to the case, and he would never have recommended making pressure round the broken part, which could not be in a displaced condition, even were the bone actually fractured in a longitudinal manner. Davenery in his "Traité des Maladies des Os," has adduced no solid arguments in favour of the doctrine of longitudinal fracture. The reader may find the present subject very judiciously investigated at the beginning of M. J. L. Petit's work. It appears from the facts and reasons there brought forward, that, on the bones of the extremities a fissure can only occur, in cases of gunshot-wounds, where the splinters sometimes extend as far as the nearest joint. Such fractures are not easy of detection. They are most frequently attended with symptoms, arising more from the violence and shock always occasioned by gunshot injuries, and the consequent mischief excited in the substance or medullary structure of the bone, than from the particular nature of the fracture itself.

But though authors differ in opinion, in regard to fissures on the long cylindrical bones, they are all of one sentiment in acknowledging the occurrence of such fractures on the bones of the cranium, in consequence of blows upon the head. Here the accident is often termed by Latin writers fissura. The crack is either plainly perceptible, or scarcely discoverable; in which latter case, the expression of capillary fissura is often used. In both cases, the solution of continuity may take place, either precisely in the place against which violence has been directed, or at some other part of the skull. Encyclopédie Méthodique; Partie Chimurgicale. Art. Fissure.

FISSURE, in Geology and Mining, generally signifies the fame with Faults, which see; but Mr. W. Martin, a late, and generally a very correct writer, defines it (Outlines of the Knowledge of Extraneous Fossils, p. 172.) to mean, a partial and superficial rift, rarely extending through more than one stratum; which definition, by the notes in this page, is made to apply nearly to mineral veins; like those in the Limelime district of Derbyshire, and by which two things very different in their nature, and the mode and period of their formation, are confounded together, as we have observed, when treating of Faults.

FISSURE Fossils, in Mineralogy, or venous or venigenous minerals, are those found in veins or fissures, and which are generally crystallized in a more or less perfect state; see Venogenous Fossils, Riders, Veins, &c.

FISSURES, in the History of the Earth, certain interruptions that horizontally or parallelly divide the several strata of which the body of our terrestrial globe is composed.

FISTELLA, or FEZZA, in Geography, a town of Morocco, the inhabitants of which are rich, courteous, and warlike; 150 miles N.E. of Morocco.

FISTER, a town of Norway, in the diocese of Bergen; 16 miles N.E. of Stavanger.

FISTRITZ, or BYSTRIZIT, New, a town of Bohemia in the circle of Becin; 28 miles E. of Budawis. N. lat. 49° 35'. E. long. 15° 1'.

FISTRITZ, a river of Moravia, which runs into the Marive, near Olmaz.
FISTULA, in Antiquity, an instrument of wood used in driving piles, and fitted with two handles. It was either raised with pulleys fixed at the head of large beams, and then let fall again directly on the piles, or was wrought by the hand only.

FISTULA, Lat. a pipe, a flute, a flageolet, a whistle. FISTULA, in the Ancient Music, an instrument of the wind kind, resembling our flute or flageolet.

The principal wind instruments of the ancients were the tibia and fistula; though how these were constituted, or wherein they differed, or how they were played on, does not at present appear. All we know is, that the fistula was at first made of reeds, and afterwards of other matters. Some had holes, some none: some again were single pipes; others a combination of several; witness the lyreings of Pan.

FISTULA, Liturgical, was the pipe, being generally made of gold or silver, through which during several ages, persons who communicated under both kinds, drank out of the chalice. The use of it was retained in the Abbey of St. Denis, near Paris, as long as it subsisted, as likewise by the kings of France, when they received the sacrament at their coronation.

FISTULA Panis, Pan's pipe. See Syrinx and Syringa.

FISTULA, in Surgery, has usually been defined, "fistus anguli, callous, profundus; aci fanie diffusus;" or, as Dionis traduces it, "un ulceré profund, et cavernex, dont l'entree est étroite, et le fond plus large; avec siffue d'un pus acer et virulent; et accompagné de calloités." In the words of Mr. Pott, a fistula is "a deep, hollow, fore, or sinus, all parts of which are so hardened, or so disfigured, as to be absolutely incapable of being healed while in that state; and from which a frequent, or daily discharge is made of a thin, discoloured saps, or fluid."

A fistula generally leads down to some cavity, commonly situated in the cellular substance, between the integuments and muscles, or in the interfaces between the muscles themselves. The cavities with which fistula communicate are usually termed sinuses. These, in some measure, serve as receptacles for whatever matter is secreted by the pustules of the abscesses, and when pressure is made upon such sinuses, a much larger quantity of saps, or matter, flows out of the external fistulous opening, than appearances would induce one to expect.

The reader will excuse us from devoting much time to criticisms on the ordinary definitions of a fistula; but we cannot refrain from observing that a fistula might be better, and more simply called a narrow track or passage, leading from the seat of an abscess, giving vent to more or less of the matter outward, and having little or no tendency to heal. However, in cases of fistula in prime, and of those of the parotid duct, the foregoing definition will not be altogether accurate, since the fistulous passage leads from parts where urine and saliva exist, instead of pus. In the preface of surgery, so many disorders are termed fistulous, which have no claim to the appellation, (according to the strict sense of the expression,) not being accompanied with any callothytes or fanious discharge, that perhaps a surgeon would be less liable to imbibe erroneous notions from the signification which we have ascribed, than from the ancient one. We are ready to acknowledge, however, that almost all definitions are difficult, objectionable in some way or another, and exposed to controversy, and we gladly quit the subject ourselves, ever ready to retract our own explanations in favour of better ones.

The fistulous which are formed in cases of ulcers and abscesses are most frequently occasioned by the confinement of purulent matter, which readily makes its way in different directions in the cellular substance, which is the softest and most yielding part of the texture of the body. If a timely opening be made into abscesses, the formation of fistulas and sinuses is generally avoided. But though a puncture be made by the surgeon at a seasonable period, if the aperture should not be made in a depending situation, so that the mafs of pus cannot freely flow out, some of the matter will be continually oozing out in a flow way, prevent the part from healing, and be the cause of a fistula. The cavity of the abscess, in consequence of being kept for a considerable time indurated with matter, instead of contracting and granulating, will acquire a disfigured state, in which a thin fanious discharge will be emitted, and the parts lose all tendency to get well of themselves.

The foregoing observations are equally applicable to cases, in which an abscess bursts of itself, in a place which is very unfavourable for the escape of the pus.

Another circumstance under which fistulae are necessarily produced, is when a dead portion of bone, or some extraneous body lodged in the flesh, maintains a continual suppuration around it. In this sort of case, the opening by which the abscess first breaks never closes as long as the secretion of pus within goes on; the matter is every now and then oozing out, and the track through which it passes becomes fistulous.

No term in surgery has been so much misapplied as the word fistula; and since the expression has always conveyed to the practitioner's mind the idea of a disease attended with a great deal of callous induration, this abuse of language has too often led, especially in former days, to methods of treatment equally unceaseful, hurtful, and barbarous. Even at present, so many disorders are called fistulas without deferring the name, at least, without being accompanied with any callous hardnefs, that, as we have already said, young surgeons would avoid imbuing many prejudices, by merely considering the phrase "fistula," as implying an outlet for some discharge, which outlet, owing to some particular cause, has not much propensity to heal. The truth of what we have here remarked will be better seen, when the subjests of fistula in man, and fistula lachrymalis, are presently treated of.

We shall next notice some of the modes of treatment which have been put into practice for the purpose of curing fistulous complaints. Some of the plans alluded to may now be said to be exploded; but there is an advantage in knowing what has been done by our predecessors, and, for this reason, we shall enter into some details, which otherwise would not have been given.

In recent cases of fistulae, many writers have recommended what they call pulinary injections to be made use of, and when the disface is in a more advanced state, and the sides of the fistulous are length of time are in a callous state, ephrastic injections and powders are prescribed. Such applications, however, have seldom or never produced any real good effects, and the too frequent indiscriminate employment of them has often rendered sinuses hard and callous, which previously were by no means indurated to heal.

In all cases in which the sides of the fistulous are in an indurated callous state, we recommend laying open the cavity from one end to the other, and removing all such parts as have become hardened, so as to convert the whole diseased place into one wound, which is to be treated on common principles.

The
FISTULA.

The simple division of a fistula throughout its whole extent is, even at this day, the most approved plan of treatment generally speaking; but the additional method of cutting out all the surrounding indurated parts has long been abandoned by all good surgeons. The absurdity and bad effects of such treatment were well explained by Pott, in his treatise on the fistula in ano, and, since his time, the lamell practitioners in this country have not disagreed themselves by the performance of exactions of this nature.

Though there cannot be a doubt, that dividing fistula throughout their whole extent is generally the most eligible mode of cure, it must be acknowledged that, in certain instances, the strictest of the parts, the disagreeableness of the fear, and the degree of danger, are formidable objections.

For example, the practice of cutting thus extensively is not applicable to cases in which fistula extend a very considerable way up the rectum; and certainly no prudent surgeon would advise fistula to be cut open which run to an inordinate depth, and, as very often happens, below large blood-vessels, nerves, and tendons.

In these last-mentioned, and several other kinds of fistula, the French surgeons are advocates for the employment of a fetcum. They observe that the object in the treatment of all fistulous discharges, is to make the sides of the fissure adhere together, so that no cavity may remain. They state, that the most effectual plan of fulfilling this indication is first to make an opening on the most depending part of the fistula, in order to give free vent to the matter; and, secondly, by a gentle irritation to excite a certain degree of inflammation over the inner surface of the cavity. It is well known that in the inflammatory state, coagulating lymph is effused, and, becoming vascular, renders the sides of the fistula permanently adherent together.

According to the French writers, the two indications, just now specified, may be best fulfilled, in the majority of cases, by introducing a fetcum from the orifice of the fistula down to the very bottom of the fissure, where a counter-opening is to be made.

The fetcum should be made of silk or cotton, and more or less thick, according to the size of the fistula. The join of silk or thread is to be gradually lessened, as the cure advances, one or two threads being removed every two or three days. At length, when the cavity of the fissure is almost filled up, and the discharge has considerably diminished, the fetcum may be entirely removed. A moderately tight bandage over the dressings will then serve to complete the cure.

Sutures are not generally preferred for the cure of fistula by English surgeons. Indeed it is obvious, they can only be used when the whole course of the fistula can be traced with a probe, and its termination is so situated that a counter-opening can be made into it. This may be said never to be the case with fistula in ano.

The simple division of fistulous fissures is generally the most judicious mode of cure. It is only when a fistula runs under parts, which it would be dangerous or hurtful to cut, that the knife must give place to other means. A director, a crooked alligator, and a probe, are the instruments which are useful in dividing fistula.

Many fistula are kept up by the presence of extraneous bodies, dead pieces of bone, &c. In such instances, it is manifest that the accomplishment of a cure cannot be effected, either by objections, or laying open the fissure; but can only be obtained by the removal of the foreign substance, or detached portion of bone.

We shall now treat of the fistula in ano, fistula lachrymalis, and fistula in perineum, all which are surgical diseases of the greatest importance.

Fistula in ano.—Clear and precise definitions of diseases, and the application of such names to them, as are expressive of their true and real nature, are (says that celebrated surgeon Mr. Pott) of more consequence than they are generally imagined to be; untrue or imperfect ones occasion false ideas; and false ideas are generally followed by erroneous practice.

The same writer remarks that it would be no difficult matter to produce infirmities of disorders, whose treatment has, for a great length of time, been accommodated more to the titles imposed upon them, than to their true and real character. Amongst these, the fistula in ano is mentioned as a most glaring proof.

"The custom of giving the appellation of fistula to every impollution, and to every collection of matter formed near to the anus, has, by conveying a false notion of them, been productive of such methods of treating them, as (though perhaps suited to such ideas) are diametrically opposite to those which ought to be pursued; such as have often rendered these cases tedious and painful, which might have been cured easily and expeditiously; and, consequently, such as have brought disgrace on our art, and unnecessary trouble on mankind.

A small orifice or outlet, from a large or deep cavity, discharging a thin gleat or fawiness, made a considerable part of the idea which our ancestors had of a fistulous force, wherever slighted. With the term fistulous, they always connected a notion of callousness; and, therefore, whenever they found such a kind of opening yielding such sort of discharge, and attended with any degree of induration, they called the complaint a fistula. Imagining this callousness to be a diseased alteration made in the very structure of the parts, they had no conception that it could be cured by any means but by removal with a cutting instrument, or by destruction with eschars, and therefore they immediately attacked it with knife or cautery, in order to accomplish one of these ends; and very terrible work, by their own accounts, they often made, before they did accomplish it.

"Several of the above mentioned circumstances so frequently attend collections of matter near to the rectum; and therefore, for want of proper attention to the true nature of the case, the custom of calling them all fistule has generally prevailed, though without any foundation in truth or nature.

"That abscesses, formed near the fundament, do sometimes from bad habits, from extreme neglect, or from gross mis-treatment, become fistulous, is certain; but the majority of them have not, at first, any one character or mark of a true fistula; nor can, without the most supine neglect on the side of the patient, or the most ignorant mismanagement on the part of the surgeon, degenerate, or be converted into one.

"Collections of matter from inflammation, wherever formed, if they be not opened in time, and in a proper manner, do often burst. The hole, through which the matter finds vent, is generally small, and not often situated in the most convenient or most dependent part of the tumour; it therefore is unfit for the discharge of all the contents of the abscess; and, instead of closing, contracts itself to a smaller size; and, becoming hard at its edges, continues to drain off what is furnished by the undigested sides of the cavity.

"This is often the case in the most muscular or fleshy parts of the body, where the cellular and adipose membranes, 

"
but altered more... 

After taking notice of the frequency of abscesses about the anus, and their being attended with considerable induration, which does not subside, particularly when they have been allowed to burst of themselves, Mr. Pott remarks that the smallness of the accidental orifice, the hardfoc of its edges, its being found to be the outlet from a deep cavity, its discharging every day a thin, glistening, discoloured kind of matter, attended with great induration of the surrounding parts, are all of them circumstances tending to confirm the idea of a true fistula.

"To this idea (says Mr. Pott) the general treatment of these cases has therefore been made to accord; upon this there has been built the prevailing doctrine of free excision, or as free destruction, without any regard to the original production of the complaint, its particular seat, its date, or any other attendant circumstances; and without examining whether it would not admit a more easy and a more expedient method of cure. In short, this notion, that all fistulas near the rectum are necessarily fistulous, has occasioned the prescription of such a manner of treating them, from their very first appearance as they can hardly ever stand in need of at any time; and a more ill founded supposition that the induration of the parts about may be owing to a diseased callous, is urged as a reason for using them with more severity than even such a fistula would require."

Mr. Pott next observes, that whoever would obtain a true notion of the disease in question, must consider it under all the forms in which it makes its appearance. These, which are many and various, both with regard to aspect, situation, and symptoms, are what shew the different nature of the complaint in different states, and are the circumstances which ought to regulate a surgeon's conduct in the cure of it.

Sometimes (says Mr. Pott) the attack is made with symptoms of high inflammation; with pain, fever, rigor, &c. the fever subsiding as soon as suppuration is fully established.

"In this case, a part of the buttock, near to the anus, is considerably swollen, and has a large, circumfered hardnes. In a short time, the middle of this hardnes becomes red and inflamed; and, in the centre of it, matter is formed.

"This, in the language of our ancestors, is called in general a phlegmon; but, when it appears in this particular part, a phyma.

"The pain is sometimes great, the fever high, the tumour large, and excessively tender; but however disagreeable the appearances may have been, or however high the symptoms may have risen before suppuration, yet, when that end is fairly and fully accomplished, the patient generally becomes easy and cool, and the matter formed under such circumstances, though it may be plentiful, yet is good.

"On the other hand the external parts, after much pain, attended with fever, sickness, &c. are sometimes attacked with considerable inflammation, but without any of that circumfered hardnes, which characterized the preceding tumour; instead of which, the inflammation is extended largely, and the skin wears an erysipelasious kind of an appearance. In this the disease is more superficial, the quantity of matter small, and the cellular membrane floughy to a considerable extent.

"Sometimes, instead of either of the preceding appearances, there is formed in this part what the French call une suppuration gangreneuse; in which the cellular and adipose membrane is affected in the same manner as it is in the disease called a carbuncle.

"In this, the skin is of a dusky red, or purple kind of colour, and although harder than when in a natural state, yet it has by no means that degree of tension or resilience which it has in either the phlegmon, or in the erysipelas.

"The patient has generally at first a hard, full, jarring pulse, with great thrill, and very fatiguing reflexes. If the progress of the disease he not stopped, or the patient relieved by medicine, the pulse soon changes into an unequal, low, flushing one; and the strength and the spirits sink in such manner as to imply great and immediately impending mischief. The matter formed under the skin to altered is small in quantity, and bad in quality; and the adipose membrane is gangrenous and floughy throughout the extent of the discolouration. This generally happens to persons whose habit is either naturally bad, or rendered so by intemperance.

"In each of these different affections, (continues Mr. Pott) the whole malady is often confined to the skin and cellular membrane underneath it; and no other symptoms attend than the usual general ones, or such as arise from the formation of matter, or floughs in the part immediately affected. But, it also often happens, that, added to these, the patient is made unhappy by complaints arising from an influence, which such mischief has on parts in the neighbourhood of the disease; such as the urinary bladder, the vagina, the urethra, the hemorrhoidal vessels, and the rectum; producing retention of urine, strangury, dysuria, bearing down, tenesmus, piles, diarrhoea, or obdurate colicines: which complaints are sometimes so prelaging, as to claim all our attention. On the other hand, large quantities of matter and deep floughs are sometimes formed, and great devastation committed on the parts about the rectum, with little, or no previous pain, tumour, or inflammation.

"Sometimes the disease makes its first appearance in an induration of the skin near to the verge of the anus; but without pain or alteration of colour, which hardfoc gradually foften and suppurate. The matter, which, when let out, in this case, is small in quantity, good in quality, and the face is superficial, clear, and well conditioned. On the contrary, it now and then happens, that, although the pain is but little, and the inflammation apparently slight, yet the matter is large in quantity, bad in quality, extremely offensive, and proceeds from a deep, rude hollow, which bears an ill-natured aspect.

"The place, also, where the abscess points, and where the matter, if left alone, would burst its way out, is various and uncertain. Sometimes it is in the buttock, at a distance from the anus; at other times near its verge, or in the perineum; and this discharge is made sometimes from one orifice only, sometimes from several. In some cases, there is not only an opening through the skin externally, but another through the intestine into its cavity; in others there is only one orifice, and that either external or internal.

"Sometimes the matter is formed at a considerable distance from the rectum, which is not even laid bare by it; at others it is laid bare only, and not perforated; it is also sometimes not only demulced, but pierced; and that in more places than one. The original seat of this mischief is, in some cases, high up in the pelvis, near the lower vertex of the loins, and the os sacrum; and the matter comes from parts so dissected, and so out of reach, that the case is hopeless from the first."

We shall here avoid inferring a few remarks, which Mr. Pott...
FISTULA.

Pott has next added, for they seem to rest on doctrines which are now generally abandoned. The different cases which have been mentioned show that there is a great variety of flates and circumstances, and that the disease must of course have the treatment varied accordingly. When inflammation attacks the cellular substance surrounding the rectum, suppuration can very seldom be prevented from taking place. In conformity to the advice of Mr. Pott, therefore, the best practitioners seldom have any object of this kind in view; but, when called at an early period of the affection, endeavour to moderate the symptoms, promote suppuration, open the abscess, so soon as the matter is formed, and treat the sore in such manner as shall be likely to produce a speedy and lasting cure.

Mr. Pott remarks: when there are no symptoms which require particular attention, and all that we have to do is to aid the maturation of the tumour, a soft poultice is the ball application. When the disease is fairly in the phlegmonous kind, the thinner the skin is suffered to become, before the abscess is opened, the better; as the induration of the parts about will thereby be more dissolved, and, consequently, there will be the less to do after such opening has been made. This kind of tumour is generally found in the condition of full, famine habits; and, who, therefore, if the pain be great and the fever high, will bear evacuation for both by phlebotomy and gentle cathartics; which is not often the case of those who are said to be of bilious constitutions; in whom the inflammation is of larger extent, and in which the skin wears the yellowish tint of the erysipelas: persons of such kind of habit, and in such circumstances, being in general seldom capable of bearing large evacuation.

According to Mr. Pott, the erysipelatous inflammation generally makes its attack with nausea, vomiting, light rigour, heat, thirst, and reftlesness.

"The quickness of the pulse, and heat of the skin (fays this distinguished surgical writer) are indications for some degree of evacuation, and, indeed, sometimes render it requisite; but, it is a very prevailing opinion with many practitioners, that these evacuations should be freely made, and frequently repeated; in short, that the cure of this kind of inflammation is safely to be effected by them; which is so far from being true, that the practice has proved fatal to many. If, for instance, blood be drawn off in such quantity, as that the patient's pulse licks suddenly, or his strength be considerably reduced by purging, it is no very uncommon thing for the inflammation to leave the part first attacked; and for such complaints to come on immediately, as soon prove destructive, and afford no opportunity to repair the mischief which the evacuation has produced.

"When the inflammation is of this kind, the quantity of matter formed is small, compared to the size and extent of the tumour; the disease is rather a floughy, putrid state of the cellular membrane, than an suppuration; and, therfore, the sooner it is opened, the better. If we wait for the matter to make a point, we shall wait for what will not happen, at all, but till after a considerable length of time, during which, the disease in the membrane will extend itself, and consequently, the cavity of the flans, or abscess, he thereby greatly increased.

"When, instead of either of the preceding appearances, the skin wears a dusky purplish, red colour; has a doughy, unyielding kind of feel, and is very little sensible; when these circumstances are joined with unequall, faulting kind of pulse, irregular shiverings, a great failure of strength and spirits, and inclination to doze, the case is formidable, and the event generally fatal.

"The habit, in these circumstances, (continues Mr. Pott) is almost bad; sometimes from nature, but much more frequently from gluttony and intemperance. What affinities art can lend must be administered speedily; every minute is of consequence; and, if the disease be not stopped, the patient will sink. Here is no need for evacuation of any kind; recourse must be immediately had to medical affinities; the part affected should be frequently fomented with hot spirituous fomentations; a large and deep incision should be made into the diseased part; and the applications made to it should be of the warmest, most antiseptic kind."

Mr. Pott afterwards notices the occasional occurrence of strangury, dysuria, and a total retention of urine, when abscesses form in the neighbourhood of the rectum and bladder, particularly, when they are situated near the neck of the latter part. Such complaints may continue from the first attack of the inflammation till the abscess breaks; or they may only last a few hours.

"Mr. Pott observes, attacks of grey and dysuria in general are easily relieved by bleeding, emetic astringents, and nitre, "But (says he) the total retention (of urine) is, while it continues, both fatiguing and alarming, They, who have not often seen this case, generally have immediate recourse to the catheter; and for this they plead the authority of precept, but, the practice is so essentially wrong, and I have seen such terrible consequences from it, that I cannot help entering my protest against it.

"The neck of the bladder, from its vicinity to the parts where the inflammation is seated, and from its being involved in the same common membrane, does certainly participate, in some degree, of the said inflammation. This will, in some measure, account for the complaint; but, whoever considers the extremely irritable state of the parts compounding that part of the urethra, (if I may be allowed to call it,) and will, at the same time, reflect on the amazing and well-known effects of irritation, will be convinced, that the principal part of this complaint arises from that cause; and that the disease is, strictly speaking, spasmodic. The reasons in which an attack of this kind is generally made, the very little dilation which the bladder often suffers, the small quantity of urine sometimes contained in it, even when the symptoms are most sufficient, and the most certain as well as safe method of relieving it, all tend to strengthen such opinion.

"But (proceeds Mr. Pott) whether we attribute the evil to inflammation, or to a spasmodic irritation, whatever can, in any degree, contribute to the exacerbation of either, must be palpably and manifestly wrong. The violent passage of the catheter through the neck of the bladder, (or violent in such circumstances it must be,) can never be right. I will not say, that it never succeeds; but I will say, that it can hardly ever be proper to make the attempt.

"If the instrument be successively introduced, it must either be withdrawn as soon as the bladder is emptied, or it must be left in it; if the former be done, the same cause of retention remaining, the same effect returns; the same pain and viole we must again be submitted to under (most likely) increased difficulties. On the other hand, if the catheter be left in the bladder, it will often, while its neck is in this state, occasion such disturbance, that the remedy, (as it is called,) will prove an exacerbation of the disease, and add to the evil it is designed to alleviate. Nor, is this all; for the resistance which the parts, while in this state, make, is sometimes so great, that if any violence be used, the instrument will make for itself a new route in the neigh-
FISTULA.

louring parts, and lay the foundation of such mischief as frequently baffles all our art—an accident, (fays Mr. Pott,) which I have known to happen to those, whose judgment and dexterity have never been doubted."

Mr. Pott remarks, that the true, safe, and rational method of relieving this complaint is by evacuation and anodyne relaxation: this not only procures immediate ease, but does at the same time serve another very material purpose, which is that of maturating the abscesses. Lots of blood is necessary; the quantity to be determined by the strength and state of the patient. The intelles should also be emptied, if there be time for doing, by a gentle cathartic: but, (fays Pott,) the most effectual relief will be from the warm bath or fomentum, the application of blisters with hot water to the pubes and perineum; and, above all other remedies, the injection of clysters, consisting of warm water, oil, and opium.

For the painful tenesmus, which is no uncommon attendant on inflammations about the rectum, Mr. Pott recommends a dose of rhubarb, joined with some warm monody. And if this plan fail, he prefers fresh clysters with opium.

The bearing down in women may be cured by the same means.

For the obstinate colliquenes, and piles, which sometimes accompany abscesses about the rectum, Mr. Pott advises phlebotomy, laxative clysters, and a low cool regimen; a soft poultice being externally applied, which softens the indurated piles, and promotes suppuration.

We shall now follow Mr. Pott in considering this disease, when the first symptoms attending the inflammation are gone off, and matter is either formed and collected, so as to require being let out, or this last step having been neglected, the pus has made its own way out.

Mr. Pott reduces all cases of this class to two general heads:

1. Thofe-instances in which the intelle is not at all interfered.

2. Thofe in which it is either laid bare, or perforated.

When the matter is fairly formed, makes a point, and requires being let out, the opening ought always to be made where such point is situated, where the skin is most thin, and the fluctuation most palpable.

Mr. Pott, after considering the plan of opening abscesses about the anus, exposes the absurdity of the opinion once prevalent, that an abscess, opened by a knife, must be immediately examined and fluffled with dressings, while that, on which a cautery has been applied, must be let alone, until the effcor is cast off. "Let the one be treated as the other is, (observes this eminent surgeon,) and as they both ought to be, and the event will be found to be alike in each; excepting this material difference in favour of the knife, that it will not necessarily occasion any destruction of parts, lots of substantia, nor any deformity, which is at all comparable with what must follow the use of the cautery.

"In making the opening, the knife or lancet should be put in deep enough to reach the fluid, and, when it is in, the incision should be continued upward and downward, in such a manner as to divide all the skin covering the matter. By these means, the contents of the abscess will be discharged at once; future lodgment of matter will be prevented; convenient room will be made for the application of proper dressings; and there will be no necessity for making the incision in different directions, or for removing any part of the skin composing the verge of the anus."

Mr. Pott has explained with great ability, that though all abscesses of this kind are called fistula, and have been supposed to effect the rectum, yet the place where the matter is formed is at such a distance from the intelle, that the latter part cannot be at all concerned, and none of these cases are, in the first instance, fistula. It does not follow, as a matter of course, that we have any thing to do with the rectum at all, not more than if it were not near the disease, which should be regarded and treated as a common abscess.

It is accurately observed by the celebrated surgical writer, whose remarks are freely quoted in this article, that wherever matter is formed in consequence of inflammation, it always leaves, upon being let out, a proportional hollow, and some degree of induration. The former of these is of different size, according to the quantity of matter, and the latter depends both on the degree of previous inflammation, and the more or less perfect suppuration of the abscesses.

The idea, formerly attached to the two circumstances of hollow and hardmess, was, that the fist arose entirely from lots of suffinace; the second, from a diseased alteration of the parts. Hence preceding surgeons, as soon as they had discharged the matter, used to fill and dilate the cavity, with a view of obtaining a gradual regeneration of flesh, and the dressings were generally of an escharotic quality, intended for the dissolution of the hardness.

"The practice (says Mr. Pott) is a necessary consequence of the theory. Whoever supposes diseased callousity, and great lots of suffination, will necessarily think himself obliged to destroy the former, and prevent the cavity formed by the latter from filling up too hastily. On the other hand, he who considers this matter as it really is, that is, he who regards the cavity of the abscess as being principally the effect of the gradual diminution and suppuration of its fides, with very little lots of suffination, compared with the size of the said cavity; and who looks upon the induration round about as nothing more than a circumstance which necessarily accompanies every inflammation in membraneous parts, especially in those which tend to suppuration, will, upon the smallest reflection, perceive, that the dressings applied to such cavity ought to be so small in quantity, as to permit nature to accomplish that end which she always aims at, as soon as the matter is let out; I mean, says Pott, the approach of the sides of the cavity toward each other; and that such small quantity of dressings ought to consist of materials proper only to encourage easy and gradual suppuration.

"The fact is so obvious to common sense, that it must appear to every one, who will coolly and impartially consider it."

"What is the part in which the disease is seated? and what are the alterations which such disease produces? The part is mere cellular membrane; and the alteration is obstruction and inflammation, ending in the formation of matter. But do these create any new body? Do not the sides of the abscess still remain cellular and adipose membrane, only inflamed, thickened, hardened, and rendered purulent? Can such alteration require any thing more towards refilling the parts to a natural state than a free suppuration from the parts so altered? Or, can it make extirpation or destruction necessary? Most certainly it cannot. How then is suppuration to be produced and maintained? Not by thrusting in such applications as by their quantity dilute, and by their quality irritate and destroy; but by dressing lightly and easily with such as appease, relax, and soften."

When an abscess near the anus is opened, the cavity, as Mr. Pott observes, is found proportioned to the quantity of matter. If the hollow be immediately filled with dress-
ings of any kind, the sides of it will be prevented from approaching toward each other, or may even be farther separated. But, if this cavity be not filled, or have little or no dressings of any kind introduced into it, the sides immediately collapse, and, coming nearer and nearer, do, in a very short time, convert a large hollow into a small fissure. The same thing happens when the collection of matter has built of itself.

Mr. Pott acknowledges, that the fissure will not always become perfectly closed, particularly in cases of fistula in ano; but, still he contends, that the conduct of nature is not the least evident, nor the hint, which art ought to borrow from her, the less palpable.

Whenever extensive ulcers or cavities exist, whether in cases of fistula in ano, or other disorders, much will depend upon the patient's constitution, and the care taken of it. When the habit is good, or properly corrected, any dressings which are not offensive in quantity or quality will prove effective; but if the constitution be out of order, or badly treated, the surgeon may try (as Mr. Pott remarks) the whole farrago of externals, and only walle his own and his patient's time.

This able writer explains, that all those cases are at first mere absceses; the consequences of inflammation; and require no other treatment than what would be proper in the same kind of case in all other parts. Some few of them are so circumstanced, with regard to the intestine, that it is certain unnecessary to meddle with it at all, but whether that be the case or not; whether the division of the rectum become a necessary part in the cure or not; they must certainly do not preserve the name of fistula, nor require that of treatment which fillulce are said and thought to stand in need of; though by being, from their very first appearance, supposed to be such, they are frequently, by mismanagement, rendered truly fissile.

By light, easy treatment, says Mr. Pott, large abscesses, formed in the neighbourhood of the rectum, may sometimes be cured without meddling with this intestine at all. But it much more frequently happens that the intestine, although it may not have been pierced by the matter, has yet been so demurred, that no consolidation of the fissure can be obtained except by laying the cavity of the abscess, and that of the intestine, into one.

Sometimes the practitioner may perceive the necessity for such a division at first; that is, on opening the abscess he may find the intestine so bare, that it is evident no cure can be accomplished without this operation. In other instances reasonable hopes of success may be entertained at first; but they may end in disappointment.

Mr. Pott observes, that when the gut is found to be in such state, that there is no reason to expect a cure without its being divided, that operation had better, on many accounts, be performed at the time the abscess is first opened, than be deferred to a future one. When done, as it always may be done, the pain which the patient must feel when the abscess is opened will be so trivially increased, that the difference will hardly be distinguished, either with regard to time or sensation. If the division be delayed, the patient must either be under the continual apprehension of a second cutting, or suffer one when he does not expect it.

The object of the operation is to divide the rectum from the verge of the anus as high as the top of the hollow in which the matter is formed, so as to lay the two cavities of the gut and abscesses into one; and by means of an open, instead of a hollow or fissure fore, to obtain a firm and lasting cure.

The best instrument for the operation is the curved, probe-pointed knife, which, being introduced into the fissure, while the surgeon's fore finger is in the intestine, will enable him to divide all that can ever require dividing; and that with less pain to the patient, with more facility to the operator, as well as with more certainty and expedition, than any other instrument whatever. If there be no opening in the intestine, says Mr. Pott, the smallest degree of force will thrust the point of the knife through, and thereby make one: if there be one already, the same point will find and pass through it. In either case it will be received by the finger in ano; and thereby be prevented from deviating; and, being brought out by the same finger, must necessarily divide all that is between the edge of the knife and the verge of the anus; that is, by one simple incision, which is made in the smallest space of time imaginable, lay the two cavities of the fissure and of the intestine into one.

With respect to the distinction between those cases in which the intestine is pierced by the matter, and those in which it is not, although it may be useful when the different flates of the disease are to be determined, yet, in practice, as Mr. Pott observes, when the operation of dividing the intestine becomes necessary, each division is of itself distinct; it makes no difference at all; nor does the kind, or quantity of force which the patient is to feel, the force required to push the knife through the tender gut is next to none; and, when its point is in the cavity, the cases are exactly similar.

Immediately after the operation, Mr. Pott recommends a soft dressing of fine lint to be introduced from the rectum, between the divided lips of the incision, as well to prevent any flight hemorrhage, as to prevent the immediate reunion of the said lips; and the rest of the force should be lightly dressed with the same. This first dressing should be permitted to continue, until a beginning suppuration renders it loose enough to be taken away easily; and all the future ones should be as light, soft, and easy as possible; confining only of such materials as are likely to promote kindly and gradual suppuration. Mr. Pott remarks, the sides of the abcesses are large; the incision must necessarily for a few days be inflamed; and the discharge will for some time be discoloured and scabby. This inflammation, and this sort of discharge, are often mistaken for signs of disfigured caries and uncovered fissure; upon which pretension, escharotics are freely applied, and diligent search is made for new hollows. The former of these, as Mr. Pott relates, must commonly increase both the hardness and the gleet, and, by the latter, new fissures are sometimes really produced. These occasion a repetition of escharotics, and, perhaps, of incisions; by which means, cases which at first, and in their own nature, were simple and easy of cure, are rendered complex and tedious.

Mr. Pott censures, in strong terms, the former custom of applying to the wound the hydrargyrum nitricus ruber, and other escharotic powders. What, says this writer, would any patron of this method of dressing say to a man, who shall order a large tent, well charged with red precipitate, to be thrust up the undivided, unwounded rectum of a person who, from any cause whatever, had an inflammation of the hemorrhoidal vesel, and inside of the said intestine? Would be not say that such tent would prove a fatiguing inflammatory suppuration? And would he not be right in saying so? Is then the rectum rendered less sensible and less irritable by being wounded? or, can that very application, which proves a painful stimulus to a gut not divided, become an easy digestive to one that is? If any man thinks that it will, Mr. Pott would advise him to make the expen-
FISTULA.

With regard to the plan of curing fistulae in ano in this state, by incision, the same method should be followed as the one already recommended in the case of a collection of matter formed juxta anum.

Notwithstanding the opinions of some former very eminent surgeons, such as Chevelden, De la Faye, and Le Dran, that the mere division of the intelleil and filns would not effect a cure, and, that unless we cut out or extirpated a portion both of the intelleil and the skin of the anus, durable relief would not be obtained, it was ably contended by Mr. Pott, and all experience strongly supports him, that the destruction of any of the parts is not only unnecessary, but injurious. As such practice is now gone completely out of vogue, we need not take up any more time in expressing our disapprobation of it.

When the fistula extends high up the rectum, further than the finger introduced within the anus can reach, it is found to be quite unnecessary to divide the intelleil throughout its whole length, even were such proceeding practicable and free from danger. If the surgeon fairly divide that part of the fistula and intelleil which he can conveniently reach with his finger, he need not concern himself about the deeper part of the disease, as in general a cure will follow without further trouble, in relation to any operation. The experience of Pott taught him this important fact, and succeeding practitioners have daily opportunities of verifying the same truth confirmed.

Thus far we have followed Mr. Pott in considering the disease either as an abscess from which the matter has been let out by an incision made by a surgeon, or from which the contents have been discharged by one single orifice, formed by the bursting of the skin somewhere about the fundament. We shall now pursue the same writer's plan, and consider the case, in which, instead of one, there are several openings.

"This state of the case," observes Mr. Pott, "generally happens when the quantity of matter collected has been large, the inflammation of considerable extent, the abdoine membrane very flabby, and the skin worn very thin before it burst. It is indeed a circumstance of no real consequence at all; but from being misunderstood, or not properly attended to, is made one of additional terror to the patient, and additional alarm to the inexperienced practitioner; for it is taught, and frequently believed, that each of these orifices is an outlet from, or leads to, a distinct sinus or hollow; whereas, in truth, the case is most commonly quite otherwise. All these openings are only so many distinct hurdles of the skin covering the matter; and do all, be they few or many, lead and open immediately into the one single cavity of the abscess; they neither indicate, nor lead to, nor are caused by, distinct sinuses; nor would the appearance of twenty of them (if possible) necessarily imply more than one general hollow.

"If this account be a true one, it will follow, that the chirurgical treatment of this kind of case ought to be very little, if at all, different from that of the preceding; and that all that can be necessary to be done, must be to divide each of these orifices in such manner as to make one cavity of the whole. This the probe-knife will easily and expeditiously do; and, when that is done, if the sore, or more properly, its edges, should make a very ragged, uneven appearance, the removal of a small portion of such irregular angular parts will answer all the purposes of making room for the application of the dressings, and for producing a smooth, even cicatrix after the sore shall be healed.

"When a considerable quantity of matter has been recently let out, and the internal parts are not only in a crude,
undigested flake, but have not yet had time to collapse, and approach each other, the inside of such cavity will appear large; and if a probe be pushed with any degree of force it will pass, in more than one direction, into the cellular membrane by the side of the rectum. But, (continues Mr. Pott,) let not the unexperienced practitioner be alarmed at this, and immediately fancy that there are for any dilated fistulas, neither let him, if he be of a more hearty disposition, go to work immediately with his director, knife, or scissors; let him enlarge, the external wound by making his incision freely; let him lay all the separate orifices open into that cavity; let him divide the intestine lengthwise by means of his finger in ano; let him dress lightly and easily; let him pay proper attention to the habit of the patient; and wait and see what a few days, under such conduct, will produce. By this he will frequently find, that the large cavity of the abscesses will become small and clean; that the induration round about will gradually lessen; that the probe will not pass in that manner into the cellular membrane; and, consequently, that his fears of a multiplicity of sinuses were groundless. Or, the contrary, if the sore be crammed, or dulled with irritating or ecarhotic medicines, all the appearances will be different, the hardnew will increase, the lips of the wound will be inverted, the cavity of the sore will remain large, crude, and foul; the discharge will be thin, gleyty, and discoloured; the patient will be uneasy and feverish; and if no new cavities be formed by the new fistulas, the parts, and confinement of matter, yet the original one will have no opportunity of contracting itself, and may very possibly become truly fistulous.

Without positively denying that there is ever more than one sinus extending along the same side of the rectum, Mr. Pott maintained, that for one instance in which the case is really so, forty are only suppositions of his. He allows that separate openings in the skin, from the same cavity or sinuses, are common; but denies that perfectly distinct sinuses, running along the same side of the rectum, are at all usual.
