Sometimes the matter of an abscess, formed in the neighbourhood of the anus, instead of making its way through the skin, externally near the anus, or in the buttock, pirces through the intestine only. This is what is called a Fistula interna fistula. In this instance, when the matter has discharged itself, the feeling subsides, and the patient experiences some degree of relief. If the evacuation of the matter does not terminate in a cure, which sometimes, though very seldom happens, some small degree of induration generally remains in the place where the original tumour was. As Mr. Pott describes, when this hardness is pressed upon, a small discharge of matter is frequently made per annum; and sometimes the expulsion of air from the cavity of the abscess into that of the intestine may very palpably be felt and clearly heard. The fluids, particularly if hard, and requiring force to be expelled, are sometimes smeared with matter; and although the patient by the burbling of the abscess is relieved from the acute pain which the collection occasioned, yet he is seldom free from a dull kind of uneasiness, especially if one fits on any considerable length of time in one orifice. Mr. Pott remarks, that the real difference between this kind of case, and that in which there is an external opening, with regard to the method of cure, is very immaterial; for an external opening must be made, and then all difference ceases. In this, as in the former, no cure can reasonably be expected, until the cavity of the abscess, and that of the rectum, are made one; and the only difference is, that in one case we have an orifice at or near the verge of the anus, by which we are immediately enabled to perform that necessary operation; in the other, we must make one.

We have next to treat of that state of the disease which really deserves the epithet of fistulous, according to the common definition. Mr. Pott observes, that various causes may produce such a condition of the parts concerned. These causes are divided by this celebrated surgeon into two classes, viz. those which are the effect of neglect, dishonoured habit, or of bad management, and which may be called, without any great impropriety, local fistulas; and those which are the consequence of disorders, whose origin and seat is not in the immediate sinuses or fistula, but in parts more or less distant, and which, therefore, are not local complaints.

The former are generally curable by proper treatment; the latter are frequently irrecoverable by any means whatever.

In the first description of cases, Mr. Pott ranks all those which were originally mere collections of matter within the costs of the rectum, or in the cellular substance surrounding this intestine, but which, by being long neglected, grossly managed, or by happening in habits which were disordered, and for which disorders no proper remedies were administered, suffer such alteration, and get into such state, as to deserve the appellation of fistula.

In the second kind of cases, Mr. Pott classes all those in which the disease has its origin and fist state in the higher and more distant parts of the pelvis, about the os sacrum, lower vertebral of the loins, and adjacent parts; and are either Bumous, or the consequence of long and much disordered habits; or the effect of, or combined with other duetemper, local or general, such as a diseased neck of the bladder, or prostate gland, or urethra; the lues venera, &c.

Mr. Pott notices, that among the very low people who are brought into hospitals, we frequently meet with cases of the first description; cases which at first were mere simple fistulas, but which, from uncleanness, from intemperance, negligence, and displeased constitutions, become really fistulous.

In these examples the general effects of intemperance, debauchery, and constitutional disease, are to be corrected, or removed, before surgery can afford any material relief.

When these great objects have been attended to, the surgery required consists in laying open and dividing the sinus or fistulas in such manner, that there may be no possible judgment of matter, and that such cavities may be fairly opened lengthwise into that of the rectum. If the internal parts of these hollows are hard, and do not furnish good matter, Mr. Pott advises us to scartify them with the point of a knife, but not to use ecarhotic applications. When, either from the multiplicity of external orifices, or from the looses, flapby, hardened, or inverted state of the edges of the wound, near the same, no hopes of healing the parts in an easy way can be entertained; such a portion of them may be cut away as will just serve that purpose. Mr. Pott recommends the dressings to be soft, easy, and light.

When the abscess is in the sinus, and the exterior of the skin is occupied with fungous flesh, a slight touch of the lunar caustic may become necessary.

In the mean while, the remedies for the improvement of the fucose must be continued, and local means alone not trusted.

When the bad state of the fistula arises from the manner in which it has been eamed, irritated, and eroded, leaving
off such treatment must of course be the means of bringing the discharge into a better condition.

Mr. Pott remarks, that a patient who has been so treated has generally some degree of fever, has a pulse, which is too hard and too quick, is thirsty, and does not get his due quantity of natural rest. A face which has been so dressed has generally a considerable degree of inflammatory hardness round about; the lips and edges of it are tumid, full, inflamed, and sometimes inverted; the whole verge of the anus is swollen; the hemorrhoidal vesicles are loaded; the discharge from the face is large, thin, and discolored; and all the lower part of the rectum participates in the inflammatory irritation, producing pain, bearing-down, tenesmus, &c. Contraria contraria (continues this able writer) is never more true than in this instance; the painful uneasy state of the face, and of the rectum, is the great cause of all the mischief, both general and peculiar; and the first intention must be to alter that. All excreta must be thrown out and diffused; and in lieu of them a soft digestive should be substituted, in such manner as not to cause any distention, or to give any uneasiness from quantity. Over this a poultice should be applied. These dressings should be renewed twice a day; and the patient should be enjoined absolute rest. At the same time attention should be paid to the general disturbance which the former treatment may have created. Blood should be drawn off from the fanganes; the feverish heat should be calmed by proper medicines; the languid and low should be allied with the bark and cordials; and ease in the parts must at all events be obtained by the injection of antiseptic ointments of tincture and opium.

If, as Mr. Pott observes, the sinus has not yet been laid open, and the bad state of parts is occasioned by septic or atypical applications, no operation of any sort should be attempted, until both the patient and the parts are safer, cooler, and quiet. When this digestible change has taken place, the sinus may be successfully divided, and, if requisite, a small portion of the ragged edges be taken away.

Lumbar abscesses sometimes form sinuses, which run down by the side of the rectum, and burst near the fundament. The discharge from these is generally large, feculent, thin, and sharp. Hence, we cannot wonder that the sinuses and orifices become hard and callous; that is, truly fibrous. But it must be obvious to every one (says Mr. Pott) who will consider it, that the surgical treatment of these sinuses and sinuses can be of very little consequence towards curing the discharges from which they arise, and which are generally out of the reach of our instruments and applications. The proper treatment of such disorders will be spoken of in another part of the Cyclopædia. See Lumbar Abscess.

Cancers and cancerous faces are sometimes formed in the cavity, or the neighbourhood of the rectum and fundament, where they make terrible havoc. See Rectum.

Fibrous abscesses are sometimes formed in the region of the bladder and urethra, and are named fistula in perineum, require separate and particular consideration, into which we shall presently enter. Pott's Treatise on the Fistula in Ano.

Fistula Lacrymalis.—Every one who has acquired that degree of anatomical knowledge which is essentially requisite in a good surgeon, is well aware that the tears and sebaceous fluid with which the surface of a healthy eye is naturally kept in a moist flake, are conveyed, as long as they become superficial, through certain tubes or ducts, down into the nose. We leave it to the anatomist and physiologist to determine, whether it is by some action like that of a fly's ringe, or of a capillary tube, or whether it is by the mucular power of the lacrimal passages themselves, that the tears are made to descend from the eye into the cavity of the nose. The secretion from the lacrimal gland, membranous lining of the eyelids, and Meibomian glands, constitutes what is commonly called the tears, the use of which is to lubricate the eye in its incipient motions, to keep the surface of the cornea in a moist, clean, bright state, fitted for the transmission of the rays of light, and lastly, to wash away any dust or other hurtful particles, which may accidentally fall upon, and irritate the organ. Mr. Pott, in his excellent account of this subject, has observed, that this fluid (meaning the tears) is derived principally from a large gland, named the lacrimal, situated under the upper edge of the orbit near the outer corner of the eye, which gland is of the conglomerate kind, and lies in a small depres.fion of the os frontis. Its excretory ducts, or thole by which it discharges the secreted fluid, pierce the tunics conjunctiva, just above the conjunctivous border of the upper eyelid.

When any irritative particles come in contact with the eye, a large quantity of fluid is immediately secreted by the lacrimal gland, and is as quickly diffused, by the motion of the eye-lids, over the surface of the eye; by which means, such particles are washed and wiped off. Sometimes, also, as Mr. Pott remarks, the passions of the mind produce an immediate increase of this secretion, which is then briskly called tears. A constant secretion of too large a quantity cures a disease, called epiphora (which few); and a deficiency of it makes the motions of the eye-lids difficult and painful.

Although the fluid, secreted by the lacrimal gland, is considerable in quantity; yet, when it is not suddenly produced by irritation from without, or passion within, it is so constantly and gradually carried off, as to create neither trouble, uneasiness, nor blennism.

The edge or border of each eye-lid, continues Mr. Pott, is fringed by a thin cartilage, the figure and consistence of which keep the lids properly expanded. These cartilages are covered by a fine membrane, and are called cilia. Their internal edges do, upon every motion, sweep over every point of the surface of the cornea. This motion, though almost imperceptible, unless attended to, is very frequently performed; and as the secretion of the fluid is also constant, the eye is by this means kept always moist, clean, and bright.

Mr. Pott next relates, that at the extremity of each of these cartilaginous borders of the eye-lids, on the side next the nose, is a small papilla or eminence; and in the middle of each there is a small hole, which, being situated in the cartilage, is not liable to collapse while the parts are in a sound state, but remains always open. They are called the puncta lacrymalis, and their office is to receive the lacrimal fluid, as it runs off the cornea, along the edges of the eye-lids, so as to prevent it from trickling down the cheek.

From each of the puncta lacrymalis proceeds a small membranous tube. These tubes soon enter, or rather expand into, a little fort of pouch, placed near the inner angle of the eye, under the orbicularis palpebrarum muscle. The bag in question is named the lacrimal sac, and its office is to receive all the lymph transmitted through the puncta and ducts. The upper part of the sac lies in an excavation, formed partly by the nasal process of the upper maxillary bone, and partly by the os nasus. The lower part of it is confined in a long channel, and forms a tube or duct, which, descending obliquely backward, communicates with the cavity of the nose, behind the os sphenoidum superior, by an opening of rather different sizes in different subjects.

This passage, says Mr. Pott, is called the ductus nasalis, and through it whatever is received by the lacrimal sac from
from the puncta does, in a healthy and sound state of these parts, pass into the nose.

The membrane which lines the lacrimal fac and nasal duct secretes a kind of mucus.

In the healthy state, the fluid secreted by the lacrimal gland readily passes off through the puncta, fac, and duct, into the nose; but when they are in a diseased state, the case is otherwise. The membrane lining the fac and duct is subjected to inflammation, by which it is often so thickened as to render the passage more or less impervious. Hence, the lacrimal fac becomes filled with its own mucus, and with the secretion transmitted into it from the eye; and when no more of this last fluid can enter the puncta lacrymalis, it falls over the eye-lid, down the cheek. The obstruction continuing, and the mucus and tears still lodging, the fac is dilated, and that tumour in the inner corner of the eye, and that discharge from the puncta lacrymalis, upon preffure, are occasioned, which characterizes the fistula of the fistula lacrymalis. See Pott's Observations on the Fistula Lacrymalis.

From what we have already stated, the reader must begin to suspect that the term fistula lacrymalis signifies no callous, indurated disease, accompanied with an acid, fuminous discharge; but merely a disorder, consisting of an obstruction in some part of those passages through which the tears have to pass into the nose, and attended with different appearances in different persons, and under different circumstances. Here the phrase "fistula" is sometimes, in consequence of ancient established usage, so improperly employed, that it is applied to a certain stage of the disease, new treated of, in which there is even no ulcerated opening at all, nor any other circumstance which, according to the dictates of common sense, could bring into the mind the idea of a fistula.

When the obstruction to the passage of the tears into the nose is only such as to occasion a watering of the eye, and a consequent necessity of wiping away the effused fluid, the disorder is commonly named epiphora; but when a fluid, somewhat similar to pus in appearance, accumulates in the lacrimal fac, and regurgitates through the puncta lacrymalis, on the fac being comprized, the complaint receives the name of fistula lacrymalis.

The eminent Scarpa, impressed with a conviction of the bad effects in practice resulting from the use of terms which convey erroneous notions, has proposed calling that stage of the disease which is attended with a discharge of a viscous, viscid, yellowish matter from the puncta lacrymalis, when the lacrimal fac is incompletely, the puriform discharge of the palpebrae. The term fistula lacrymalis is restricted, by this author, to that stage of the complaint in which the lacrimal fac is not only greatly dilated, but ulcerated, and in a fungous state on its internal surface; and in which there is also an external opening, occasionally attended with a caries of the os unguis.

The varieties of the disease commonly called fistula lacrymalis are referred, by Mr. Pott, to five principal circumstances, viz.

1. The degree of obstruction in the nasal duct.
2. The state of the cellular membrane covering the fac.
3. The state of the fac itself.
4. That of the base underneath.
5. The general state and habit of the patient.

Sometimes the lining of the fac and duct is so thickened, that the fluid cannot pass through it into the nose; and this forms the whole of the complaint. The cellular membrane on the outside not being diseased, there is no appearance of inflammation. In this case, as Mr. Pott describes, the duct is stopped, and the facculus dilated, but without any alteration in the colour of the skin. A fence appears in the corner of the eye next the nose; and upon the application of a finger to this tumour, a clear, viscid mucus is discharged through the puncta lacrymalis. The patient feels no pain, nor finds any inconvenience, except what is produced by the discharge of this mucus, and by the trickling of the tears down the cheek.

The same writer next adds, that, in some cases, the mucus is not perfectly clear, but is sometimes cloudy, and looks as if it had a mixture of milk or cream in it. At first, waking, some of it is generally found in the corner of the eye; and the eye-lids, being smeared over with it during sleep, most commonly adhere together in the morning.

Mr. Pott remarks that this is the most simple state of the disease, and what the French have called la beree, or hydrops facui lacrymalis. It is frequently met with in the children who have been rickety, or are subject to glandular obstructions; and, in this state, it sometimes remains for some years, subject to little altertions, as the health or habit of the patient vary. When the fac is not much dilated, the discharge small, and produced only by preffure, the chief inconvenience are the weeping eye, and the gumming together of the eye-lids after sleeping; but these, by being attended to, may be kept from being very troublesome; and, if the disease makes no further progress, may be so regulated as to render any more painful procésse totally unnecessary.

When the dilatation is considerable, says Pott, the swelling is more visible, and the quantity of mucus is greater. It is also in this state more frequently mixed and cloudy, and more troublesome, from the more frequent necessity of emptying the bag. But if the patient be adult, it may, even in this more dilated state of it, be kept from being very inconvenient.

If an inflammation comes on, the tumour is thereby considerably increased, the discharge is larger, as well during sleep as upon preffure; the skin covering it loses its natural whiteness and softness, becomes hard, and acquires an inflamed redness; and with the mucus a mixture of something which in colour resembles matter, is discharged, especially if the preffure be made with any force, or continued for any time. This circumstance, added to the painful swelling and inflamed appearance of the parts, has been productive of a supposition, that there is either an ulcer or an abscess within the fac or duct; an opinion which Mr. Pott has taken great pains to refute.

We shall here introduce Scarpa's sentiments concerning the manner in which the fluid which dilates the fac is formed. The viscous, viscid, yellowish fluid, mixed with tears, which regurgitates from the puncta lacrymalis, is not altogether secreted by the fac itself, as some have conjectured. The greatest part of it passes into the fac from the eye-lids, through the puncta lacrymalis, from which it regurgitates on preffure being made on the fac. This puriform fluid is chiefly secreted by the lining of the eye-lids, especially by the lower eyelid along the tarsus, and by the glands of Meibomius. The viscid matter, which is furnished by these glands, is not only secreted more abundantly, but assumes an irritating quality. Besides the viscid fluid from the glands just now specified, a thin mucus,
is effused from the lining of the eye-lids; which mucus greatly increases the quantity of viscid matter which is spread over the eye and eye-lids.

It becomes manifest that the puriform fluid, which comes out of the lacrimal fac, is derived from the sources which have been pointed out, by turning the eye-lids, particularly the lower one, outward, and comparing their appearance with that of the found ones of the opposite side of the face. The lining of the former always seems redder than natural, and exhibits a villous appearance, particularly along the tarsus. The margin of the eye-lid is swollen, and marked with a great number of little varicose vessels. The glands of Meibomius are more turbid and prominent than natural, and, when looked at with a magnifying glass, frequently seem to be somewhat ulcerated.

The villous texture, which the inside of the eye-lids acquires in these cases, is converted into an organ which secretes an unusual quantity of a fluid like visceral lymph, which, being blended with the febaceous secretion from the glands of Meibomius, makes the tenacious matter which is smeared over the eye-lids, and which, passing through the puncta lachrymalis, sometimes detains the lacrimal fac in a very extraordinary degree.

If the lacrimal fac be emptied of this matter by means of pre furious, and the eye and inside of the eye-lids be carefully washed, so that none of the glutinous secretion which issues from the fac may remain upon them, and the inside of the eye-lids be turned out half an hour afterwards, their inner surface, especially that of the lower one, will be observed to be covered with a new edition of mucus, mixed with a febaceous secretion; which fluids have manifestly not regurgitated from the lacrimal fac to the eye, but have been formed between the eye and eye-lids by the villous inside of the last-named parts, and the glands of Meibomius.

As a further proof, that the lacrimal fac has no other concern in this disease than that of receiving the tears and puriform fluid which are transmitted from the eye-lids, Scarpa mentions, that if the morbid secretion from the eye-lids be retarded or stopped, either by accident or the effect of applications, little or none of the viscid, curdy fluid accumulates in the lacrimal fac, or can be pressed out of the puncta lachrymalis.

The membrane which lines the lacrimal fac is one that has no sebaceous glands, and is only calculated for the secretion of a thin mucus. A small addition of this latter may be made to the puriform fluid and tears which are collected in the fac, but the quantity cannot be considerable.

We shall now reduce the account of the different states of the disorder, as delivered by Mr. Pott. The inflammation of the integuments covering the fac is a circumstance which makes a considerable difference, both in the appearance of the diseas and its requisite treatment. In some cases, it is confined merely to the surface of the tumour; in others, it spreads full farther, affecting the eye-lids, cheek, and side of the nose.

When the parts are in this state, continues Mr. Pott, the mucus within the bag has generally the appearance of being matter, that is, it wears a deep yellow colour, and is of a more thin consistence. If the puncta lachrymalis are naturally large and open, and the inflammation confined to the surface of the fac, its contents will pass off pretty freely, and the skin will remain entire. This is what the ancients called the simplex or imperfect ulceropy.

But, says Mr. Pott, when the skin covering the lacrimal bag has been for some time inflamed, or subject to frequently returning inflammations, it most commonly happens that the puncta lachrymalis are affected by it; and the fluid, not having an opportunity of passing off through them, detains the inflamed skin, so that at last it becomes floughy, and bulks externally. This was named the perforated ulceropy or ulceropy.

The discharge used to be made through the puncta lachrymalis, while the skin was entire, is now made through the new opening, and by excoriating the eye-lids and cheek, increases the inflammation, and gives the diseas a much more disgraceful appearance. In some, the matter bulks through a small hole, and, after it has discharged itself, the tumour subsides, the neighbouring parts become cool, and, though the skin covering the surface of the fac is floughy and foul, yet there is no reason to believe that the fac itself is much diffused below. In others, the breast is large, the skin remains hard and inflamed, and, from the appearance of the fore, there is reason to suppose the whole inside of the bag to be in a diseased state; and, in some cases which have been much neglected, or irritated by ill treatment, the cavity of the fac seems to be filled with a loose, ill-natured fungus, which glects largely, and produces inflammation and excoriation of all the parts about.

Mr. Pott observes, that there is another circumstance which is sometimes found to attend this disorder, viz. a curious flate of the bones. The practitioners, in ancient times, used to suppose this complication was a very frequent one; and hence they so freely had recourse to the caudical, cauterity, and scalping, in the treatment. But cases is now ascertained to attend the complaint but few.

When the fistula lachrymalis is a symptom of the lues venerum, as it sometimes is, the bones are indeed often curious; but then the fistula is not the original complaint, but produced secondarily, and is a consequence of the diseased state of the os ethmoides and ossa longitum of the nose, and is not curable by any local means or applications, but depends entirely on the cure of the diseas of which it is a symptom.

A very material difference, as Mr. Pott accurately explains, will be occasioned both in the appearance of the disorder, in the prognostic, and in the proper method of treatment, by the combination of other diseases, either of the constitution, the parts themselves, or adjoining ones. The patient, for example, is sometimes subject to an habitual ophthalmia or lippitudo, which will increase the deformity, and give a good deal of additional trouble during the cure. Mr. Pott also observes, that an ozum, or some other disease of the membrane and cells of the ethmoid bone, or a polypus within the nose, may be combined with a fistula lachrymalis. Strumous complaints are other frequent attendants; and, if we may believe Mr. Pott, it sometimes becomes cancerous.

We shall now proceed to speak of the treatment of the diseas; and, for the sake of rendering this subject as easily intelligible as possible, we shall imitate the above-mentioned writer, by dividing the disorder into four states.

The first consists of a simple dilatation of the fac, and an obstruction of the nasal duct, discharging upon pressure, a mucus either quite clear or a little cloudy.

In the second, the tumour is somewhat larger; the skin which covers it is in an inflamed state, but entire; and the discharge made through the puncta lachrymalis is of a pale yellow or purulent colour.

In the third, the skin covering the fac is become floughy, and bulks, by which means the fistula is in some measure filtered; but the mucus which, while the skin was entire, used to be pressed out through the puncta lachrymalis, now discharges itself through the new aperture. The nasal duct, both
both in this and the preceding flate, is not otherwise diseased
than by the thickening of its lining.

The fourth, the passage from the lachrymal fac into the
nofe is totally obliterated; the inside of the former being
either ulcerated or filled up with a fungus, and attended
sometimes with a caries of the bone underneath.

In the flirt or mull simple flate of the disease, viz. that
of mere obstruction, without inflammation, various plans
have been devised with a view of returning the parts to their
natural flate and ufe, without making any wound at all.
The chief of these methods have been the introduction of a
probe, the injection of a fluid, and a confluent compression,
made on the outside of the fac, in the corner of the eye.

A French surgeon, named Anel, invented a probe of fo
small a flize as to be capable of pacing through one of the
puncta lachrymalm, down into the nofe. As the instrument
was thus pushed through the lachrymal fac and nafal duct,
M. Anel conceived that it would be able to break any small
obftruction which might be met with.

The fame gentleman also invented a fyringe, furnifhed
with a very minute pipe, which admits of being introduced
into one of the puncta lachrymalm; and in this manner any
fluid may be injected into the fac and duct, in order to clear
away any thickened mucous or matter, which may be the
caufe of the tears not fianding their way, as they ought to
do, down into the nofe.

With regard to the introduction of a small probe through
one of the puncta lachrymalm, Mr. Pollock observes that the
plan has a very plausible appearance, but is unequal to the
talk affigned; the very small flize of the probe, its flexibility,
and the little resistance which it is capable of making, are
manifest deficiencies in the instrument. He allows that fuch
a probe may be paffed through one of the puncta down into
the nofe; but he contends, that the pain which it gives,
and the inflammation which it often excites, are much
greater than any benefit which does or can arise from it.

As for the idea, that this probe may be of ufe in removing
any obftruction in the puncta lachrymalm, it is an unfounded
one; for fhuch an obftruction is feldom met with at all, and
never can exit in this flate of the fiftula lachrymalm, one
principal symptom of which is a discharge into the inner
corner of the eye, when prefure is made on the fac. This
discharge is made from the fac, through the puncta, and
proves that the latter are open. The obftruction really
forming the fiftula is one that hinder any thing from paffing
from the fac into the nofe, and not from the eye into the
fac.

On the subjed of the fcrew, which Fabricius of Aquas-
pendente invented, for making prefure on the lachrymal
fac, we need only fay, now that it has gone into perpetual
difeafe, that though it anfwered the purpofe of compreffing
the fac very well, it did not operate in any way whatever on
the obftruction in the nafal duct, the primary caufe of the
difeafe.

M. Anel's fyringe is entitled to a much higher fhare of
recommendation than has been given to his probe. Indeed,
the plan of injecting fluids through one of the puncta lach-
rymalm into the lachrymal fac, for the purpofe of removing
any flight, recent obftruction in the nafal duct, is what re-
ceives the fummon of all the best furgeons and ocufilts of
the present day. It is evident, however, that it is a method
which can only be adopted while there is no ulcerated open-
ing in the fac, and only then, with much hope of success,
as long as the floppage in the nafal duct is flight, and fuch
as would be occafioned by the lodgment of thickened
mucus.

Before entering upon the defcription of the manner in
which the eminent Mr. Ware employs Anel's fyringe for
the cure of the epiphora, or first flate of the fiftula lachry-
malm, it is proper to acquaint the reader that, in the year
1780, Sir William Blizard made the propofal of injecting
quickfliver instead of water into the lachrymal fac, by means
of a pipe fmall enough to be introduced through one of the
puncta lachrymalm, and fixed on the end of a long glass
tube. In short, the instrument is exactly like what an
Anfelellian furgeon used to employ for the injection in the
lymphatics. The glass tube being filled with the mercury, as
high as the practitioner may deem necessary, and the little pipe in-
truded into one of the puncta lachrymalm, the quickfliver
deposited by its specific gravity into the lachrymal fac, as
soon as a little fcrew is turned, and, by reafon of its weight,
is, in Sir W. Blizard's opinion, more calculated than water
propelled from a fyringe for removing the obftruction in the
nafal duct. The force with which the mercury acts de-
pending entirely on its weight, it must be manifeflt that the
higher the column of the metal is made, the greater must be
the power with which it operates.

There cannot be a doubt that Sir William Blizard's
method is an exceedingly good one; but perhaps it has no
real advantage over the ufe of the fyringe, since the fluid
injected by this instrument is one which is always ready at
hand, and operates with as much power as mercury, when
the practitioner chooses to propel it with force into the
lachrymal fac.

Mr. Ware made a trial of Sir William Blizard's method,
but he at leafts preferred the employment of Anel's fyringe.
With this he usually injects warm water through the lower
punctum lachrymalm into the lachrymal fac, while a finger
is put over the lower punctum, in order to prevent the fluid
from making its way outward. The lachrymal should also
be now and then compressed, for the purpofe of promoting
the defcent of the water down into the nofe. In particular
instances, Mr. Ware has ufed the injection three times a
day; but, in general, much less frequently. This gentle-
man relates, that his practice has been attended with con-
siderable success.

Mr. Ware commonly commences his method of treat-
ment by injecting some water through the inferior punctum
lachrymalm, and he repeats the operation four or five days
in fuccefsion. If, in this space of time, none of the water
should pafs through the duct into the nofe, and the watering
of the eye be as troublesome as it was before the injection
was employed, he commonly orders the angular vein to be
opened, or a leech to be applied near the lachrymal fac. How-
ever, Mr. Ware is careful in forbidding the leech to be put
on either of the eye-lids, lest it should occasion an extra-
vation of blood in the adjacent cellular membrane.

About the time when blood is taken away from the vic-
inity of the eye, Mr. Ware is in the habit of changing the
injection, and trying the effects of a weak, vitriolic, or
anodyne lotion. In fome instances also, when, after se-
veral attempts, he has not been able to inject any part of
the liquid through the duct, he has introduced a golden probe,
about as large as a briflle, through the superior punctum
lachrymalm, and, attending to the direcHon of the duct, he
has infinuated the end of the instrument through the obftruc-
tion, and conveyed it fully into the nofe. Immediately after
this, Mr. Ware has found, that a liquid, injected
through the inferior punctum, has passed without any diffi-
culty into the nofe; and, by repeating these operations a
few successive days, the perversus flate of the paffage has
been re-established, and a cure accomplished.

On some other occasions, Mr. Ware has advised a strong-
ly fimalating fcrumentory to be nuflled up the nofe, about
18
FISTULA.

an hour before bed-time. Thus a large discharge has been
existed from the Schneidierian membrane, which discharge,
according to Mr. Ware's account, has had the effect of
materially contributing to remove the stropage in the nasal
duct.

Very few cases present themselves which are not reme-
diable by some of the above means. In certain examples
which have been attended with a factitious discharge, Mr. Ware
has corrected this bad quality, by injecting a vitriolic lotion
into the lachrymal sac.

The celebrated Scarpa of Pavia, who has lately pub-
lished some excellent observations on the diseases of the eye,
has set forth the doctrine, that the primary and proved
case of the lachrymalitis does not exist either in the
lachrymal sac or the nasal duct, as surgeons have hitherto
supposed, but in the morbid state of the eye-lids. Hence
the same writer contends, that every method of treatment
which is merely calculated to heal the ulceration of the sac,
or remove the obstruction in the nasal duct, cannot accor-
dingly a permanent cure of the disease, without the employment
of such other remedies as are proper for correcting the dif-
fected secretion from the eye-lids.

In the first stage of the fistula lachrymalis, called by Scar-
pa " il flullo palpebrale puriforme," this surgeon's practice
confists in fulfilling two indications: viz. first, that of check-
ing the secretion from the lining of the eye-lids, and the
ducts of Mollusca, from which disced fluid he thinks
that the fistula lachrymalis originates; secondly, that of
diligently washing out the lachrymal passages throughout
their whole extent.

For the first object, Scarpa recommends the use of Jania's
ophthalmic ointment, which is composed of half an ounce
of hog's lard, two drams of prepared titty, the same
quantity of Armenian balsam, and one dram of the calx
hydrgyri alba. The lard, after being washed three times
with rofe water, is to be well mixed with the other ingre-
dients, after they have been made into a fine powder.

When this ointment is first used, it is to be rendered weaker
by the addition of a larger proportion of lard than what is
above-mentioned. A bit of the ointment, about the size of
a barley-corn, is to be put on the end of a blunt probe,
and applied between the eye-lids and eye-ball, near the ex-
ternal angle, every morning and evening, and all the edges
of the palpebrae are also to be smeared with the same appli-
cation. The patient is then to rub his eye, and gently rub
his eye-lids, in order to diffuse the ointment all over their
internal surface. A compress and bandage are next to be applied.
At the end of two hours the eye may be unco-
 vered, and washed with cold water. A collyrium of zinc
vitrulatum, and mucilage of quince seeds, is also to be used
three or four times a day.

When there are small excoriation upon the edges of the
eye-lids, Scarpa recommends the ungumentum hydrgyri nit-
trati to be applied at bed-time to the little fores. When
this remedy fails, he says the argentum nitrum must be
gently rubbed along the margin of the eye-lids, and the eye
immediately afterwards washed with new milk.

Just before every time of making these applications to the
eye-lids, Scarpa, in order to fulfill the second indication
above specified, advices some plantain-water, containing a
little spirit of wine, to be injected into one of the puncta
lachrymalis, by means of Auel's syringe.

With regard to the truth of the theory advanced by
Scarpa, concerning the primary cause of the fistula
lachrymalis, we cannot help having our doubts; but of the
practice which we have been describing, we have
to express our entire approbation. If the origin of the
disease always depended on the morbid secretion from the
lining of the eye-lids and the glands of Mollusca, why do
we not have a fistula lachrymalis as an attendant on nu-
merous ophthalmias in which we know and feel that such se-
cretion is in a diseased state? Besides, in the practice of
surgery, we have most positive evidence that the ductus na-
fals very frequently becomes obstructed by the pressure of
polypi and other tumours in its vicinity; and although
this cause cannot be assigned as the ordinary one of the
disease, yet it proves that a fistula lachrymalis may sometimes
originate without the secretion of the eye-lids being con-
cerned in its production. Experience also shews,
that colds which inflame and thicken the Schneidierian membranes,
sometimes bring on obstructions in the nasal duct. Nor is
the statement of Scarpa altogether correct, when he ob-
erves that the disease can never be permanently cured by re-
medies which only operate in clearing away the obstruction
in the duct, without acting upon the diseased inner surface
of the eye-lids. We have daily proofs that the epithora,
the incipient state of the fistula lachrymalis, or, as Scarpa
terms it, the palpebral puriform discharge, can be cured by
merely injecting warm water, with Auel's syringe, through
the lower punctum lachrymalis.

The ample experience of Mr. Ware is a confirmation of
what we have just now remarked.

Much, however, as we have differed from Scarpa in rela-
tion to the primary causes of the fistula lachrymalis, we
entertain the most favourable opinion of that part of his
practice which arises out of his theory. We allude to the
plan of applying some such ointment as Jania's, or the un-
geualtum hydrgyri nitrat, to the edges and inside of the
eye-lids. Scarpa's description of the diseased state in which
the inner surface of these parts is found, is perfectly ac-
curate, and whether such state be regarded with him as a
cause, or with us only as an effect, there can be no doubt
that something should be done to rectify it.

We have now to speak of the treatment of the second and
third stages of the fistula lachrymalis, or of those in which
the skin covering the lachrymal sac is either inflamed or
burst.

This part of surgery has only attained its present improved
state within a few years; and Mr. Pott, who wrote so well
on every surgical subject which attracted his notice, has
recommended in his works a mode of treating these states
of the fistula lachrymalis much less simple and efficacious
than what modern surgeons now universally prefer. For infla-
ence, when the face is burst, he directs the opening, if neces-
sary, to be enlarged with a knife, and, in other cases, an incision
to be made through the skin into that cavity. He then ad-
vises us to dissuss the wound moderately with dry lint, or
prepared sponge, so as to be able, in two or three days,
to ascertain the state of the inside of the face, and of the ductus
nasalis. When the former is not flougy nor diseased, and
the obstruction in the latter flight, a cure will sometimes es-
ue, according to Mr. Pott, on a free discharge taking place,
and superficial dressings being applied to the fore.

When this method is not attended with success, Pott
advises us to render the nasal duct pervious, by introducing
a probe, a piece of catgut, or a bougie, from the wound
down into the nose. When one of these incisions will not
pass all the way down at once, it is to be gently introduced
again and again until a pallage is obtained.

About the year 1786, Mr. Withen tried the effect of in-
roducing a cannula into the nasal duct. His object was
not only to form a communication between the eye and the
nose, but, by letting the wound heal over the instrument
without the obstruction from returning afterwards. In

Vol. XIV.

this
FISTULA.

this way many cures were effected; but, after a time, the method was found to be subject to difficulties. The tubes, as Mr. Ware relates, frequently changed their position in the duct; sometimes they rose too high; at other times they sunk too low; and, in consequence of these accidents, the tears often became obstructed again, and all the old symptoms returned.

A French oculist, M. Pellier, invented some canules, which had two projecting edges; one at the top forming a kind of brim, and another about the middle of the instrument. The intention of these was to keep the tube from ascending or descending, after granulations had occupied the space between the two projecting brims.

Notwithstanding the favourable accounts which have been given of canules for the cure of the fistula lachrymalis, Mr. Ware has experienced much disappointment from their use: and, among the objections to them, mentions the difficulty which sometimes attends the attempt to withdraw them from the duct, in which they have become fixed.

For the second and third stages of the fistula lachrymalis, the treatment which now obtains universal preference is that which Mr. Ware introduced into practice. Whenever a patient applies to this gentleman for relief, on account of an obstruction in the nasal duct, be always thinks it right to endeavour to free the canal from any thickened mucous which may be lodged there, by injecting some warm water through the lower punctum lachrymale. At the same time he tries, when necessary, the effect of other remedies, mentioned in his writings, upon the eye-lid. But if no benefit be perceptible after employing these means about a week or ten days; or, from the long continuance of the obstruction, such treatment cannot be expected to succeed; he recommends the operation which we are about to describe. However, with respect to children, Mr. Ware advises it to be deferred till they are eight or nine years old.

If the disease has not occasioned any external opening in the lachrymal sac, or if there is an opening which is not situated in a right line with the longitudinal direction of the nasal duct, Mr. Ware advises a puncture to be made into the sac, at a small distance from the internal commissure of the eye-lids, and nearly in a line drawn horizontally from this commissure towards the nose. This opening is to be made with a very narrow sharp-pointed lancet. The blunt end of a silver probe, which must be rather smaller than the probes commonly used by surgeons, ought next to be introduced into the wound, and be gently, but steadily, pushed on in the direction of the nasal duct, with a force sufficient to overcome the obstruction in this canal, and until there is reason to believe that it has freely entered into the cavity of the nose. Mr. Ware remarks that the position of the probe, when thus introduced, will be nearly perpendicular; its side will touch the upper edge of the orbit; and the space between its bulbous end in the nose and the wound in the skin will usually be found in a full grown person to be about an inch and a quarter, or an inch and three-eighths. The probe is then to be withdrawn, and a silver flyle, of a size nearly similar to that of the probe, but rather smaller, about an inch and three-eighths in length, with a flat head, like that of a nail, but placed obliquely, in order that it may be close on the skin, is to be introduced through the duct in place of the probe, and to be left, for a continuance, in this situation. For the first day or two after the flyle has been introduced, Mr. Ware informs us that it is sometimes advisable to wash the eye with a weak farraine lotion, for the purpose of obviating any tendency to inflammation, which may have been excited by the operation. However, the same gentleman observes that this inflammation is in general to flight, that he has seldom found it necessary to use any application for its removal. The flyle should be withdrawn once every day for about a week; and afterwards every second or third day. Each time some warm water should be injected through the duct into the nose, and the instrument be then replaced in the same manner as before. Mr. Ware next blackens the head of the flyle with sealing wax.

On the first trials of this method, Mr. Ware entertained no expectation that any relief would be obtained till the use of the flyle was left off. He had the gratification of finding, however, that the watering of the eye ceased as soon as the flyle was introduced, and the sight became proportionally better and stronger.

In cases in which there is no external opening in the lachrymal sac, or no opening which will answer the purpose, Mr. Ware only makes a puncture of just sufficient size to admit the end of the probe or flyle. This aperture soon changes into a fistulous orifice, through which the flyle may be passed without the least pain. In short, says Mr. Ware, in about a week or ten days, the treatment becomes so easy, that the patient, or any friend, is fully competent to do what is necessary. It merely consists in withdrawing the flyle two or three times a week, occasionally injecting some warm water, and then replacing the instrument in the same position which it held before.

With respect to the time which the flyle should be worn, no determinate rule can be laid down. Mr. Ware acquaints us that some persons, who find no inconvenience from the flyle, and are afraid to leave it off, wear it for years. Many others leave it off in about a month or six weeks, and continue quite well.

The forces which are frequently met with over the lachrymal sac generally heal as soon as the tears begin to find a passage down into the nose. Two examples, however, are related by Mr. Ware, in which the ulcerations did not heal until the patient had taken a weak solution of the hydrargyrum nitrate and bark.

The fourth and last stage into which the fistula lachrymalis is divided, is that in which the natural passage from the sac into the nose is so diseased as to be quite obliterated, or in which bones are carious.

In either of these circumstances the object to be attempted is to form an artificial passage for the descent of the tears into the nose.

Mr. Pott has explained, in a very clear manner, that the upper and hinder part of the lachrymal sac is firmly attached to the os unguis, a small and very thin bone just within the orbit of the eye. This bone is so situated, that if it be by any means broken through or removed, the two cavities of the nose and of the orbit communicate with each other; consequently, the os unguis forms the partition between the hinder part of the lachrymal bag, and the upper part of the cavity of the nose. It is, says Mr. Pott, by making a breach in this partition, that we attempt the formation of an artificial passage for the lachrymal fluid.

For making a perforation in the os unguis Mr. Pott always employed a curved trocar, the point of which was turned obliquely downward from the angle of the eye towards the infide of the nose. Some make the breach in the bone with a knife; others with some such instrument as a gimblet. As soon as the communication between the sac and infide of the nose is made, the circumstance will be indicated by a discharge of blood from the nostril, and air from the wound, upon blowing the nose.

Without lengthening this article by detailing how the ancients
ancients used to make the breach in the os unguis with the actual cautery, which the celebrated Scarpa even now prefers, or by explaining how practitioners a very few years back were wont to maintain the breach open by cramming in tents, prepared sponge, a piece of bougie, &c. we shall proceed at once to describe what is generally regarded as the best plan of keeping the artificial opening pervious.

Here we have to make the reader acquainted with an improved mode of treatment, for which the public and the profession are indebted to the ingenuity of Mr. Ware. After the perforating instrument is withdrawn, this gentleman advises us to introduce a nail-headed fylle, about an inch in length, through the new aperture, in the same manner in which such an instrument is passed through the nasal duct, in cases in which the obstruction is not so great as to prevent its passing in this direction. The fylle may also be left in the opening made in the os unguis, with as much safety as in the natural ductus nasalis, and this for as long a time as may be deemed requisite for removing all chance of the new passage becoming closed again. FISTULA in Perinizo.—Very often, in consequence of various irritations affecting the urethra, inflammations and abscesses are occasioned around this canal. These collections of matter may burst inwardly into the urethra, or externally, or in both ways, in which latter case more or less of the urine flows out of the opening, whenever the patient has need of discharging this fluid. Sometimes the artificial passage through which the urine is evacuated heals up, after the irritation in the urethra is softened. In other instances, the cause of the preternatural opening remains unremoved, and the urine passing into the abscess by the inner orifice, and, making its escape by the external one, keeps up a constant irritation in the fore, prevents the fides of the passage from uniting, and converts them into a hard callous substance, the inner surface of which, as Mr. Hunter has remarked, loses the disposition to union, and assumes the nature of an outlet. Every opening which is thus caused, which partakes of this nature, and is flitted in the perineum, or even in the periculum, is, with the general consent of surgeons, denominated a fistula in perinizo.

The kind of irritation in the urethra most frequently occasioning fistula in perinizo, is that which attends the obstruction produced by fustures in this canal. When this latter disease is very bad, and the urethra considerably obstructed, nature frequently endeavours to procure relief by ulceration on the inside of that part of the urethra which is between the bladder and the fylure. The urine then passes into the loofe cellular membrane of the cerumen and penis, and the irritating quality of this fluid becomes a cause of suppuration wherever it is extravasated, and even of mortification, first, of all the cellular substance, and then, of several portions of the skin. If the patient continues to live, all these flouglis are detached, and the fones contract, till nothing but the fibrous aperture remains, through which the urine makes its escape. In some examples the urine infiluates itself into the corpora spongiosa urethrae, is diffused all over this substance, even into the glans penis, and produces a flouging of all the parts in which it is lodged.

In irritable constitutions, in old persons, and in subjects whose systems have long been under the influence of the East or West India climate, fistula in perinizo seem to be more easily excited. We have often seen, in such patients, abscesses and openings, through which the urine flowed, occasioned by gonorrheas, which could not be regarded as severe ones, and by fustures which had not made sufficient obstruction in the passage even to render the persons themselves conscious of having any stoppage of this kind at all.

Mr. Hunter advises us to treat inflammations which occur in the vicinity of the urethra in the same manner as inflammations in other parts. Resolution is very desirable, though hardly to be expected, when a fylure is the cause, in which case suppuration almost inevitably ensues. When matter is formed, the sooner an external opening is made into the abscess the better, as by this means we may sometimes, though not often, prevent it from bursting inwardly into the urethra. Mr. Hunter recommends the external opening to be made large.

In certain instances it happens, when the collection of matter bursts internally, that the fylure is removed by the ulceration, and is thus fortunately cured. But when the fylure continues, as it almost always does, an attempt must be made to destroy it by some of the methods which will be described in a subsequent part of the Cyclopaedia. (See Stricture.) While the urine passes through the artificial passage no cure can be hoped for.

From what has been already delivered, it must be obvious, that in every instance in which a fylure is known or suspected to have occasioned the abscesses and fistula in perinizo, it is proper to examine the urethra with a bougie. If the obstruction has been more or less destroyed by ulceration, so that this instrument, of a certain size, can be passed, its employment should be almost incessantly continued, and its fize regularly increased as fall as circumstances will allow, in order to procure a free passage onward to the bladder. Some practitioners, in the same kind of case, would prefer the use of bougies armed with cautic; but this subject more properly belongs to the article in which fystures will be considered.

Some practitioners recommend hollow bougies to be used after the fylure is in part removed, with a view of preventing the urine from passing into the artificial opening. Mr. Hunter remarks, that this instrument allows the urine to dribble away continually; but that its orifice may be stopped up, and the urine only allowed to flow when the patient has an inclination to make the evacuation. The hollow bougie, according to the same great surgeon, becomes, under certain circumstances, the worst instrument possible; for if its canal is not of a size sufficient to let the water pass as freely as the contraction of the bladder requires, the fluid will easily pass by the side of the bougie, and not being able to get more forward than the remaining part of the fisture, will of course run into the abscess in the perineum. In order to avoid this disagreeable occurrence, as much as possible, the hollow bougies should be as large as the fyluted part will allow, and their fides should be as thin as possible, so that their cavity may be the wider. On these accounts the elastic gum catheters ought to be preferred to common hollow bougies, made with spiral wire, covered with waxed cloth.

Mr. Hunter himself entertained doubts whether the abscesses in the perineum was really prevented from healing by the passage of the urine through it, and, consequently, had very high opinion of the use of hollow bougies. He observed, that after lithotomy the parts healed very readily, when they were free from fisture. Hence he suspected that abscesses and fones in the perineum, the want of dispositions to heal arose from the fisture not being taken care of, or the deeper parts not being in a healthy state.

When suppurations in the perineum are neglected, and no attempt is made to cure the fylure, the latter forms those oles entirely, no bougie can be passed through it, and all the
the urine passes through the artificial passage. For such
incisions calibre bougies are such as ought to be employed.
In cases in which suppuration takes place in the peri-
num, in consequence of stricutures in the urethra, the sur-
geon should not limit his attention to the removal of the
latter affection only; he should also make use of every means
which is proper for diminishing the local inflammation.
Bleeding, and exposing the parts to the stream of hot water,
are measures fraught with peculiar efficacy. All prac-
titioners likewise acknowledge the great benefit which is
derived from the use of opium, administered both by the
mouth and in glycers. Irritation and spasm will be most
effectively relieved by confining with the foregoing treat-
ment the employment of the warm bath.
In some examples matter forms in the perineum, and
builds both internally and externally, so that a passage
is made, through which the urine escapes; but in consequence
of the abscess being circumcised by the adhesive inflam-
mation, which fluxes up the cavities of the cellular sub-
stance, the urine does not become diffused.
The avoidance of such an extravasation, however, is fre-
quently not in the power of the surgeon; an unfortunate
truth, because sloughing and abscesses generally arise in
every place into which the irritating fluid infiltrates itself.
As the mischief continues to increase as long as the urine
cannot find a free vent outward, and is, consequently, in-
jected more and more into the cellular membrane, the prac-
titioner must not be guilty of delay. It very often happens
that all the methods related above prove insufficient, or un-
productive of the prompt relief which is urgently demanded.
In this circumstance the surgeon must try by other means
to unload the bladder, and prevent the increasing extravas-
ation in the cellular membrane of the perineum, femur,
and adjacent parts. These two great definable objects may be
effectually disposed of by making an opening into the urethra, somewhere
beyond the stricture; though the nearer to it the better.
With this view, Mr. Hunter advises a director or stict to be
introduced into the urethra, as far as the stricture, and
an incision made down upon the end of the instrument. The
cut is then to be lengthened a little towards the anus, so as
to open the urethra just beyond the obstruction.
In cases in which the stricture happens to be situated op-
posite the femur, we are recommended by Mr. Hunter to
make an opening into the urethra in the perineum. It is
obvious that in such incisions we cannot have the stict to
hold us, and we must be directed by our knowledge of
anatomy. A cannula is then to be passed from the wound to
the stricture, and another cannula from the glans penis
also to the obstruction, so as to meet the other tube. A
perforating instrument is then to be pushed from one can-
nula into the other, by which means the stricture will be pe-
netrated.

The next step is to withdraw the two tubes, and
introduce a gum-catheter, which is to be worn till the wound is
healed.

These proceedings, however, are only to be considered
as proper in certain very urgent cases. In others, the in-
creasing diffusion of urine may be stopped by merely making
an opening into the urethra, somewhere between the stric-
ture and bladder; and, indeed, in the generality of in-
cidences, a diligent use of bougies, and making depending
apertures for the discharge of the urine, which becomes
extravasated, will remove all occasion for more severe mea-
ures.

Nor should the important considerations which we have
already stated be overlooked in the practitioner’s at-
tention. Other matters also require his care. That inflam-
mation, which is constantly excited wherever the urine is
extravasated, should be diminished as much as possible.
Fomentations and poultices should be applied, and the same
incisions and incisions which serve to let out the urine,
and prevent its spreading further in the cellular substance,
will also serve to give vent to whatever pus may be collected.
When there are sloughs, which is too frequently the case,
the incisions should of course rather be made in the infec-
tious dead parts than in the living ones. However, the
advantage of having a depending opening ought even to be
paramount in the surgeon’s mind, to the falsely humane
relief of not subjecting the patient to pain. By submitting
to requisite operations, it is true the latter suffers for a time,
but it is equally obvious that he would certainly suffer
much more, and perhaps ultimately die, were such opera-
tions neglected. It is frequently the case in surgery, that
these proceedings which to an unthinking person seem
to be so bold, bloody, and cruel, are in reality, with regard to
what the patients must feel, the most tender and humane,
and, with regard to his safety, the most direct. Were
the surgeon’s knife not used when diseases require it, the
patient certainly would not feel the sharp edge of the
inflammatory; but he could not in this way clade pain, which
would be tenfold greater, when resulting from the increas-
ing ravages of the disease, than when inflicted by the surgeon,
with this material difference, that in one instance it is suf-
fering for the chance of a recovery; in the other, it is suf-
ferring in all probability to die.

In cases of old fistula in perineum, in which the dangers aris-
ing from an extravasation of urine are over, either common or
armed bougies are to be used for the purpose of making the
urethra as free from obstruction as possible. When the stric-
tures give way, and the urine can flow freely forward, the
fistulous openings in the perineum often spontaneously
heal.

When the urethra is completely free from stricutures, and
yet the fistula in perineum do not heal, the fistulas are to be
laid open like all others which have no disposition to get
well. One great object in performing such operations is to
cut as little as possible of the sound urethra. On this ac-
count, Mr. Hunter advises us to find the inner orifice of the
fistula, if possible, by introducing a stict, which is to meet
the end of a probe pitted through the fistula into the
urethra. Surgeons ought to understand, that though fistula
in perineum often have several external openings, they seldom
or never have more than one internally, with which they com-
unicate with the urethra. A director is the most con-
venient instrument when the straight course of the fistula
will allow it to be introduced. When the fistulous passage is
tortuous, a probe is best, because it can be bent into any
shape.

The probe or director being introduced so as to meet the
stict, the surgeon is carefully to lay open the fistulas, through
which it pales, and he is to do this till he has cut as far as the
stict.

When no probe nor director can be made to enter so far
to touch the stricture, the surgeon must lay open as much of the
fistula as the instrument enters, and then endeavour
to find the continuation of the fistula.

As soon as the fistulous fistulas are all laid open down to
their termination in the urethra, a gum catheter should be
introduced, and worn at first almost without intermission.
However Mr. Hunter recommends the catheter to be
slid, as soon as the fores become stationary, as it some-
times has the effect of preventing them from healing.

The same eminent surgeon also advises us to dree the
wounds at first down to the bottom. If this prudent method
were neglected, the superficial parts might close, while the
deeper
deepers ones remained unhealed, and fresh abscesses and fistulas be the consequence.

**Fistula, Salivary.** See Salivary Fistula.

**Fistula Palatini.** In Anatomy, a term used by some writers for the *alvea arteria.

**Fistula Sacra.** is that part of the back-bone which is perforated.

**Fistula Urinaria.** the name of the urethra.

**Fistular, or Fistulous.** is applied by the surgeons to wounds and ulcers which degenerate into fistulas.

**Fistulae.** is also applied to the leaves of plants which are round and hollow within; as the leaves of leeks, &c.

**Fistular Flowers, among Herbalists.** are those made up of many small, long, hollow flowers, like pipes.

**Fistularia.** in Ichthyology, a genus of abdominal fishes, the finout of which is cylindrical; jaws distant from the eyes; gill-membrane with seven rays; body round, and gradually tapering from the jaws to the tail.

**Species.**

**Tabacaria.** Tail blind, and ending in a ferocious proc. Linn. *Tabanula, Marcq. Tobacco-pipe fish. Will.*

A very singular species, found in the seas of America and Japan. The usual length of this fish appears to be from twelve to eighteen inches, exclusive of the bright-form processes which proceeds from the extremity of the body between the two lobes of the caudal fin, and in general measures rather more than one-fourth of the length of the body. Some writers, however, assure us that the tobacco-pipe fish grows to the length even of three or four feet.

The shape is that of an eel, the skin smooth, of a livid brown colour above, and silvery beneath; the back and sides are marked with longitudinally series of blue spots, disposed on each side the middle of the back in two distinct lines; the lateral line is straight, and the fins pale red. In some examples of this fish the tail exhibits two of the above-mentioned filament appendages instead of one; whether his ought to be considered as an accidental circumstance, or as a criterion of sexual difference is uncertain; Dr. Blyth observes that the finout of these with two appendages to the tail is fertilised. According to the remarks of Count de Cepède the finout of this fish is very peculiar in structure, the fifth vertebrae being of immoderate length, the three next much shorter, and the rest gradually decreasing as they approach the tail. The species inhabits on smaller fishes, marine infests or worms, &c, which the structure of its finout enables it to obtain, by introducing that part into the cavities of the rocks.

**Chinensis.** Tail rounded, and without the long appendage. Linn. *Chinensis trumpet fish.*

A native of the Indian seas, and Possesses the fame habits as the former. Its general shape resembles that of the common eel. The head is elongated, somewhat bony, and compressed; the front tubular and rather broad; mouth small; eyes rather large; and the body covered with scales of moderate size. The prevailing colour is reddish-brown, of a pale hue, with three or four whitish stripes extending from the gills to the tail; the upper part of the body variegated with dusky spots, and the fins pale yellow.

A species apparently described in the first instance by Seba, and since with yet greater accuracy by Pallas. This fish is of the smaller kind, being only from two or three inches in length, or four inches at the utmost. The body is whitish-ah; with obsolete brown rivulets; the first dorsal fin and tail blackish; compressed, and spiny at the interjection of the lines. The head is rather small; eyes large, at the base of the snout, and with a triangular spine on each side before the orbit. The snout is remarkably long, straight, horny, and terminated in a mouth of small dimensions. The tip is armed with three spines; the gill-openings are shallow, small, and divided with a few prominent lines. The first dorsal fin is long, retracted, and banded with black; the pectoral fins are very broad; the ventral remarkably large, with the rays deeply and divided, and connected by means of a fleshy membrane in the form of a longitudinal pouch.

**Fistulator, Lat. a pipe.**

**Fistulosus Uccer.** See Fistula.

**FIT, in Medicine, an access, exacerbation, or paroxysm of disease.** The term is applied particularly to intermittent or periodical diseases; as we pay an ague-fit, the cold or hot fit of the same complaint; and also to all sudden or violent disturbances of the system, as to the attack of apoplexy, epilepsy, hysteria, &c. The word fits, when used without any epithet, applies principally to hysterical attacks in women, to the convulsions of children, and, among the vulgar, to epilepsy. See Convulsions, Epilepsy, and Hysteria; also Cold Fit.

**Fits of easy reflection and easy transmission.** See Light.

**Fits of the mother.** See Hysteric affection.

**Fitaque, or Floquii, in Geography, a town of Japan; 35 miles E. of Jeddo.**

**Fitchburg, a town-of America, in Worcester county, Massachusetts; 25 miles N. of Worcester. It contains 1500 inhabitants.**

**Fitchic, or Feach, in Heraldry, is when the lower part of any cross is sharpened into a point fit to fix into the ground. Thus, he bears azure, a cross-potent fitche.**

The origin hereof McKenzie ascribes to the primitive Christians, who used to carry their crosses with them wherever they went; and when they stopped at any place in a journey, fixed them in the ground.

**Fitches, in Agriculture, a common name often applied by farmers to vetches.** Crops of this sort are grown in the field both as a green food for live-stock, and their produce in feed. They are mostly sown broadcast over the land, and harrowed in by a light harrow; but occasionally in drills at narrow distances.

The feasons for putting the crops into the ground are either the autumn or spring, according as they are wanted.

They are occasionally likewise cultivated as a green crop, for being turned into the field as a manure. This is usually done just before they come into full bloom, when they are in their most luxuriant state. See Mansel.

When used green for toting cattle, they are an excellent food; and when given in the pod extremely fattening. See Tares and Vetches.

**Fitchet, a name used in some places for the weasel; called also the flickel and the ficitel. See Vivera Putoria.**

**Fitsil Head, in Geography, a cape of Scotland, on the W. coast and S. extremity of Mainland, one of the Shetland islands. N. lat. 59° 50'; W. long. 14°.**

**Fitting-out, in Naval Language, the act of providing a ship with a sufficient number of men to navigate and
FIT and arm her for attack or defence; as also of furnishing her with proper masts, sails, yards, ammunition, artillery, cordage, anchors, and other naval furniture, together with sufficient provisions for the ship's company. See Crew.

FITTRE'S, or FIDERI, in Geography, a country of Africa, otherwise called Lusit, and Cougu or Cougu, situated on the borders of a large lake to the south of Begarme. It is governed by a sultan, and his dominions have been much diminished by the encroachments of the sultans of Begarme and Wadye. The inhabitants live in small tents, and are said to be in a low degree of civilization. They have no salt, except what they procure from the ashes of gollib. The lake is situated 210 miles S. of Bordon, N. lat. 15° 56'. E. long. 22° 30'.

FITZ, a French term, literally denoting fan; sometimes given by way of addition to the natural fans of the kings of England; as James Fitz-Roy, duke of Grafton, &c. FITZHERBERT, Sir Anthony, in Biography, a learned lawyer and judge, who obtained the distinguished Henry VIII. was the younger son of Ralph Fitzherbert, esq. of Norbury, in the county of Derby. He was educated at Oxford, and pursued his studies, as preparatory to the practice at the bar, in one of the inns of court in the metropolis. He attained the degree of sergeant at law in 1511, and received the honour of knighthood about the same time. In 1523 he was appointed one of the justices of the court of Common Pleas, in which office he passed the remainder of his life, and was distinguished by many valuable legal works, as well as by such an honourable discharge of the duties of his office, as made him entitled to an oracle of the law. In the discharge of his duty he feared no man, and opposed the arbitrary proceedings of Wolsey in the height of his power. On his death-bed he is said to have exacted a promise from his children that they would neither accept grants, nor make purchases of lands of the dissolved religious foundations, to which they commonly adhered. He died in the year 1530, leaving a numerous posterity. His principal writings are, "The grand Abrége," a collection of cases abridged; "The office and authority of Justices of Peace," "The office of Sheriffs, Bailiffs of Liberties, Constables, &c." and "The new Natura Juris." He is supposed to have been the author of a work entitled "Of the surveying of Lands," and also of "The book of Husbandry." Biog. Brit.

FITZHERBERT, Thomas, grandson of Sir Anthony, was born in the county of Stafford in the year 1552, where he received the early parts of his education, after which he went to Oxford to pursue his studies. On account of his rigid adherence to the Catholic principles, in which he had been brought up, he exposed himself to occasional reproofs from his superiors, and at length became an object of persecution, and was committed to prison in the year 1572. Harsh measures rarely make a man less tenacious of his principles; and, upon his liberation, he became more active in promulgating the doctrines of popery than he had ever been, till at length he was obliged to seek safety in concealment. In the year 1580 he connected himself closely with some Jesuits sent into England as missionaries, afflicting them as far as he was able with money and advice. By this conduct he incurred the penalties of "pernunnire," and, alarmed at the risks he was every day running, he went to France. This was in the year 1584; he interested himself very much in behalf of Mary queen of Scots; and when the death of that unfortunate princess rendered his exertions no longer of any avail, he went to Madrid to implement the protection of Philip II. in behalf of the catholics, and their religion in England. From Madrid he went to Rome, took a lodging near the English college, and observed the same devotion as the inmates of that house, and spent the remainder of his time in writing books in defence of the catholic religion. In 1614 he became a member of the Society of Jesus, was admitted to priest's orders, and almost immediately afterwards removed to Flanders, to preside over the English mission there. Here he displayed great learning and talent, and acquired so much esteem by his behavior and conciliating manners, that he was invited to accept the rectorship of the English college at Rome, the duties of which he discharged with high reputation for twenty-two years. He died at Rome in the year 1640, at the very advanced age of eighty-eight. As an author his works are numerous, but being chiefly on controverted points of religion, they have little claim to notice. Biog. Brit.

FITZHUGH'S Sound, a narrow channel of the N. Pacific ocean, between Calvert's island, and the W. coast of North America.

FITZJAMES, James, in Biography, duke of Berwick, natural son of king James II. by Arabella, sister to the great duke of Marlborough, was born in 1657 at Moulins, in France, where his mother was, in her return from the battles of Bourbon. He was educated for the military profession, and distinguished himself at an early age at the siege of Buda and battle of Mohatz in 1686 and 1687. On his return his father conferred upon him the title of duke of Berwick, &c. with the order of the garter. At the revolution he accompanied the abdicated king to France, and afterwards went over to Ireland to command in the absence of Lord Tyrconnel. He fulfilled important commands at the siege of Londonderry and the battle of the Boyne, and when all was lost in that country he returned, and served in the armies of France. In the service of Louis XIV. he distinguished himself in a very high degree, and in 1703 he was appointed commander-in-chief of the troops sent into Spain to the assistance of Philip V., and intently obeying his duty as a general, he in a single campaign reduced a number of important places. As a reward for his great services, and for the many victories which he had obtained, he was made marshal of France in 1706. In the same year he returned to the command in Spain, and signalized his military skill by a campaign, in which, without fighting a battle, he obliged the enemy to evacuate Castile, "conducting them," says his biographer, "from port to port as a shepherd leads his flock." In 1707 he obtained a signal victory over the English and their allies, for which he received the highest honours in rank and titles that the crown of Spain could confer. He was afterwards entrusted with the army on the Rhine, opposed to that of the empire, and in 1710 he commanded in Dauphine, where with great skill he foiled all the attempts of the duke of Savoy with a superior army to break into France. He was now created a duke and peer of France by the title of Fitz-James. Notwithstanding his attachment and obligations to France, in the year 1710 he obeyed the orders of Louis, in taking upon the command of an army destined to invade that country, and soon made himself master of Fontarabie. He was afterwards commander-in-chief of the troops in the south-western provinces of France; and in the year 1720 was made governor of Straubing. War being renewed between the empire and France, he was appointed general of the French army.
army in Germany, and, in 1734, undertook the siege of Philippoburgh, during which he was killed by a cannon-shot on June 12th, at the age of sixty-three. He was naturally of a cold, reserved, and satiric temper; but he was a man of principle, sincere, upright, and disinterested. He made few promiscuous and professions of friendship, but no man performed more services to his friends. He avoided all intrigues, and never spoke ill of any man. As a general his great talent was in defensive war, and he declared nothing so much as to have a good fortification to defend. He estimated his own merits with modesty, but was the public and general opinion of him, that his death was regarded by the French, in whose cause he died, as a great national calamity. Moreri.

FITZROY ISLAND, in Geography, a small island near the N.E. coast of New Holland; 5 miles N.E. of cape Grafton.

FITZSTEPHEN, William, in Biography, who flourished in the 12th century, was descended from a noble Norman family, and born in London. When he had made a considerable progress in literature at home, he went to France to complete his studies. Upon his return he entered into the monastic state at Canterbury, and by his learning and talents obtained the notice and patronage of the archbishop, Thomas Beckett. To this prelate he became attached by habits of intimacy and strict friendship, adhering most zealously to him and his cause in the different reverses of his fortune. After the murder of Becket he exhibited his attachment by drawing up a life of that prelate in the Latin language. The life of the archbishop is introduced by a description of the city of London, and a detail of the manners and customs of the inhabitants in that period. This is said to be the earliest account extant of London, and is to be seen in Stowe's Survey. Fitzstephen died in the year 1191.

FITZWILLIAM, in Geography, a township of America, in Cheshire county, New Hampshire, about 16 miles E. of Connecticut river, and separated from Royallton in Massachusetts by the state line; incorporated in 1773, and containing 1240 inhabitants.

FIVE BONNETS, a cluster of small islands in the Mergui Archipelago. N. lat. 10° 29'.

Five Brothers, a cluster of small islands in Lake Huron. N. lat. 44° 35'; W. long. 83° 28'.

Five Fathom bank, a bank in the East Indian sea. S. lat. 5° 53'; E. long. 119° 2'.

Five Finger's point, a cape on the S.W. coast of New Zealand, forming the north cape of the fourth entrance into Dusky bay; the rocks of which bear some resemblance to the five fingers of the hand. This point is a narrow peninsula stretching off from Resolution island, of a moderate and equal height, and wholly covered with wood.

Five Island harbour, a bay on the W. coast of the island of Antigua. N. lat. 17° 13'; W. long. 61° 35'.

Five Nations of North America, so called by English writers, are the Iroquois of the French, being the Mohawks, Oneckoes, Onondagas, Cayugas, and Senecas, forming five classes joined in an old confederacy of offence and defence.

Five leaved Grafs, Cinquefoil, in Heraldry, is used by such as would introduce a blazon by herbs and flowers instead of metals and colours, to signify vert or green.

FIVEL, in Geography, a river of Holland, which runs into the Eems, near Delfzyl, and gives name to a small country on its banks between Groningen and the mouth of the... small towns and villages.

FIUMARA di Murro, a town of Naples, in Calabria Ultra; 8 miles N. of Reggio.

FIUMARELLA, la, a river of Naples, which runs into the gulf of Squillace, 2 miles S. of Cantarezzo.

FIUME. See St. Veit.

FIUME FREIDLE, a town of Naples, in Calabria Citra; 11 miles W.S.W. of Cosenza.

FIUMICINO, a sea-port in the dominions of the Pope, at the mouth of the Tiber, with a custom-house, where vessels pay for their goods on board; 2 miles S.W. of Pons Venetus.

FIXATION, the act of fixing, or of rendering a thing firm and fixed. Fixation is applied in the general to any process that fixes and binds together what, of its own nature, is volatile; and enables it to sustain the loss of fire for some considerable time.

Geber defines fixation an operation whereby a volatile thing, i.e. a thing that cannot endure the fire, is rendered capable of enduring it. In the general, fixation is the changing of a volatile body into a fixed one.

Fixation, among Alchemists, denotes a peculiar preparation of mercury, whereby it is to be put in a condition to bear the fire without evaporating, or the hammer without flying or separating.

The alchemists hold, that if they had the true secret of fixing mercury, without the addition of any foreign, less heavy and solid ingredient, they could make gold, or at least silver.

M. Hamberg had a long process of many months to prepare an oil from the succulent matter of human excrements; which he imagined would have fixed mercury into silver: but it failed.

FIXED AIR. See Air, Carbonic Acid, and Gas.

Fixed Bodies, in the general, are those which neither the fire nor any corrosive has such effect on, as to reduce or resolve them into their component elements; or, absolutely to destroy them.

Chauvin holds it not sufficient to denominate a body fixed that it can withstand the fire or any one agent, but it should withstand all. He contends, that fixation should not be restrained, as it usually is, to an absorption from evaporation, but from destruction, or resolution into primary elements: in this sense, gold, precious stones, and glass, and even sulphur, and mercury itself, are properly fixed bodies; for mercury and sulphur retain their nature notwithstanding all their evaporation.

The chemists divide all natural bodies into fixed and volatile, i.e. such as bear the utmost force of the fire without dissipating or spending themselves in flame, and such as do not.

Of fixed bodies, the principal are platinum, gold, silver, precious stones, particularly the diamond: telluric &c.

Of all metals, gold and silver alone are fixed; i.e. on remaining a long time exposed to the most intense flame, they, alone, lose nothing of their weight.

Where this property should arise is difficult to say. If the reader is not contented with the causes enumerated under Fixity, he may add the following one from Boerhaave, viz. the homogeneity and equality of the parts. The parts, or gr. of gold being all homogeneous and equal, will equally sustain each other, and leave equal spaces between them: through which pores, when fused, the fire taking an equal passage, goes off, without carrying anything of the metal with it: or rather the particles of gold being of all others the most solid and heavy (as appears from the weight of that metal) and of all others the most strongly unison bound
bound together (as appears from the immense ductility of that metal), the force of the fire is not sufficient to overcome so powerful a resistance; the solidity of the particles, and their freedom from air, prevents their being rarefied, or set farther apart, which might lessen their specific gravity, and diminish their vis cohesivis: so that what has the chief effect in the raising of fumes and vapours, viz. the rarefaction or expansion of the body being here precluded, the metal maintains its natural weight and tendency to the centre.

Mr. Boyle, the Prince of Mirandola, M. Homberg, and others, have made numerous experiments on gold, silver, &c. to see how far their fixity extended; in these pure gold, kept in an intense heat for two months, lost nothing sensible of its weight; silver, under the like circumstances, and the like time, lost one-twelfth part of its weight; but Mr. Boyle attributes this to the metal's not being fine and pure.

Indeed, by the great burning glasses of Mefirs. Tschirnhausen and Villette, the mott fixed bodies, as gold itself, are rendered volatile, and lose of their weight; so that there is no body in all nature absolutely fixed.

Fixed Ecliptic, a certain imaginary plane, which never changes its position in the heavens from the action of any of the parts of the solar system on each other; but, like a centre of inertia, remains immovably fixed. The existence of such a plane is demonstrated by Laplace, who has shewn the method of determining it from the situations, velocities, &c. of the planets, and other bodies of the solar system. The rule for determining it is as follows.

If at any instant of time whatever, and upon any plane passing through the centre of the sun, we draw straight lines to the ascending nodes of the planetary orbits referred to this plane; and if we take on these lines, reckoning from the centre of the sun lines equal to the tangents of the inclinations of these orbits to this plane; and if, at the extremities of these lines, we suppose lines equal to the masses of the planets, multiplied respecively into the square of the radius of their orbits, and by the cubes of their inclinations; and lastly, if we determine the centre of gravity of this new system of bodies, then the straight line, drawn from the centre of the sun to this point, will be the tangent of the inclination of the invariable plane to the asumed plane; and continuing this line to the heavens, will there mark its ascending node.

Whatever changes the succession of ages may produce in the planetary orbits, and whatever be the plane to which they are referred, the plane determined by this rule will always be the same. It is true, its position depends on the masses of the planets, but those which have satellites have the greatest influence on its position, and the masses of the others will soon be sufficiently known to determine it with exactness. In adopting the values and the elements of their orbits, as given under Element, we find that the longitude of the ascending node of the invariable plane was 102° 56′ 56″ at the commencement of 1750, and at the same time its inclination to the ecliptic was 1° 35′ 40″. In this computation we have neglected the comets, which, nevertheless, ought to enter into the determination of the invariable plane, since they make part of the solar system. It would be easy to include them in the preceding rule, if their masses, and the elements of their orbits, were known. But in our present ignorance of the nature of these objects, we suppose their masses too small to influence the planetary system, and this is the more probable, since the theory of the mutual attraction of the planets suffices to explain all the inequalities observed in their motions. But if the action of the comets should become sensible in length of time, it should principally affect the position of the plane which we suppose invariable, and in this point of view, the consideration of this plane will still be useful, if its variations could be recognized, which would be attended with great difficulties.

The situation of this fixed ecliptic is at present nearly half way between the orbits of Jupiter and Saturn, and it is inclined in a small angle to the plane of the earth's orbit or true ecliptic.

The property by which it is determined is that the sum of the areas described by the radius vectores of the bodies of the system multiplied respectively by the masses of these bodies, is a maximum.

Fixed Line of defence, a line drawn along the face of the bulwark, and terminating in the curtain. See Defence.

Fixed Nitre, a preparation of saltpetre, made by fusing it in a crucible, and then inhaling it, with throwing in a few coals; and thus again and again, till no more flame or detonation arise; then letting it cool, they pulverize and dissolve it in water, and afterwards evaporate it into a fine white salt, which serves to draw the frits out of vegetables. This salt, per diem, yields what they call the liquor of fixed nitre.

Fixed Salts, are those extracted or gained from bodies by calcination and leution. See Salts.

They are called fixed, because the fire was not able to sublimate or raise them; as those carried off in the course of calcination by the sublimation of fire are called volatile.

The ashes of all plants yield fixed salts. See Lixivium.

Fixed Signs of the Zodiac, according to some, are the signs Taurus, Leo, Scorpio, and Aquarius.

They are so called because the sun passes them respectively in the middle of each quarter, when that fraction is more settled and fixed than under the sign which begins and ends it.

Fixed Stars are such as contantly retain the same position and distance with respect to each other.

By which they are contra-distinguished from erratic or wandering stars, which are continually shifting their situation and distance.

The fixed stars are what we properly and absolutely call stars; the rest have their peculiar denomination of planet and comet.

FIXEN, among Sportsmen. See Vixen.

FIXES is a name given by the workmen in gold and silver to a solution in salt, from its use in carrying down and fixing the heterogeneous acids mingled with aquafortis.

FIXITY, or Fixedness, in philosophy, the quality of a body which denominates and renders it fixed; or a property which enables it to endure the fire and other violent agents.

According to Chauvin, fixity consists in this; that the component principles of the body are to eachly united or held so strongly, and are mixed in such proportion, that they cannot easily be divided either by fire or any other corrosive menstrua, or their integral parts separated and carried off in vapour; for a body may be fixed to be fixed in two respects.

First, when, on being exposed to the fire, or a corrosive menstruum, its particles are indeed separated, and the body rendered fluid, but without being resolved into its inert elements. The second, when the body sustains the active force of the fire or menstrea whereto its integral parts are not carried off in fumes. Each kind of fixity is the re-
full of a strong or intimate cohesion between the particles mixed.

FIXITY, or Fixedness, in Chemistry, is, in a peculiar manner, used for the affection opposite to volatility; i.e. the property whereby bodies bear the action of the fire, without being devitated in form or nature. The principal causes of fixity, or the qualifications that contribute most to the rendering a body fixed, according to Mr. Boyle, are, 1. That its corpuscles be finely of a certain proportionable bulk, too big and unwieldy to be carried by heat, or buoyed up in the air. 2. That they have also a proper degree of weight or solidity. 3. That their figure be such as unfitts them for evaporation or flying off; some being branched, others hooked, &c. So that being entangled with one another, they cannot easily be extricated, loosened and separated. To these may be added a fourth circumstance, viz. the nearness of the particles, and their being contiguous in a great many points, or large extent of surface, which produces a stronger force of attraction and cohesion.

FIXLMILLNER, Placidus, in Biography, was born at a village near Liez, in Auvergne, in May, 1720. He was educated by his uncle, Alexander, who was abbot of Kremmmunster, to whom that institution was indebted for the establishment of a school and observatory in a very early period he used to take much delight in delineating mathematical figures. At a proper time he went to Salzburg, where he went through a course of philosophy, and attended the mathematical lectures of professor Stuart, who had this peculiarity in his mode of teaching, that he never made use of figures, and yet gave to clear an idea of the different propositions as rendered the comprehension of them easy. In the year 1737, he took the vows of a monastic life, and applied himself diligently to the study of philosophy and mathematics. Nor was he left indifferent in laying a solid foundation in the modern and oriental languages, history, and antiquities. He obtained the degree of doctor in theology, and in 1745 took priest’s orders at his monastery. He also undertook the professorship of ecclesiastical law at the school belonging to the monastery, which was frequented by the young nobility from Auvergne; an office which he discharged for forty years. He was about the same time made dean of the higher schools, and regent of the young nobility. His general knowledge of the law rendered him a fit person to be consulted in regard to law-suits; and, on a similar account, he was appointed "Notarius Apostolicus in Curia Romana." As his high reputation brought many students to Kremmmunster, he did not confine himself to the public hours of teaching, but repeated his lectures privately, and was always ready to assist his hearers, and to give them every explanation in his power. Notwithstanding his diligence and zeal in the way of education, it was not on this that his fame was built; but his attachment to astronomy rendered him most conspicuous, and known in foreign countries. His uncle, Alexander, resolved, in the year 1747, to found an establishment in his monastery, for the purpose of diffusing mathematical knowledge. With this view, he fitted up an apartment to contain the necessary instruments, and for making experiments of every kind. He also caused an observatory to be built in his garden, and in the course of time Fixlmillner was appointed astronomer, retaining at the same time his office as professor of the ecclesiastical law. His application to the study of this science was so intense, that he made the most rapid progress in it, and published several works, in a few years, of great merit. His service, however, to practical astronomy confines chiefly in his having made and collected, at the desire of Lalande, a great many observations on Mercury, and thereby enabled the French astronomer to construct his tables of that planet. This service Lalande publicly acknowledged, and likewise inferred his observations in the supplemental volume to his astronomy. Fixlmillner was also one of the first astronomers who calculated the orbit of the Herschel planet, and constructed the tables which were adapted to it. He was the person who proved the truth of professor Bode’s conjecture, that the thirty-fourth star of Taurus, observed by Flamstead in the year 1690, was the new planet; and by applying Flamstead’s observations to calculation, he produced a theory which fully agreed with the phenomena of it. It would take us much beyond the limits allowed for the article, were we to attempt recording all that this active astronomer did for his favourite science. He had also an uncommon genius for mechanics, and invented many practical helps to observation; such as a new micrometer, and a machine for grinding concentric circles on glasses with great accuracy. His indefatigable industry injured his health; and he died in August, 1791, in the 71st year of his age. He was simple, uniform, and constant, like the laws of nature which he studied and illustrated; his character displayed that mildness and integrity, which never fail to inspire esteem and love. His life was passed in great harmony with his monastic brethren; and it was in his capacity of general joy to the whole establishment, when, in the year 1788, he celebrated the fiftieth anniversary of his residence in it.

FIXTELA, in Geography, a town of Morocco, 4 miles from Tetuz.

FIZES, Anthony, in Biography, an eminent physician of Montpellier, was the son of Nicholas Fizes, professor of mathematics in that university, and was born in the year 1690. He received his early education entirely from his father, who defined him his successor in the mathematical chair. But in the course of his attendance in the classes of the college, he acquired a great disposition to the study of medicine, which he pursued with so much ardour and advantage, that his father was induced to yield to his solicitations; and, notwithstanding the mediocrity of his income, sent Anthony to complete his medical education at Paris, under the tuition of Du Verney, Lemery, and the two Meilifs. De Jullieu. On his return to Montpellier, he employed himself in observing diseases in the hospital de la Charité, and in public teaching. On the death of his father, he was appointed joint professor of mathematics with M. De Clapiers, and became his sole successor. He held the mathematical chair until the labours of his medical course, and the extension of his practice, compelled him to resign it. In 1732, the medical professorship in the university became vacant by the resignation of M. Du Dider, and Fizes was elected his successor. He fulfilled the duties of this chair with great propriety, but with little zeal. It was in the practice of his profession that his superiority was particularly conspicuous, for he possessed an extraordinary talent for observation. Being endowed likewise with a sound judgment, and an uncommon memory, he appreciated at once the character of the most complicated disease; and was above all admired for the accuracy of his prognostics. These qualifications placed him at the head of his profession at Montpellier; his fame extended to the metropolis, and he was invited to the office of physician to the duke of Orleans. His age was now, however, advanced; and the fear of the jealousy which this high appointment might produce among his brethren, led him to make some efforts to be permitted to decline this honour. He removed to Paris, nevertheless; but, unwilling to the intrigue, and rat-
FLACCIUS, C. Valerius, a Roman poet, who flourished in the reign of Vespasian, and died at an early age, in the time of Domitian. From an epigram in Martial, it should seem that he was in no affluence; for he advised him as a friend to quit the modes for the more gainful pursuits of the forum. The work on which his fame rests as a poet is entitled "Argonautica," in eight books. It is in imitation of the Greek poem of Apollonius Rhodius on the same subject, and may rank among the most respectable of the Latin epics after the Iliad, the manner and style of which he aims at copying. The lost edition of it is that of Limpricht, 1724, in 4to. It contains sublime and splendid passages, and is free from the hamblab and extravagance of most of the second race of Latin poets; but it is in general deficient in poetical spirit, and is likewise wanting in plan and contrivance. Rom. Hist. See Flaccurtia.

FLACCUS, a Roman musician, who set the comedies of Terence to music.

FLACHSTADT, in Geography, a small island in the North Sea, about 40 miles from the coast of Norway. N. lat. 68.

FLACCIUS, or Franciscoz, Matthias, in Biography, was born at Ascona in Iulia, in the year 1520. His father, who was a literary man, undertook the education of his son; but dying while the youth was quite young, he fell into hands who were either incapable of affording him assistance, or negligent of the charge committed to their care. But by his own application, and some occasional assistance which he received from a learned Italian, he made considerable progress in classical literature and the belles lettres. He went to Venice, and studied under Pathila Egnatius; and when he was but 17 years of age, he felt a strong inclination for theological pursuits, and, from his straitened circumstances, was desirous of entering a monastery; but he was diffused from the plan, and went to Bafli, where he studied some months, and embraced the opinions of the reformers. From Bafli he proceeded to Tubingen, where he received the instructions of the celebrated Camerarius; and in 1541, he became the disciple of Luther and Melancthon, the latter of whom gave him very substantial proofs of his regard and liberality. After he had taken his degree, he married, and was appointed public professor of Wittenberg. During the war between the confederate Protestants and the emperor Charles V, the adherents were divided from the Saxony fanatics, and Flaccus went to Brunswick, where he obtained a high reputation by his lectures, and upon the termination of hostilities in 1547, he returned to Wittenberg, to resume his former situation in that university. In the year 1548, a controversy took place among the adherents of Luther, in which Flaccus published a leading part, and displayed much bigotry and intolerance. It originated in the debates among the Saxony divines concerning the expediency of submitting to the famous edict of Charles V, called the "interim." Melancthon and others concurred in the opinion, that in matters of inferior importance one was due to the imperial edicts; and in this they placed precedence things which had appeared of the highest importance to Luther, among which were the doctrine of justification by faith alone, the necessity of good works to salvation, the number of the sacraments, extreme unction, and certain rites and ceremonies relative to church discipline. On the other hand, the defenders of the primitive doctrines of Lutheranism, with Flaccus at their head, attacked with much bitterness and fury these accommodating divines, and accused them of apostasy from the true religion. Among other absurd notions which Flaccus, in the heat of argument, avowed, was this, that original sin was not an accident, but the very "substance" of human nature. The odium which he excited by embracing this strange notion, rendered it necessary that he should relinquish a professorship at Jena, which he had held five years; he accordingly withdrew to Ratisbon, where he continued to publish many books. In the year 1567, he was invited, with some other Lutheran ministers, to Brabant, to model some churches in that country on the principles of the Augsburg confession; but they were soon dispersed by the bloody persecution under the duke of Alva, when he removed to Straßburg, and afterwards to Frankfurt on the Main. The number of his adherents had greatly declined in Germany; and he died in 1575, when he had completed the 55th year of his age. He was a man of excellent talents, great learning, and overbearing zeal against papistry; but his turbulent, factional, and quarrelsome temper rendered his good qualities of little avail. He was the author of many works, which are enumerated at large by Moretus; the principal are, "Clavis Sacrae Scripturae,"
FLA

FLACOURTIA, in Botany, so named by L. Heritier, in memory of Stephen de Flacourt, a native of Orleans, fuperintendent of a colony for some time established by the French in Madagascar, and author of an account of that island, published in quarto at Paris in 1658, and at Troyes in 1661. He was the first who gave a history of the rich natural productions of that country, and through, as Hailer observes, not a deep naturalist, he was certainly not disinterested in observation. He describes many new and rare plants, especially such as are useful for food, giving figures of the leaves only. L'Herit. Strip. Nov. 59. Schreb. 702. Mart. Mill. Dict. v. 2. Art. H. Kew. v. 3. 413. Jull. 291. Cliffs and order, Directa Polyandra, Dryander. D. vauvandia, L'Herit. Nat. Ord. 71, cex, Jull.

Gen. Ch. Male, Cal. Perianth of one leaf, in five or more deep, roundish, obtuse, nearly equal, ascending segments. Cor. none. Stam. Filaments numerous, from 50 to 100, rather longer than the calyx, papillary, spreading, equal, inserted into a central hemispherical receptacle; anthers roundish, of two cells. Pist. wanting, though sometimes the abortive rudiments of one are discernible.

Female, Cal. Perianth inferior, of five or more roundish, erect, cloosed leaves, downy on their inside. Cor. none. Stam. none. Pist. German inferior, ovate, sessile, rather longer than the calyx; style none; stigma filiform, or from five to nine spreading, oblong, obtuse, furrowed rays. Peric. Berry globular, becoming angular by drying, umbilicated, of many cells. Seeds two in each cell, one over the other, obovate, compressed, with a furrow on the upper edge.

F. Ramonciti is the only known species. L'Herit. Strip. Nov. 59. t. 50. Lamarec t. 826. Native of Madagascar, where, according to Flacourt, it is called Aloe, and according to Poirier Ramonciti. This is a shrub eight or ten feet high. Branches spreading, alternate, round, smooth, leafy, dotted, armed with five lateral spines. Leaves alternate, on short downy stalks, spreading, ovate, acute, smooth, veiny, with many shallow furrows, often purplish at the edges. Stipulas none. Flowers small, few, in terminal clusters; the male ones chiefly conspicuous by their yellow anthers; the female appearing before the fresh leaves come out. Fruit like a small plum, at first green, then of a fine red, and finally of a deep violet, sweet and edible, but leaving a slight acrimony in the mouth. Seeds bitterish, like the kernel of a cherry. An island on the coast of Madagascar, to leagues to the south of Point point, was named by the French l'ile aux pruniers, plum island, because they found it covered with bushes of Ramonciti.

Propagation and Culture.—This shrub flowers in our flowers in June and July, but has not yet produced any fruit. L'Heritier says both sexes bloomed at Paris, where the plant was kept in the green-house, but he had never happened to see them both in one summer. It is propagated by cuttings or layers, but has little beauty or utility to recommend it to our care in this country.

FLADABUNA, in Geography, a small island near the N.W. coast of Scotland; 7 miles N. from the island of Skye. N. lat. 57° 32'. W. long. 6° 17'.

FLADD, a small island of Scotland, near the N.E.

coat of the island of Skye. N. lat. 57° 37'. W. long. 6° 30'.

FLADDA, three small islands among the western islands of Scotland, about 1 mile W. from the island of Sandera. N. lat. 56° 37'. W. long. 7° 32'.

FLADHUNA, an inconsiderable island of Scotland, to the north of Huisn, not far from Skye, and at some distance from the coast, which was formerly inhabited. In its vicinity are six or seven rocks, one of which is about 300 paces in circuit, and flat on the summit, with a deep well in it.

FLADSTRAND, a sea-port town of Denmark, in North Jutland, and diocese of Aalborg, on the east coast, with a harbour defended by three forts. The chief employment of the inhabitants is fishing; 30 miles N.W. of Aalborg. N. lat. 57° 27'. E. long. 10° 32'.

FLADUGEN, a town of Germany, in the bishopric of Wurzburg; 40 miles N. of Wurzburg. N. lat. 52° 37'. E. long. 10° 29'.

FLAG, a general name, including colours, standards, banners, ensigns, &c. which authors frequently confound with each other.

The fashion of bearing the flags pointed or triangular, which now obtains, Roderich. Toletania afforts us, came from the Mahometan Arabs or Saracens, upon their seizing of Spain, before which time all the ensigns of war were square, stretched, or extended, on crosst pieces of wood, like church-banners; on which account they were called in Latin vaga, q. d. vaga, a cell diminutus, as is remarked by L'Heritier.

The pirates of Algiers, and those throughout the coast of Barbary, are the only people who bear a hexagonal flag. It is gules, charged with a Morock head, coiled with its turban, &c. though this be expressly contrary to their law, which prohibits the making any image or representation of a man, founded on an opinion, that they who make them shall be obliged at the day of judgment to find souls for them, and that in defiance hereof they shall be damned. But this portrait which they carry is that of Halil, Mahomet's son-in-law, to whom party the Africans all return, who ordered that his effigy should be expressed on their flags and standards, believing himself to be formidable to the Christians, that the bare sight of his image would carry undoubted victory over them. L'Heritier.

Flags, in the Military Art, are small banners of distinction stuck in the baggage-wagons of the army, to distinguish the baggage of one brigade from another, and of one battalion from another, that they may be marshaled by the waggon-masters-general, according to the rank of their brigades, to avoid the confusion that otherwise might arise. See Colours and Standards.

Flag is more particularly used in Sea-Language, for the colours, ancient, standards, &c. borne on the top of the masts of vessels, to signify the quality of the person who commands the ship, of what nation it is, and whether it be equipped for war or peace.

In the British navy flags are either red, white, or blue, and are displayed from the top of the masts of vessels, to signify the quality of the person who commands the ship, of what nation it is, and whether it be equipped for war or trade.

In the British navy flags are either red, white, or blue, and are displayed from the top of the masts of vessels, to signify the quality of the person who commands the ship, of what nation it is, and whether it be equipped for war or trade.
music Loricata), that in six days he could discharge an entire century, by a whipping of three hundred thousand flutes. His example was followed by many penitents of both sexes; and as a vicarious sacrifice was accepted, a family disciplinarian might expiate on his own back the sins of his benefactors. These compensations of the purifies and the penitents, introduced, in the 11th century, a more honourable mode of satisfaction, the merit of military service, which was followed by the crucifaces. See Croisades, Discipline, Indulgence, and Penance.

The parliament of Paris prohibited all public flagellations by an act of 1693. See Flagellantes.

Flagellation is a term more peculiarly appropriated to the sufferings of Jesus Christ, when whipped and lacerated by the Jews; from the Latin, flagellum, a scourge, or whip.

We say, a painting of the flagellation; or simply, a flagellation, to denote a picture or print representing this torment inflicted on the sufferer of the world.

In this sense we say the flagellation of such a painter, &c.

Flagellation, Feasst spec. See Diamastigosis.

Flagelliformia Caulis, in Estonia, a long and pliant stem in which Periploca gregga, and many other plants. See Caulis, where this term is accidentally omitted. The common jasmine is a good example of it.

Flagelloe, a flagellum, a kind of little flute; or a musical instrument of the flute kind, used chiefly by shepherd and country people.

It is usually made of box, or some other hard wood, sometimes of ivory. It has five holes or flaps, besides that at bottom, the mouth-piece, and that behind the mouth, &c.

The ambit of the flagellum, according to the scale exhibited by Mercenius, is two octaves from g to e at upwards.

Flaherti, Roderic, in Biographia, an Irish antiquarian and historian, who published at London, A.D. 1685, a book under the singular and mystic title of "Ogygia, or Rerum Hiberniarum Chronologia," containing chronological memoirs upon the antiquities of the kingdom of Ireland; compiled, as he observes, "ex pervetuti monumentis fidele rer coelatis cras, atque facris et potentibus litteraris primoribus orbis gentium, tum genealogiae, quum chronologiae suffulta praestat." This work, a quarter-volume containing about 600 pages, he dedicated to the then duke of York, afterwards king James II. of England. The author commences his history from the deluge, continues it to the year of Christ 528, and has divided it into three parts. The first describes the island, its various names, inhabitants, extent, kings, the manner of their annual election, &c. The second is a kind of chronological parallel of the Irish affairs with the events that happened during the same period in other countries. The third is a more ample detail of particular transactions, in the same kingdom. To this is added a profoundly exact chronological table of all the Irish kings who have ruled over Ireland, from A.D. 282 till A.D. 1022; and a brief relation of the most prominent historic features of the island, till the time of Charles II., in 1685. To this succeeds a chronological poem, which forms a summary of Irish history to the same period. At the end is a very curious catalogue of the Scottish kings,Irish, who have reigned in the British isles. In his genealogical remarks on the regal house of the Stewarts, the author attempts to prove they were originally an Irish family. It is surprising, that neither the author nor his work has been noticed by Macpherson or Whisker in their controvery respecting the peoples of Hibernia, and the origin of the Caledonians; although he is particularly noticed by O'Halloran in his History of Ireland. See Moreri, Grand Dict.Hist.

Flagellum, in Rural Economy, a well known implement or tool made use of in threshing different sorts of corn. It consists of a hand-flail, and a short beating part, which are attached to each other by a strong thong of leather, passing through loops or flaps, fixed on the ends of the different pieces. Since the introduction of machines for threshing, the flail method has been much less had recourse to, except upon farms of small extent, as being more laborious and troublesome, and his expedients in the execution of the work. See Threshing Machine.

Flagel, in Sea Language. The seamen say that the work doth flour-overs, when a ship being houled in near the water, so that the works hang over a little too much, and thus is let out broader afloat than the due proportion will allow.

Flamis, in Ichthyology, a name given by some to the skate, a species of raja.

The ancient Greeks called this bato, when they spoke of the male, and of the female, latis.

Flag, in Gardening, a name given by florists to those flowers of the carnation kind which have only two colours, and very large stipes, all of which go quite through the leaves.

Flag, White, in Painting, is lead corroded by means of the preluding of grapes, or a curvile prepared by the acid of grapes. It is brought here from Italy, and far surpasses, both with regard to the purity of its whites and the certainty of its blending, all the curvile or white lead made with us in common. It is used in oil and varnish painting, for all purposes where a very clean white is required. The white flag should be procured in lumps as it is brought over, and levigated by those who use it, because that which the colourmen fell in a prepared lode is levigated and mixed up with flars, and often with white lead, and worse sophifications.

Flamant, of Flamingo, in Ornithology. See Phoenicopterus ruber.

Flamantville, in Geography, a sea-port town of France, in the department of the Channel, with a good harbour, 10 miles S.S.W. of Cherbourg.

Flambeau, or Flamboy, a luminous made of several thick wicks, covered over with wax, serving to burn at night in the streets, &c. as also at funeral processions, illuminations, &c.

Flambeaux differ from lights, torches, and tapers. See Torch.

They are made square, sometimes of white wax, and sometimes of yellow; they usually consist of four wicks or branches near an inch thick, and about three feet long, made of a sort of coarse hempen yarn, half twisted. They are made with the ladle, much as torches or tapers are, viz. by first pouring the melted wax on the top of the several supended wicks, and letting it run down to the bottom; this they repeat twice. After each wick has thus got its proper cover of wax, they lay them to dry; then roll them on the table, and so join four of them together by means of a red-hot iron.

When joined, they pour on more wax till the flambeau
is brought to the size required, which is usually from a pound and a half to three pounds.

The last thing is to finish their form or outline, which they do with a kind of polishing instrument of wood, by running it along all the angles formed by the union of the branches.

The flambeaux of the ancients were different from ours. They were made of woods, dried in furnaces, or otherwise. They used diverse kinds of woods for this purpose; the wood most usual was pine. Pliny says, that in his time they frequently also burnt oak, elm, and larch. In the seventh book of the Antiquities, mention is made of a flambeau of pine; and Servius, on that passage, remarks, that they also made them of the cornel tree.

FLAMBO, in Natural History, a name given by some to a long anguilliform fish, called euryagra. See Cephalosoma.

FLAMBOURGH, in Geography, a township of England, in the West Riding of Yorkshire, on the coast of the German sea, containing about 730 inhabitants; 3 miles by N. of Flamborough Head, a lofty cape or promontory of England, on the E. coast of the county of York. N. lat. 54° 8' W. long. 0° 2'.

This promontory is formed of lime-stone of a snowy whiteness, and stupendous height, visible far off at sea. A light-house has been lately erected on this head, in which is exhibited a triangular revolving light, distinguish'd from the revolving lights of Tynemouth and Cromer by shewing a face every two minutes, one of them being coloured red.

FLAMBOURGH, a factory of the Hudson bay company, on the south-western side of Hudson bay.

FLAMBOURGH, a township in Upper Canada, distinguish'd by E. and W. Flamborough, in the West Riding of the county of York, and lying W. of the Missisaga lands, and fronting Dundas street.

FLAME, (flamma, Latin,) is the actual burning; attended with heat and light, of a volatile combustible substance; and this substance may be either a comminuted solid, (viz. a powder,) or a vapour, or a gas.

The powder of rosin, and of other brittle resinous bodies, the fibres of several plants, and some other powdered combustibles, when projected through the flame of a candle, or of a piece of burning paper, instantly take fire, and the flame spreads through the whole pow'dery cloud. Powders of this sort are used at the play-houses for representing a flash of lightning or other sudden light. Powdered rosin, and the powder of lycopodium, have been found to produce this effect equally well; yet the latter, when it may be procured, is by far preferable to the former, and that on account of its being an unadulterated light powder, easily spru'lled off from any thing, whereas the powdered rosin sticks to, and foils every thing that it happens to fall upon.

The vapour of certain inflammable fluids, such as spirit of wine, ether, spirit of turpentine, &c. is instantly inflamed by the contact of a candle, or other flaming body, or by a spark of electricity, and continue to burn as long as there is a sufficient supply of it.

The inflammable gases, when they are extricated either by the action of heat, or otherwise, from substances that contain them, may also be inflamed, and will burn in a similar manner. Thus, if iron filings and diluted sulphuric acid be placed in a bottle, an effervescence takes place, together with a copious production of hydrogen gas, which comes out in a stream from the aperture of the bottle, and it may be inflamed either by a lighted candle, paper, wood, &c. or by puffing an electric spark through it. Thus also, when coals are lighted in a common fire, the heat softens their bituminous parts, and expels the inflammable gases, which burn and consolute the flame, as every body must daily experience. But besides the inflammable gases, heat expels from coals an aqueous vapour, a thick fluid like tar, and some gases that are not of a combustible nature, and these products are neither equal nor constant, that is, sometimes some of them predominate, and sometimes the other. The consequence of which is, that the flame of coals is continually waving both in shape and intensity of colour. It frequently shifts from one place to another, and what gave a beautiful white light a few seconds before, has become a stream of dense and dark smoke. It may be hardly worth observing that the changeable inclination of the flame is owing to the motion of the air, which runs towards the fire in various directions.

The like thing takes place in the combustion of wood, and vegetable matter in general. The heat extricates the volatile and inflammable materials which take fire, and produces the flame.

In the combustion of charcoal, and of coal, (viz. carboniferous mineral coal,) the flame and the smoke are very trifling, because the operation of charring has previously expelled from those materials a great portion of their volatile ingredients.

With respect to the process of the combustion, the five requisites are necessary with the combustion of volatile substances, which produce the flame, as with the combustion of solids; viz. the combustible must be heated to a certain degree, a fire must be communicated, and the combustion can only take place in contact with oxygen gas, or with substances which contain oxygen. See Combustion.

Thus, we have given a general sketch of the nature of flame; but there are several remarkable particulars belonging to every part of the above mentioned process, which are highly deserving of notice, and which, of course, we shall now endeavour to point out successively.

The purposes for which mankind employ light, or combustion in general, are either for the use of the heat, or for the use of the light. The heat is subservient to the numerous and important purposes of cooking victuals, of warming apartments, and thus rendering inhabitable such climates, as otherwise the human species could not live in; of giving existence to all metallicurgic operations, to the making of glass, of lime for building, &c. &c. The light is subservient to purposes equally important. In short, it enables human beings to follow their operations, during the absence of the day-light merely, if not full as well, as in the day-time. The flame of a single candle animates a family; every one follows his occupations, and no dread is felt of the darkness of night. Were it not for artificial light, how great a portion of the advantages of industry, and of real comfort, would the human species be deprived of.

When heat is wasted, then rough solid combustibles are used, which give it in abundance, and at a cheap rate; but when light is wanted, then the purest and the most uniform combustibles must be used, otherwise an indiffere't effect is produced, and a considerable quantity of materials is expended. In some uncivilized countries, flax-seed faggots of some kind of resinous wood are used by way of candles. When lighted at one end they burn gradually, and afford a good deal of light, but it is indifferently, and encumbered with a good deal of smoke. Besides, these faggots are readily burnt out, and must be quickly replaced by new ones.

At present, in all civilized countries, the principal combustibles
bubbles that are used for the production of a bright and luminous flame, are wax, the fat of animals, under the general name of tallow, oil, either of fish or of vegetables, and the inflammable gas of coals, which has but lately been introduced, at least in this country. The extensive consumption of these materials, and the successive increase of their price, has obliged the industrious to devise the best means of producing the greatest effect with the least possible quantity of materials.

Wax, tallow, and oils must be rendered volatile before they will produce a flame, but for this purpose it is sufficient to volatilize a small quantity of any of them, successively; for this small quantity will suffice to give a useful flame, and hence we must admit the simple, yet wonderful contrivance of a common candle or lamp. This contrivance contains a considerable quantity of the combustible subflance, sufficient to last several hours; it has likewise, in a particular place, a flender piece of porous vegetable subflance, called the wick, which in fact is the fire place, or laboratory where the whole operation is conducted. The wick which, in the formation of the candle, or preparation of the lamp, has been partly or entirely soaked in the wax, or tallow, or oil, is set fire to by the approach of some other subflance actually burning; this heat renders volatile and inflames that part of the wax, oil, &c. which is in the wick, and at the same time softens which is next to it; the first portion of the wax, &c. being thus consumed, the wick is, in consequence of its capillary attraction, enabled to imbibe more materials for the maintenance of the flame, and so on in succession until the whole is exhausted.

There is a circumstance frequently attending the first lighting of a candle, which demands a short explanation in this place. It is, that at first the candle sometimes burns dimly, and looks as if it would go out. The method of reviving the flame in such cases is to lift up the candle perpendicular with a quick motion, three or four times successively, which action in some degree re-adjusts the flame, and the position of the first dimness is that the wax or tallow, by being too cold or too hard, is not melted by the combustion of that small portion which is in the wick, and of course cannot supply the waste of the wick; but by the lifting up of the candle, the air heats down the flame upon the wax or tallow adjoining to the wick, which melts it, and enables it to run up into the pores of the wick, where it is rendered volatile, and is inflamed, &c.

That part of the combustible which is successively rendered volatile by the heat of the flame is not all burnt, but part of it escapes in the form of smoke through the middle of the flame, because that part cannot come in contact with the oxygen of the surrounding atmosphere; hence it follows, that with a large wick and a large flame, this waffle of combustible matter is proportionately much greater than with a small wick and a small flame. In fact, when the wick is not greater than a single thread of cotton, the flame, though very small, is, however, peculiarly bright, and free from smoke; whereas in lamps with a very large wick, such as are often suspended before butcher's shops, or with those of the lamp lighters, the smoke is very offensive, and in great measure eclipses the light of the flame.

In order to avoid this inconvenience, the ingenious Mr. Argand made that famous contrivance of a lamp, which now justly goes by his name. He made the burner or wick thin and circular, with a free passage for the air through the middle. In this construction a very thin and circular flame comes in contact with a vast quantity of air both within and without the circle, in consequence of which none of the volatilized oil escapes without burning, and the flame is very brilliant and active. This shows the reason of what is commonly said of this lamp, namely, that it consumes its own smoke. With respect to the original contrivance, and the successive improvements of this admirable lamp, we must refer the reader to the article LAMP.

Instead of a circular form, the wick has also been made thin and oblong; but though this construction has some advantage over the common lamp, yet it is far inferior to Argand's. A circular or an oblong wick has likewise been tried in wax or tallow candles, but the attempts have not been attended with any remarkable advantage.

Another consequence of the want of oxygen in the middle of the large flame of a lamp or candle, is the formation of a cloudy concretion at the extremity of the wick. This arises from the coaly or groffer particles of the combustible which are too large to be volatilized, and at the same time do not come in contact with the oxygen which is necessary for their combustion; hence they accumulate and spread out something like a fungus. If the wick be incised a little, so that the end of it may project out of the flame, which always goes straight upwards; then no coaly concretion is formed. In the lamps which illuminate the streets of London, the wick lies nearly horizontal, in consequence of which they seldom contract any coaly concretion.

Of the three principal materials for producing a useful bright flame, viz. wax, tallow and oil, the first and second are mostly used within doors in this country; but the fifth oil, the combustion of which is attended with an unpleasant smell, is mostly used for street lamps and other out of doors purposes; excepting indeed when Argand's lamps are used, for in these the oil gives no bad smell. Oil of olives burns without any offensive smell; therefore much use is made of it for lamps in private houses in those countries where it may be had at a cheap rate, as in Italy, the south of France, &c.

Besides the above, a new material has of late been attempted to be introduced in this country, for the purpose of lighting houses, streets, manufactories, &c. the material is the inflammable gas of coals. Every body must know, that when coals are burning in a common fire place, a flame more or less luminous (according as it is more or less enceumered with incombustible smoke and vapour) issues from them; and they frequently emit some very beautiful streams of flame remarkably bright. All this, as we have already mentioned, arises from the gases which are excreted from the coals by the heat. It was natural to imagine that such gas might be received in proper receivers, and might afterwards be forced out of small apertures, which being lighted might serve, as the flames of candles, to illuminate a room or other place. The trial was easily made, and it was attended with the desired effect. The principle of the apparatus and of the operation is as follows: The coal is placed in large iron vessels, called retorts, to the apertures of which iron pipes are adapted, which terminate in a vessel, or vessel, called gasometers, or receivers, which is inverted in water. The retorts thus charged are placed upon the fire, the heat of which extracts the gas from the coals that are within the retorts, together with an aqueous vapour, a thickish fluid, or tar, &c. These products are conveyed through the above-mentioned pipes under the gasometers where the gas is washed, and remains ready for use. There are then other smaller pipes from the gasometer, which branch out into smaller ramifications, until they terminate into the places where the lights are wanted. The extremities of the pipes have small apertures, out of which the gas issues, and the flames being lighted at those apertures, will burn with a clear and constant flame as long as the supply of gas continues. All the pipes which come from the gasometer
The method of producing the gas being thus contrived, the next step was to determine how far such lights might be employed, consistently with expense, safety, &c. A few shops in London were lighted with it, but the use was soon discontinued, as it was found, principally on account of the unpleasant smell. A proposal, and some attempts were made for lighting some of the streets of London by means of this coal gas; but either the mysterious nature of the propo-

sals, or the expence attending the operation, or some other cause of obstruction, has not as yet allowed the adoption of the plan. Other attempts of the like nature have been made elsewhere, but of their success we have no authentic account, excepting however one, which was laid before the Royal Society by the operator, Mr. Murdoch, and is published in the Philosophical Transactions for the year 1828. The precision with which the particulars are stated in Mr. Murdoch's account, and the essential use of which such statements may be to a vast number of persons, who are now engaged in similar examinations in this new branch of civil economy, induce us to transcribe the most essential part of the account in the present article; referring to add what future improvements may come to our notice to the article Gas Lights.

"These facts and results, Mr. Murdoch says, were made, during the present winter, at the cotton manufacture of Melfi's. Philips and Lee, at Manchester, where the light obtained by the combustion of the gas from coal is used upon a very large scale; the apparatus for its production and application having been prepared by me at the works of Melfi's. Bolton, Watt, and Co. at Soho.

"The whole of the rooms of this cotton mill, which is, I believe, the most extensive in the United Kingdom, as well as its counting-houses and store-rooms, and the adjacent dwelling house of Mr. Lee, are lighted with the gas from coal. The total quantity of light used during the hours of burning has been ascertained, by a comparison of shadows, to be about equal to the light which 2500 mould candles, of six in the pound, would give; each of the candles with which the comparison was made consuming at the rate of 4-10ths of an ounce (175 grains) of tallow per hour.

"The burners are of two kinds: the one is upon the principle of the Argand lamp, and resembles it in appearance; the other is a small curved tube with a conical end, having three circular apertures or perforations, of about a thirtieth of an inch in diameter, one at the point of the cone, and two lateral ones, through which the gas issues, forming three divergent jets of flame, somewhat like a fiver-de-lis. The shape and general appearance of this tube has procured it, among the workmen, the name of the cockspur burner.

"The number of burners employed in all the buildings amounts to 271 Argands, and 633 cockspurs; each of the former giving a light equal to that of four candles of the description above-mentioned, and each of the latter a light equal to two and a quarter of the same candles; making therefore the total of the gas light a little more than equal to that of 2500 candles. When thus regulated, the whole of the above burners require an hourly supply of 1250 cubic feet of the gas produced from cannel coal; the superior quality and quantity of the gas produced from that material having given it a decided preference in this situation over every other coal, notwithstanding its higher price.

"The time during which the gas light is used may, upon an average of the whole year, be rated at least at two hours per day of 24 hours. In some mills, where there is over-work, it will be three hours; and in the few where night work is still continued nearly twelve hours. But taking two hours per day as the common average throughout the year, the consumption in Melfi's. Philips' and Lee's mill will be 1500 \( \times \) 2 = 2500 cubic feet of gas per day; to produce which 700 weight of cannel coal is required in the retort. The price of the best Wigan cannel (the fort used) is 15\( d. \) per cwt. (1.47, per ton) delivered at the mill, or at about eight shillings for the seven hundred weight. Multiplying by the number of working days in the year (313), the annual consumption of cannel will be 110 tons, and its coal 15.7.

"About one-third of the above quantity, or 40 tons of good common coal, value ten shillings per ton, is required for fuel to heat the retorts, the annual amount of which is 227.

"The 110 tons of cannel coal, when distilled, produce about 21 tons of good coal, which is sold upon the spot at 1s. 4d. per cwt. and will therefore amount annually to the sum of 93.

"The quantity of tar produced from each ton of cannel coal is from 11 to 12 ale gallons, making a total annual produce of about 1270 ale gallons, which not having been yet sold, I cannot determine its value.

"The interest of the capital expended in the necessary apparatus and buildings, together with what is considered as an ample allowance for wear and tear, is fixed by Mr. Lee at about 55\( d. \) per annum, in which some allowance is made for this apparatus being made upon a scale adequate to the supply of a still greater quantity of light, than he has occasion to make use of.

"He is of opinion that the cost of attendance upon candles would be as much, if not more, than upon the gas apparatus; so that, in forming the comparison, nothing need be flouted upon that score, on either side.

"The economical statement for one year, then, stands thus:

\[
\begin{array}{ll}
\text{Coal of 110 tons of cannel coal} & \text{£125} \\

"If the comparison were made upon an average of three hours per day, the advantage would be still more in favour of the gas light.

"At first, some inconvenience was experienced from the smell of the unconfined, or imperfectly purged gas, which, may in a great measure be attributed to the introduction of successive improvements in the contrivance of the apparatus, as the work proceeded. But since its completion, and since the persons to whose care it is confided have been
F L A M E.

Some familiar with its management, this inconvenience has been obviated, not only in the mill, but also in Mr. Lee's house, which is most brilliantly illuminated with it, to the exclusion of every other species of artificial light.

"The peculiar softness and cleanliness of this light, with its almost unvarying intensity, have brought it into great favour with the work-people. And its being free from the inconvenience and danger resulting from the spars and frequent snuffing of candles, is a circumstance of material importance, as tending to diminish the hazard of fire, to which cotton mills are known to be much exposed."

In the burning of candles or oil lamps, the heat of the flame softens and attenuates the materials, and converts them partly into an elastic fluid which takes fire successively and maintains the flame. In the burning of coals, wood, turf, &c. various gasses, as well as vapours, are extracted from them, but these products are not all combustible; therefore those which are not combustible tend to check the activity of the flame which arises from the combustion of the others. The gasses which are principally extracted from the above-mentioned materials are hydrogen gas, azotic gas, and carbonic acid gas; the first of which only is highly inflammable in all its combinations; and it is hardly ever yielded pure by any of the above-mentioned materials. Its usual combinations are either with sulphur, or with carbon, or with phosphorus; hence it derives the denominations of sulphurated, carbureted, or phosphorated, hydrogen gas.

The flames of different combustibles are not all attended with an equal production of heat and light. Sulphur burns with a weak flame; phosphorus with a very dense one. Spirit of wine burns with a very light flame in point of light, but a very powerful one with respect to heat; so that if an Argand Lamp be charged with oil, and another similar lamp be charged with spirit of wine, the flame of the latter will not have a quarter of the light of the other, but it gives more than twice as much heat as the other. The flame of spirit of wine is not accompanied with any smoke. The flame of ether is denser, but produces smoke. The flame of spirit of turpentine is attended with a very dense smoke. The flame of pure hydrogen is very faint. This flame of hydrogen produces a remarkable phenomenon, which deserves to be mentioned in this place.

If a phial, containing the materials proper for the production of hydrogen gas, (viz. iron filings and diluted sulphuric acid,) be furnished with a tube having a small aperture for the exit of a stream of the gas, and if this stream be lighted, a flame will continue to burn at that aperture as long as the materials continue to give out the gas. Now, if a glass tube of about an inch in diameter, and about a foot long, be held straight up, with its aperture just over the above-mentioned flame, a sound will be heard, somewhat like a delicate sound of an organ pipe. This sound varies according to the size of the tube. No very satisfactory explanation has, as yet, been given of this singular phenomenon.

The flames of volatile combustibles that are more compound in their nature, vary considerably with respect to the intensities of their heat and light. A curious phenomenon takes place in uniting the flames of two candles, viz. the light is considerably increased. Let a person hold two candles before his face, at first separate, and then with their flames joined. Upon the junction of the two flames, his face will appear much more illuminated than it was before.

It is conjectured," Dr. Priestley says, "that the union of the two flames produces a greater degree of heat, and that this causes a farther attenuation of the vapour, and a more copious emission of the particles of which light consists."

The effects which we have just been enumerating are such as take place in common atmospheric air.

The various colours of the flames of simple and compound bodies are likewise highly deserving the attention of philosophers. Certain combustibles, even of the purest kind, burn with flames having peculiar tints; but much stronger colours may be communicated to their flames by the admixture of various substances, especially of those that are of an earthy or metallic nature.

The flame of a common candle is far from being of an uniform colour. The lowest part of the flame is always blue; and when the flame is sufficiently elongated, so as to be ready to smoke, the tip is always red.

As for the colours of flames that arise from coals, wood, and other usual combustibles, their variety, which hardly amounts to a few shades of red, or purple, intermixed with the bright white light, seems principally to arise from the greater or less admixture of aqueous vapour, dense smoke, or in short, of other incombusible products.

Spirit of wine burns with a blueish flame. The flame of sulphur has nearly the same tinge. The flame of zinc is of a bright white. The flame of most of the preparations of copper, or of the substances with which they are mixed, is greenish-blue. Spirit of wine, mixed with common salt, burns with a very unpleasant effect, as may be experienced by looking at the spectators who are illuminated by such light. If a spoonful of spirit of wine and a little boracic acid be stirred together in a cup, and then be inflamed, the flame will be beautifully green. If the spirit of wine be mixed with a little iron oxide in powder, or with any of its saline preparations, it will afterwards, on being inflamed, burn with a red, or rather purple flame. If the spirit of wine be mixed with barytes, its flame will have a beautiful yellow appearance. Such are the principal means of colouring flames, the admixture of various other substances will also impart some shades of colour to flaming bodies, but not nearly so strong as the above.

Some years ago an elegant and curious exhibition, under the title of "Philosophical Fire-works," was shewn in London by an industrious foreigner, named Diller. The exhibition consisted of the flames of certain gasses or vapours which issued out of a variety of small apertures at the ends of short tubes, which were disposed in the forms of wheels, pyramids, spirals, tridents, &c. Out of these apertures the flames were gradually made to increase and decrease alternately; so that sometimes the room looked as bright as if it were illuminated by the sun, and at other times the flames would be barely discerned. But the most pleasing effect arose from the colours of these flames, as there were beautiful greens, yellows, reds, purples, &c. Mr. Diller died, and it seems that he did not leave the secret of the preparations behind him; for no one has since been able to exhibit anything equal to those philosophical fire-works. The smell of ether, which predominated in the exhibition room, seemed to shew that Mr. Diller made great use of that liquid.

The combustible vapours and gasses are not all inflamed with equal readiness. Hydrogen gas may be inflamed not only by the contact of another flaming body, but even by a very small electric spark. An electric spark a little more powerful will set fire to spirit of wine and ether, especially when those fluids are a little warm. Spirit of turpentine, and some effential oils may be inflamed, not only by the above-mentioned means, but even by the action of cold acids. Put about a spoon full of oil of turpentine in a cup, and pour over it about half that quantity of strong nitrous acid previously mixed with a few drops of sulphuric acid. The oil
of turpentine will immediately burst out into a flame merely in conformance of the action of the acid.

The thick fat oils must be heated to a considerable degree, and in that state a flaming body must be brought in contact with their vapour, before they will be inflamed. Even when raised to a very high temperature, they seldom will of themselves burst out in a flame. If a vessel containing oil be set upon a fire, a smoke or vapour begins to rise from it, which grows by degrees denser and denser; and at last it begins to shine in some places near the surface of the oil, somewhat like an electric light; yet it does not flame; but if in this state a flaming body, like a candle, &c., be brought within the vapour, the latter will be instantly inflamed, breaking out with a fort of explosion, and will continue to burn until the oil is in great measure consumed.

Besides the use of their light, the flames of candles, and especially of lamps, are often used for the sake of the uniform heat which they give; and when no very great degree of heat is wanted, the use of such flames must be allowed to be incomparably more commodious, and more economical than a common fire. The enameller, the mineralogist, and the philosophical instrument makers, make great use of the heat of candles and lamps, the flames of which they frequently urge by means of the blow-pipe. An Argand lamp, especially when charged with spirit of wine, (for which purpose, however, the lamp must be made in a particular manner,) instead of oil, forms a pretty powerful furnace for small dilatations, decoctions, &c., but even the flame of a single common lamp is sufficient for a great variety of delicate purposes.

The word flame, besides its true meaning, which we have already explained, and which denotes the combustion of a volatile combustible body attended with the emission of heat and light, has often been indiscriminately applied to every kind of luminous appearance, provided its light had a pretty evident degree of intensity. Thus all phosphorescent bodies, electrical light, northern lights, &c., have been called flames by a variety of writers. Certain phenomena really have much the appearance of true flames; yet their real nature has not been sufficiently investigated. Thus the ignis fatuus, or Jack-a-lantern, is supposed to be nothing more than phosphorated hydrogen, which being extricated from certain materials in particular places, comes out of the ground, and burns on the surface of it; for it is a property of that gas to take fire of itself; the moment it comes in contact with the air, it burns. The nature of those appearances in the sky, which have been called flames, is mostly unknown to us. See Meteors, and Ignis fatuus.

By some authors, flame is defined to be light emitted from fire; by others, who have followed Newton, flame is said to be a vapour heated red-hot; for Newton in his Optics says, "Is not a flame a vapour, fume, or exhalation heated red-hot, that is, so hot as to shine? For bodies do not flame without emitting a copious fume, and this fume burns in the flame."

With respect to the first definition, we imagine that the preceding part of the present article has clearly shown that not all the light which is emitted from a fire is flame; and such for instance is the light emitted from a red-hot cinder, or of a coal nearly exhausted of its gas. As for sir I. Newton's query, it may be fairly said, that the state of chemical knowledge at his time could not furnish him with better ideas respecting the nature of flame.

Flames, Vital, Flamma, or Flammula vitalis, a fine, warm, igneous subsance, suppos'd by many, both of the ancients and moderns, to reside in the hearts of animals, as necessary to life, or rather as that which constitutes life itself.

To the preservation of this flame they suppose air as necessary as it is to the preservation of common flame; and hence they ascribe the necessity of respiration to animal life.

Mr. Boyle, by experiments in an exhausted receiver, found that the vital flame of animals, if life may be so called, adheres or outflashes the flame of spirit of wine, or of a wax or tallow candle, &c. Some animals would remain alive and well in vacuo for three or four minutes, whereas no common flame would last there one minute. The light of the glow-worms, he found, would not chiefly be destroyed by exhausting the air, and retrieved again upon its re-admission. Dr. Quincy could find nothing more in the notion of vital flame than the natural warmth, which is the effect of a circulating blood, and which is always as its velocity. See Animal Heat.

Flameel, or Flamel, Bertholet, in Biography, a painter of historical subjects, born at Liege in 1614. He began his studies in Flanders, but at the age of 24, he went into Italy to cultivate his talents by a view of the works of the renowned painters of that country. He took up his residence in Rome, there copying the best works of the great masters. He soon acquired a reputation which recommended him to the court of Florence, to which the grand duke invited him, and there employed him in several works, the execution of which acquired for him the estimation of that prince, and the applause of the public. In returning from hence homewards, after an absence of nine years, he went to Paris, and there painted, in the cupola of the church of the bare-footed Carmelites, Elijah ascending to heaven, and Elisha below endeavouring to catch the falling mantle of the prophet, thus miraculously borne from the earth.

At Liege he was received with great warmth, and to confirm the high opinion which his countrymen had conceived of his merit, he painted a crucifixion for the collegiate church of St. John, in which he introduced a great number of figures with great propriety and perspicacity. He also painted, in St. Paul's church, the conversion of that saint. And in the cathedral of the city another picture, representing the resurrection of Lazarus.

The chief of his life is a melancholy instance of the frail tenure on which man holds either his mental or bodily capacities. Notwithstanding that wealth, reputation, and fame attended him, he fell, unaccountably, into melancholy, and dejection of spirits, which incessantly oppressed him, till ultimately he funk under it. It was by many supposed to be owing to poison given him by an intimate friend named Brinivilliers, but there is no proof of that supposition being true. He died in 1675, aged 61.

By his residence in Rome, he adopted the taste of design of that school, being careful in his selection of objects, and correct in the representation of them. He introduced into his pictures a great deal of architecture, in which he was a proficient; he had great knowledge also of antiquities, and was careful in observing the costume; these, united with a lively imagination, render his works very interesting.

Flamen, among the ancient Romans, was a priest or minister of sacrificers.

There were as many kinds of flamen at Rome as there were gods who had priests and sacrificers offered them. Romulus and Numa, at first, only instituted three: one for Jupiter, called flamen Diator; another for Mars, called
The FLAMEN MARITALLVS; and a third for Romulus or Quirinus, called FLAMEN QUIRINALIS. Plutarch and Dionysius Halicarnassianus maintain, that Numa created only the first, in honour of Romulus; but Livy affirme, that Romulus had instituted only the first, and that the two others were added by Numa; and Varro speaks in the plural number of the flamines instituted by Numa. In after-times two more were added, which made the number of flamines fifteen.

The three first were taken from among the patricians, and were held of a rank and distinction superior to the rest. They were called greater flamines, flamines majoris, in contradistinction to the other twelve, who were chosen from among the plebeians, and were therefore called lesser flamines, flamines minores. The flamens Dialis, or of Jupiter, was the first instituted, and held in the greatest repute. He bore a peculiar ornament on his head, called albagalerus, which was made of the skin of a white victim sacrificed to Jupiter.

One of these priests revived an ancient pretention to a seat in the senate in right of his office, which, by the indulgence of his predecessors, had not been claimed or enjoyed for many generations. The pretor rejected his claim, nor would suffer him to sit in that assembly; but upon his appeal to the tribunes of the people, that is, to the people, his right was confirmed, and he was allowed to take his place as a senator. Liv. xxvii. 6. Middlet. of Rom. Sen. P. 40.

The cap worn by the priest was called flamum or apex. It was made of a fleece, skin, with the wool on; to which was fastened a little branch of an olive-tree. That of the flamens of Jupiter ended in a point called tutulus. It was tied under the chin with strings; but in the summer-time it was only a woolen thread tied round the head, it being prohibited them ever to appear quite bare-headed. And hence, according to Tullius, came their denomination of flamai, viz. from flamem or filum, thread.

Though the flamines bore one common appellation, yet did not they constitute any company or college. Each god had his several sacrifices, feasts, and ceremonies a-part; nor had one flamens any relation to another, only they were all subordinate to the pontifex maximus. Anius Gallus affirms, that they were created by the people in the comitia curiata; but the pontifex maximus afterwards consecrated them. Their priesthood, called flammatius, was perpetual, though on some occasions they might be deposed.

The names of the several flamines are as follow: the three great flamines, as already observed, were the flamens Dialis, flamens Martialis, and flamens Quirinalis; the twelve lesser were the flamens Carmentalis, or priest of the goddess Carmenta, mentioned by Cicero in his Brutus; flamens Faber, or priest of the god Falerus, a name whose origin, Varro olorwes, is not known; flamens Florialis, or of the goddess Flora; flamens Furialis, whose etymology is not known; flamens Ilevicalis; flamens Lucinaris; flamens Palatilis, whom some moderns will have to be the priest of the goddesses that presided over the patuam, though Varro owns himself at a loss for its original; flamens Pomonalis, or of Pomona, goddess of fruits; flamens Virbius, or of the god Virbius, whom some take for the same with Hippolytus; flamens Vulcanales, or of Vulcan; and flamens Volturinalis, or of the god Volturinus. Some authors also speak of the flamens Hadrianus, or priest of Hadrian; flamens Iulii Cesaris; of Julius Cesar; and flamens Auguiulais; and Commodus likewise had a flamens created under the title of flamens Herculanens Commodianus.

They had also their flavia or flaminices, who were wives of the flamines, or the priestesses of the deities. In an ancient marble, quoted by Gruter, p. cccclx. n. 9, the word flavia is used for priestesses; and in the same author, p. cccviii. n. 3, the priestesses of the goddesses Peronia is called flamifera, that is, flavia, or flapinica. The flavia bore the flamens ornament on her head with the flamens. She had also the same form of office with her husband, as flavinae Dialis, Martialis, &c.

FLAMETTE, in Conchology, a name given by the French writers to a species of chama or shell-fish of the bilva kind, with its shells always more or less open; this species is as hot as pepper to the taste.

FLAMINGO, in Ornithology. See Phoenicopterus ruber.

FLAMINIAN WAYS, one of the Roman ways, which, as it is corrected from the Itineraries and best modern maps by d'Anville, may be thus slated: Rome to Narri, 51 Roman miles; Terini, 57; Spoleto, 75; Foligno, 88; Nocera, 103; Cagli, 143; Intericia, 159; Possobromone, 169; Fano, 176; Pelaro, 184; Rimini, 268; about 189 English miles.

FLAMINIO, Marcantonio, in Biography, was the son of a man of letters, and born at Serravalle in 1498. He was educated with great care by his father, and when he was about fifteen years of age, he was introduced to pope Leo X., who received him very graciously, and in order to put his talents to the trial, caused the youth to dispute on certain questions in the presence of many cardinals, when he acquitted himself so well as to excite the surprise and admiration of all who heard him. His success induced his father to leave him to pursue his own fortune. The young man went to Naples, and from thence to Urbino, and in both places he had favourable opportunities of exhibiting the great power with which he was gifted. His father, dreading the influence of flattery, removed him to Bologna, to the pursuit of severer studies. In 1523, he revisited Rome, and from thence he went to Genoa, and was elected one of the academy. After this he passed into the service of Giberti, with whom he resided at Padua, and then, for some years, at Verona. His patron presented him with a farm situated on the back of Lago di Garda, where he spent much of his leisure time, and wrote a Latin paraphrase of Aristotle's Metaphysics, which was printed at Basle in the year 1557. In the following year, being in an ill state of health, he went to Naples, in which city he remained till 1551. Here his health was perfectly restored, and here, by the conversation which he had with some favourite of the Reformation, he was himself almost a convert. On his return from Naples he spent some time at Viterbo with cardinal Pole, who took great pains to restore him to the orthodoxy faith. In 1543, he was at Trent with the cardinal, and was after this offered the high post of secretary to the council of legates, which he declined. He was, however, the constant attendant and friend of cardinal Pole, and greatly beloved by many other cardinals and great men of his time. After a tedious illness he died at the house of his patron in 1550. His death was universally lamented, and his contemporaries are lavish in their praises, as well for the goodness of his disposition and his Christian virtues, as the depth of his erudition and the elegance of his genius. "His works," says his biographer, "appear to be dictated not by the understanding but by the heart." His poems rank him with the best poets of the Latin school. Of these, some in his early youth partake of the licence of the times, but the admonitions of his father and the febirdity of his own disposition called him to
to more serious strains. The greater part of the "Carmina quinque illustrium poetarum" consists of the works of Flaminio. His elegant poetical paraphrases of thirty psalms, published a few years before his death, and his Italian letters, are very highly esteemed. Some years after his decease his orthodoxy was suspected, his works prohibited, and it was intended to dig up his body for the purpose of committing it to the flames; but wiser and more deliberate councils determined otherwise. Moretti.

FLAMINUS, or FLAMININUS, Titus Quinctius, an eminent Roman, was born about the year 229 before Christ. He was brought up to the practice of arms, and acquired himself so well in several things which he undertook, that he was in early life appointed to the command of important expeditions. At the age of 30 he was candidate for the consulship, and was chosen though he had not served any of the inferior and preparatory offices in the state. He obtained, by lot, the conduct of the war in Macedonia; and performed, in various parts of Greece, many exploits recorded in history, till at length he treated with Philip, and made a peace on condition that the king should withdraw all his troops from the Greek towns. Commissioners were sent from Rome to affix Flaminus in disapproving of his conquests: these wished Roman garrisons to be kept at Corinth and other places, regarded then as the keys of the country, but the conqueror persuaded them to content to the full and complete liberation of Greece from foreign dominion. The decree was proclaimed during the Ithomian games. A vast multitude assembled from all parts, uncertain of their future fate, and filled with the utmost anxiety for themselves and their country. Silence was proclaimed by the found of a trumpet, and a herald advanced into the middle of the arena, where, in the name of the Roman people and of the proconsul Flaminus, he declared by name all those cities and states of Greece free which had been possessed by Philip. The proclamation was repeated, and the people, as with one voice, rent the skies with their shouts: so tremendous was the noise, that the birds were said to have been struck to the ground by the concussion of the air, and Flaminus himself was in danger of suffocation from the people who rushed upon him to kiss his hand in gratitude for his kindness. To him it was a glorious day; but the Romans refused to ratify the decree, and in a short time they dictated what terms they chose to the Greek republics, which now were declared free by Flaminus. The confiding left Greece with many tokens of gratitude from the people, but with none which he so highly prized as a present of 1200 Romans made captive in the war with Hannibal, who had been sold for slaves in the Greek states, and whom the Achaeans had carefully collected and redeemed, in order to send back with him. In the habits of manumitted slaves those men followed the chariot of their benefactor at the splendid triumph granted him on his return. Flaminus was afterwards long kept as a resident in Greece; the attachment of the nation to him, and his accurate knowledge of the views and interests of the several states, rendering him very useful as a negotiator. About the year 190 B.C. he was created cenfo at Rome, after which he was employed as an ambassador to Prussia, king of Bithynia, whom he persuaded to violate the laws of hospitality in delivering up Hannibal, who had taken refuge in his court, but the veteran soldiery prevented the treachery by taking poison. This is the last recorded transaction in which Flaminus engaged. Universal History. Plutarch.

FLAMMA Jovis, a name given by many writers to a plant of the elenmieris or virgin's bower kind, called by the Greek writers philocous.

FLAMMULA, or FLAMULA, under the Eastern Empire, was a kind of flag terminating in a point somewhat like a flame, serving as a mark or badge to distinguish the followers of the several companies, battalions, regiments, &c. In Greek it was called 6xamnus; it was sometimes placed on the caque, sometimes on the cuirafs, and sometimes at the end or tip of the pike, &c.

The emperor Maurice ordered that the flammeul of each division should be of a particular colour, to distinguish them from the other battalions or brigades.

They used to lay aside the flammeul before an engagement, lest it should prove an incumbrance. The cavalry laid also flammeul on their horses, to distinguish the troops they belonged to.

FLAMMULA, in Botany, a name given by some authors to a particular species of the crow-foot, commonly called the ranunculus flammeus.

FLAMMULA Auri, in Natural History, a name given by Dr. Woodward, and others, to those small pieces of gold found among the sands of rivers in some places. They are sometimes found in roundish pieces, but more usually in their shining flakes, whence the name flammeul seems to have been given them, as being very bright and glossy. This form of gold is pure and malleable, and loses scarcely any part of its weight in fusion.

The gold dust, as it is called, which is brought from Guiney, is much of this kind; its particles are usually very small, though sometimes lumps of the size of a pea or hordeon bean are found, and sometimes masses of an irregular figure of three or four ounces weight: but these lose the name of flammeul when they become so thick and solid, and so large, and are called by the merchants rock-gold.

FLAMSTEED, John, in Biography, an eminent English astronomer, was born at Denby, in Derbyshire, in the year 1646. He received his classical education at the free school at Derby, and it was intended that he should pursue his studies at the university, but a very severe illness at the age of 14, when he had attained the highest place in the school, rendered it necessary for his friends to change their original plan with regard to his future pursuits. Soon after he had quitted the grammar school he met with Sampson's astrologer's work, intitled "Diurnals," which he read with delight, and some parts of which he immediately translated. He now sought for other treatises connected with the same subject, among which was Street's "Astronomia Carolina," from this he learned the method of calculating eclipses and the places of the planets. In 1669, having calculated an eclipse of the sun, that was omitted in the ephemeris for the following year, he sent this, with other astronomical speculations, to lord Bruncker, president of the Royal Society, who laid them before that learned body, by whom they were greatly approved. From this period he kept up a correspondence on literary and scientific subjects with many of the most learned men of his time. In 1670, his father made him an offer of taking a journey to London, that he might become personally known to his ingenious and learned correspondents, which he gladly accepted. He was now introduced to Mrs. Celli, Mr. Oldenburg, and to Jonas Moore, the latter of whom became a most valuable friend and patron to Mr. Flamstead. On his return he passed through Cambridge, visited Dr. Barrow, Mr. Hooke, Newton, and other learned men; and entered himself a student of Jesus college. Mr. Flam-
FLA

flood, applying himself most vigorously to the study of
astronomy, wrote in the year 1673 a treatise on the true
and apparent diameters of all the planets, which Sir Isaac
Newton made use of in the 4th book of his Principia. He
wrote also on other subjects, as the tides, which were
more popular and adapted to practical uses, and of which
one was presented to the king. To whom, likewise, by
means of his friend Sir Jonas Moore, he presented a pair
of barometers, with directions for their use. These were new
instruments at that period, and excited the attention of
the monarch and of the nobility, to whose patronage he had
been carnesly recommended. Mr. Flamsteed now deter-
mine to take orders, and was ordained in 1673 by bishop
Gunning; but he did not obtain any preferment in the
church for several years. Sir Jonas, however, prevailed
on the king to erect a new office for him, viz. that of
astronomer-royal, and the foundation of the Royal Obser-
vatory at Greenwich was built and named after him, Flam-
steed House. In 1681, his work intitled "The Doctrine
of the Sphere," was published by Sir Jonas Moore in his
"System of Mathematics;" and, in 1684, he was presented
with the living of Dursford in Surrey, the only instance
of preferment to which he attained, notwithstanding the high
estimation in which he was held by persons of the first rank
among his contemporaries. He now maintained a close and
constant correspondence with the immortal Newton, with
Halley, and all the great men of that illustrious age, and
among his foreign correspondents was the celebrated
Caffini, who was held in the highest respect by him.
To any and all his friends he was ever ready to give assistance
in facilitating their studies, and he took pleasure in contrib-
uting, by his sagacious and honest, to the extension of their
reputation. He spent the remainder of his life in pro-
fecuting his labours in the improvement of astronomy with
unwearied exertion and activity, and died at the end of the
year 1719, at the age of 73. He published many small
tractes, a vast number of papers in the Philosophical Trans-
actions, in almost every volume from the fourth to the
twenty-ninth. But his great work, and that on which his
celebrity depends, is intitled "Historia Cælestis Britannica;
" in three volumes. The first of which contains the ob-
ervations of Mr. Gascoigne, taken at Middleton in York-
shire; and likewise those made by Mr. Flamsteed at Derby,
between the years 1638 and 1643, with tables, &c.
done at the Royal Observatory between the years 1675 and
1689.

The second volume contains his observations, made with
a capitol telescope, on the zenith distances of the fixed
stars, sun, moon, and planets, with their tranits over the
meridian; also notes and observations on the diameters of
the fun and moon, with their eclipses, and those of Jupi-
ter's satellites, between the years 1669 and 1719. The
third volume comprises a catalogue of the right ascensions,
polar distances, longitudes, and magnitudes of nearly 3000
fixed stars. The preface to this volume contains an account
of all the astronomical observations made before his time,
with a description of the instruments employed, and much
other curious and highly important matter. The printing
of this noble work was not finished at the time of our
author's death, and the care necessary to its completion de-
volved on Mr. James Hodgson, by whom it was published
in the year 1725. Few men posseved more zeal and appli-
cation in the pursuit of scientifick knowledge than the first
astronomer-royal; and scarcely any man ever attained to
higher respect among his contemporaries. In common life
he was free, easy of access, and pleased with the company

of those who with scientifick research could unite their share

FLANCH, Flanque, or Flaque, in Heraldry, an
ordinary form'd by an arched line, which begins at the
corners of the chief, and ends in the base of the escut-
cheon.

He beareth ermin two flanches vert. Flanches are al-
ways borne by pairs.

Leigh makes flanque and flaque two distinct bearings,
whereof the former is more beant than the latter; but
Gibbon judiciously makes them but one, which he calls
flaque.

FLANCONNADE, in Fencing, is the action of drop-
ping the point of your sword under your adversary's hilt,
in seizing with force the feele or foible of his blade; which,
binding without quitting it, form the parade in octave, and
then throw in your thrust. This thrill is seldom practised,
except on favourable occasions, when the adversary holds
his sword low on guard.

FLANDERS, in Geography, a maritime province of
the Netherlands, was formerly very considerable, and
bounded on the north by the mouth of the Scheldt and the
German ocean, on the east by Brabant and Hainaut, on the south
by Hainaut and a part of France, formerly called Artois and
Picardy, and on the west by the English channel and Artois.
Its greatest length is estimated at about 60 miles, and its
breadth about 50. It contained 30 cities or walled towns, a
great number of market towns, 1544 villages, and several
religious houses. Flanders was generally divided into
Austrian, French, and Dutch Flanders. The first extended
from the sea to the Dender, being bounded on the north by
Dutch Flanders, on the east by Brabant, on the south by
French Flanders, and on the west by the channel, and con-
verted several considerable cities, as Ghent, Bruges, Ostend,
Oudenard, Dendermond, Nieuport, Furnes, Dixmude,
Courtray, Ypres, Tournay, &c. &c. French Flanders con-
tained Lille, Dunkirk, Gravelines, Cassel, &c. &c. The
third, or Dutch Flanders, bordering on the Scheldt, towards
its mouth, contains the towns of Hull, Axel, Bouchout,
Assenede, Ardenburg, &c.; and this seems to be the only
part which retains the name of Flanders. By the treaty
of Formio, A.D. 1797, the whole of Austrian Flanders was
annexed to the dominions of France, and converted into the
departments of the Lys and the Scheldt. The climate of
this country is temperate and balustrous; the soil in gen-
eral is fertile and fit for tillage; and in some places it is
uncommonly fertile. The land produces all kinds of grain
and vegetables. This is a very considerable commodity, and
has greatly contributed to the wealth of the country. The
patter grounds are excellent, and furnish a valuable breed
of cattle, which yield rich cheese and butter. The breed of
horses and sheep is also considerable. The Flemings were at
one time the principal manufacturers of Europe; and by
them the English were taught the art of weaving, and pro-
ably that of agriculture. Their trade was also very ex-
tensive. The most beautiful table linen is still the manufac-
ture of this country, and its lace is superior to every other.
The principal rivers are the Scheldt and the Lys.

FLANDERS, a town of New Jersey; 23 miles N.N.W.
of New Brunswick.

FLANEL, or Flannel, a kind of flight, loofe, woollen
stuff, not quilted, but very warm, compofed of a woof and
warp, and woven on a loom with two treadles, alter the man-
ner of bays. As flannel is a bad conductor of heat, it must
evidently form an useful garment in cold weather; its un-
fitness for conducting heat is obvious from its lax structure;
for the fibres of wool touch each other slightly, and therefore the heat moves slowly through the interfaces, which, being filled with air, afford little affinity in carrying it off. Count Rumford made many experiments on this subject; whence it should seem, that though linen, which readily receives humidity from the atmosphere, appears to possess a greater degree of attraction with respect to water than other substances; yet those substances which receive water in its unelastic form with the greatest ease, or are most easily moistened, do not, in all cases, attract the moisture of the atmosphere with the greatest avidity. "Perhaps," says he, the apparent dampness of linen to the touch arises more from the cafe with which that substance parts with the water it contains, than from the quantity of water it actually holds; in the same manner as a body appears hot to the touch in consequence of its parting freely with its heat, while another body, which is really at the same temperature, but which withholds its heat with great obstinacy, affects the sense of feeling much less violently. It is well known that woollen clothes, such as flannels, &c. worn next the skin, greatly promote inelastic perspiration. May not this arise principally from the strong attraction which subsists between wool and the watery vapour which is continually suffusing from the human body? That it does not depend entirely on the warmth of that covering is clear; for the same degree of warmth produced by wearing more clothing of a different kind does not produce the same effect. The perspiration of the human body being absorbed by a covering of flannel, it is immediately distributed through the whole thickness of that substance, and by that means exposed by a very large surface to be carried off by the atmosphere; and the loss of this watery vapour which the flannel abounds on the one side, by evaporation, being immediately restored to the other, in consequence of the strong attraction between the flannel and this vapour, the pores of the skin are difencumbered, and they are continually surrounded by a dry and exhilarating atmosphere." He expresses his surprise that the custom of wearing flannel next the skin should not have prevailed more universally. He is confident it would prevent a number of disputes; and he thinks there is no greater luxury than the comfortable sensation which arises from wearing it, especially after one is a little accustomcd to it. "It is a mistaken notion," says he, "that it is too warm a clothing for summer. I have worn it in the hottest climates, and at all seasons of the year; and never found the least inconvenience from it. It is the warm bath of perspiration confined by a linen shirt, wet with sweat, which renders the summer heat of southern climates far insupportable; but flannel promotes perspiration, and favours its evaporation; and evaporation, as is well known, produces positive cold."

It has been observed that new flannel, after some time wearing, acquires the property of shining in the dark, but loses it on being washed. Phil. Trans. No. 483. § 7. See Electricity.

FLANK, or FLANC, in the Manege, is applied to the sides of a horse's buttocks, &c.

In a strict sense, the flanks of a horse are the extremities of the belly, where the ribs are wanting, and are below the loins.

The flanks of a horse should be full, and at the top of each a feather. The distance between the last rib and haunch bone, which is properly the flank, should be short, which they term well coupled, such horses being most hardy, and fit to endure labour.

A horse is said to have no flank if the last of the short ribs be at a considerable distance from the haunch bone; as also when his ribs are too much straightened in their compass.

FLANK of an Army, in Military Language, is the exterior point, or part, towards either end of every line, the same as the terminations of the files of a battalion or company are their flanks respectively. It has ever been held among military men of the first importance to preserve the integrity of the flanks, by supporting them in the most effectual manner against every assault. This, however, is not always practicable when opposed to a superior force, unless by the aid of such a formation of the line as may render any such superiority, not extending to more than a fifth or sixth, of less avail than it would obviously be, were the two armies to be drawn up parallel to each other: in such case the greater force must cover a greater extent of ground, and thus be enabled to "out-flank" its opponent. When such an opportunity may offer, it will generally be seen, that while the residue are left upon equal terms, man to man, and gun to gun, the excess of numbers is devoted to such a powerful charge on one flank as should seem to be irreparable. Thus, the attack is either made in column, usually concealed by a body of cavalry until the moment of assault, or an angle is formed in advance, which is called "offering a flank," for the purpose of beating in the flank by an oblique or a circuitous approach to, not only its extremity, but even towards its rear. In such case the lighter body necessarily avails itself of that simple evolution termed "refusing a flank," by throwing back a portion of its extremity in an angular direction, so as to become parallel with the flank "offered" by the stronger party. The first figure, Tactics, Plate II. shews the attack made in column, by an army A, superior on one flank, together with the deploy of the cavalry B, that covered or fixed the manoeuvre towards the flank of the line D, with the view to "turn" it; that is, to beat it in towards the centre, and thereby to throw the whole into confusion. The dotted lines at E shew the change made from D, for the purpose of "refusing a flank," and of thus bringing a column to oppose the charge intended to be made. The village G serves to "cover the flank" from the cavalry that deployed for its attack.

In fig. 2. the line H I K is superior to the line L M N; the former "offers the flank" I O, which the latter renders unavailing (at least so far as lesser can render greater forces) by "refusing a flank" in the direction M P, parallel to I O. This, considered mathematically, will be found sufficient; because, under the supposition that the lines L M and M P are chords of arcs having their common centre somewhere in their rear, it is evident that the parallels H I and I O, being, of course, concentric therewith, but exteriorly situated, must occupy a greater extent, and yet, in effect, not outflank their inner parallels. We do not mean to calculate that the superior force is not still the superior force, but only to shew how the lighter body can, by a judicious arrangement, either render that superiority less availing, or, perhaps, induce to a break near the centre, whereby an opening may offer for the cavalry of the weaker army to dash in so as to divide the enemy's line, and to facilitate the defeat of at least one wing.

FLANK of a Balloon, in Fortification, is that part which forms an angle, generally of about 110°, or in flat baloons of 130°, with the contiguous face. The flank of a balloon is generally intended to defend the face of the other balloon standing at the further extremity of the same curtain; therefore usually stands at right angles, or nearly so, therewith: hence it is necessary to shew the flanks of the contiguous baloons, both right and left, before the flanked angle.
F L A

angle of that battalion flanking between them, though perfectly braced, can with propriety be formed.

Flank, Lawn, covered, or retired, is the platform of the cememt which lies hid in the battalion; otherwise called the orillon.

Flank Fichout, is that from whence a cannon playing, fireth bullets directly in the face of the opposite battalion.

Flank Rear, or right, is the point from whence the line of defence begins, from the conjunction of which with the curtain, the first only reft the face of the next battalion, which happens when the face cannot be discovered but from the flank alone.

Flanks, Simple, are lines going from the angle of the shoulder to the curtain, whole chief office is for the defence of the moat and place.

Flank walls, in Engineering, are the same with wings or return walls of a lock or bridge. See CAVAL.

FLANKED, Flanquis, is used by the French heralds to express our party per faltier; that is, when the field is divided into four parts, after the manner of an X.

Though Colombiure uses the term in another sense, which appears more natural, viz., for the taking of flankers or rounding fections out of the sides of the enclofes; the firt from the angles of it, the latter in straight lines, forming an angle at the fets, without making any faltier.

Flanked Angle, in fortification, is the angle formed by the two faces of the battalion, and which of courfe forms the point of the battalion.

Flanked Line of Defence. See Angle and Line of Defence.

Flanked Tenaille, is called also tenaille.

FLANKING, in the general, is the act of discovering and firing upon the side of a place, body, battalion, &c.

To flank a place, is to dispose a place or other work in such a manner as that there shall be no part of the place but what may be played on, both in front and rear.

Any fortification that has no defence but just right forwards is faulty; and to render it complete, one part ought to be made to flank the other. Hence the curtain is always the strongest part of any place, because it is flanked at each end.

Battalions also are faid to be flanked by the wings of the cavalry. A house is sometimes faid to be flanked with two pavilions, or two galleries, meaning it has a gallery, &c. on each fide.

Flanking Angle. See Angle.

Flanking Batteries, are fuch as defend each other mutu- rally, such as the face of a ravine, and the contiguous face of its linette; which fland nearly at right angles, and form a re-entering angle. In general, the term is applied only to that battery whose fire, when direct, grazes the front of the work it is to defend, as fhewn above in defcribing the flank of a battalion; but in that infatuation the defecnes do not afford reciprocal support. Works that are not flanked by others can be ftrong only in confequence of natural advantages. See Field Fortification, and Construction, Military.

Flanking Line of Defence. See Line of Defence.

FLANNAN ISLANDS, in Geography, or Seven Hunters, a group of small uninhabited islands in the North Sea, about 17 miles N.W. from the island of Lewis. They yield good paffure for sheep. On the largel are the ruins of a chapel dedicated to St. Flannan. N. lat. 58° 26'. W. long. 7° 25'.

FLANSKER, a small island on the E. side of the gulf of Bothnia. N. lat. 63° 24'. E. long. 21° 26'.

FLASHERS, in Engineering, are a kind of strings erected upon navigable rivers to raise the water upon any shoals therein, while the vessels or craft are passing. See CANAL.

FLASK, in the Artillery. See Powder flask.

Flats, Flats, a bearing more properly called flanque or flank.

FLASKET, in Geography, an island near the coast of Norway, 88 miles S.W. of Drammen.

FLAT, is a character in Music, expressed by a small b, of which the effect is lowering the note to which it is added a semitone minor. Guido d'Arezzo having given names to six sounds of the octave of which he constituted his celebrated hexachord, left the seventh of the natural scale unprovided with any other appellation than the letter b, which is wanted in the male hexachord, when the same sound becomes the fourth of the key of F. (See Hexachords and Musical Characters.) Flats on keyd instruments are the nominal half notes below, that is, on the left hand of the natural notes, as sharps are on the right hand. There are two ways of using flats, the one accidental, which has no effect beyond the angle bar in which it occurs; the other is the flat or flats placed at the clef, in the beginning of a movement which affect all the notes on the same line or space throughout a movement, unless accidentally discharged by a natural, &c. The placing the flats at the clef is not arbitrary, as the first necessarily is on B, the second on E, the fourth above or 5th below, &c. in the following order:

\[ \text{Bb} \quad \text{Eb} \quad \text{Ab} \quad \text{Db} \quad \text{Gb} \]

For these five flats upon keyd instruments, there are five short keys; flats, however, sometimes occur in C and G, but for these the two long keys are obliged to be used of B and E natural, the two half notes below C and F natural. If it is necessary in practice to lower any found already flat at the clef a semitone, it is done by double flats; as B is Bbb, E double flat D natural, &c. See Scales, Characters, and Transpositions.

Flat Third. See Minor Third.

Flat Key. See Minor Third.

Flat, Double, is a term used where a note already flat is required to be again depressed by a half-note, and is marked thus Bbb or Bb; the quantity or exact depressing effect of which will only be constant in the equal temperament, and in all other systems of temperament will partake of all the uncertainty which we have shewn to prevail with regard to B. See Flat.

Flats are a kind of additional or half-notes contrived, &c. together with sharps, to remedy the defects of musical instruments.

The natural scale of music being limited to fixed sounds, and adjusted to an instrument, the instrument will be found defective in several points; as particularly, in that we can only proceed from any note by one particular order of degrees; that for this reason we cannot find any interval required from any note or letter upwards or downwards; and that a long may be fo contrived, as that if it be begun by any particular note or letter, all the intervals or other notes shall be justly found on the instrument, or in the fixed series; yet where the song begun with any other note, we could not proceed.

To remove or supply this defect, musicians have recourse to a scale proceeding by twelve degrees; that is, thirteen notes, including the extremes, to an octave; which makes the instrument so perfect that there is but little
little to complain of. This, therefore, is the present
system of the scale for instruments, viz. between the ex-
tremes of every tone of the natural scale is put a note,
which divides it into two unequal parts, called 
semitones; and the whole may be called the semitone scale, contain-
ing twelve semitones between thirteen notes in the compass
of the octave.

Now, to preserve the diatonic series distinct, these in-
serted notes either take the name of the natural note next
below with a character called a sharp; or they take the
name of the natural note next above with a mark called
flat. Thus D flat signifies a semitone below the D na-
tural; and it is indifferent, in the main, whether the inserted
notes be accounted as a flat or a sharp.

The semitone series or scale is very exactly represented
by the keys of a pianoon; the forefoot range of keys be-
ing the natural notes, and keys behind, the artificial notes,
or the flats and sharps. The flat is denoted by the letter
b in the writing and printing of music, and denotes that the
note to which it is prefixed is to be lowered a half-note or semi-
tone, and of course made to coincide with the note imme-
diately below, in all such instruments as have but 22 intervals
in the octave; it must however, be observed, that except in the
Equal Temperament of the scale (which see), the flattening
effect of b is not always the same, but varies according
to the magnitude of the half-notes in each different system
of temperament or part of the same system, as observed
under Finger-key intervals.

Writers on the theory of music are by no means agreed
on the magnitude of the interval which they affix to a
flat. Dr. Robert Smith (Harmonics, p. 160.) defines it to
mean the minor limma of his different tempered sylluns
(which see). Mr. Maxwell, (Essay on Tuning, p. 5.1.) fixes
it to his major limma, which has a ratio of $\frac{\sqrt{5}-1}{2} = 47 \frac{7}{12}$
$+ 4 m$ and is the mediis Semitono (which see). Dr. Cal-
cott (Musical Grammar, p. 112.) defines it to mean his chro-
matic semitone, or the apotome which has a ratio of $\frac{\sqrt{2}}{2} \frac{448}{445}$
$= 58 \frac{4}{12} + 5 m$; in numerous other instances, we find
the flat defined to mean the limma whose ratio is $\frac{24}{25} \frac{24}{25}$
$= 46 \frac{4}{12} + 4 m$. If we examine the MSS. of Mr. Overend,
we find the flat fourth of Tuttini and himself, and also
what he calls the greater of the flat fourths and flat eighths,
and each of them depressed below their natural intervals
by the minor semitone, whose ratio is $\frac{24}{25}$ $= 36 \frac{4}{12} + 3 m$.

See Sharp.

Flat, in Sea Language, denotes a level ground lying at
a small depth under the surface of the sea, and is also called
a flat or shallow.

Flat Bottom, in Fortification. See BASTION.

Flat-bottomed Boats are such as are made to swim in
shallow water, and to carry a great number of troops, ar-
illery, ammunition, &c. They are constructed with a
twelve-pounder, bow-chafe, and an eighteen-pounder, stern-
chafe; their keel is from ninety to one hundred feet, and
from twelve to twenty-four feet beam: they have one main,
a large square main-fall, and a jib-fall, are rowed by eighteen
or twenty oars, and can carry four hundred men each.
The gun takes up one bow, and a bridge the other, over
which the troops are to march. Those that carry heres
have the fore-part of the boat made when open to
the men to mount and ride over a bridge. See Boat.

Flat-bottomed Boat. See Boat.

Vol. XIV.
FLAT, or FLATTENED. See COMPRessed.

FLATTENED Fisss, in Natural History, are such mineral substancess, organic remains in particular, as seem to have suffered a compression or flattening, since their first deposit in the strata; Mr. W. Martin observes (Outlines, p. 72.) that such compressed, or flattened form of relicka, is often the consequence of the mode in which the mineral change has been brought about, and not the effect of a similar structure in the original. Some relicka retain the form only of one side, or of one half, of the organized body represented; while others present the whole of the external or internal organic fabric, according to the manner in which the mineral matter has been united to the animal or vegetable figure. See Compressed Fissi.

FLATTER, or FLATTENFR. See COining.

FLATLYE, Cape, in Geography, a cape on the N.W. coast of North America, so called by captain Cook in his third Voyage (March 1778), because it presented an open bay, which flattened the navigators with this hope of a harbour, but disappointed them; the opening being closed by low land. It lies in N. lat. 48° 15'. E. long. 235° 3'. Over it is a round hill of moderate height; and the adjacent land is well covered with wood, and exhibited a very pleasant and fertile appearance. In this latitude geographers have placed the pretended free of Juan de Fuca. But our navigators saw nothing like it; nor, say they, is there the least probability that ever any such thing existed.—Allo, a cape on the N.E. coast of New Holland. It lies in S. lat. 14° 56'. W. long. 214° 23', and is a lofty promontory, making next the sea two hills, which have a third behind them, with low sandy ground on each side; but it may be better known by three islands out at sea; the largest, and northern most, lying about five leagues from the cape, in the direction of N.N.E. This is supposed to be the same with that which capt. Dixon called Cap e Cox.

FLATTY, or FLATTENING. See COining.

FLATTENING-coarse, among Brick-makers. See BRICK.

FLATTENING—mille. See MILL AND Gold-stein.

FLATTS, signify the fame with dirt-bottoms or floats, which are rectangular flat-bottomed and very shallow vessels, used on the Mersey and other navigable rivers, for moving Flast to repair the banks of a canal, and other purposes; in some places the ordinary trading boats are so called.

FLATULENCE, in Medicine, from the Latin, status, a puff, or blast of wind, signifies the generation and discharge of air, or gas, in and from the human body, especially in the flomach and intestines.

There are only two sources from which air can be generated in the passages just mentioned; namely, their contents, and the blood-vessels which secrete other fluids into them. The first of these, the substancess contained in and passing through the alimentary canal, are the ordinary fources of stAtus: for although we know that in some animal structures, as in the air-bladder of fishes, the vessels appear to be adapted for the secretion of air; and although it is not improbable that, in some morbid conditions of the organs of the human body, the blood-vessels occasionally secrete air, as was formerly believed by Mr. John Hunter; yet, in general, we have a much more natural fulction of the problem, in the difengagement of air from the substancess taken for the purpose of nutriment. All animal and vegetable substancess difangage a considerable quantity of air in the course of their decomposition, whether by fermentation or putrefaction. It appears from the experience of Dr. Hales, that an apple, and many other kinds of alimen, give out six hundred times their own bulk of an elastic gas during fermentation. But the procw of digestion, when well performed, prevents this fermentation from taking place; and the soluble power of the gastric juice converts the food into chyle without any difengagement of air. When, however, the digestive procw is imperfectly carried on, the alimen, and especially the vegetable part of it, is difposed to go into a partial fermentation, of which the difengagement of air is a necessary conquence. Flatulence, therefore, is not so much a disease in itself although generally considered to by those who are troubled with it, as a symptom of indigestion, or of a weakened condition of flomach; and hence, although a flatulent difension of this organ may be relieved by the means which we shall enumerate, it can only be entirely cured by restoring the strength of the flomach. See Dyspepsia, and Indigestion.

Flatulence occasions various feelings of displeasure, according to the part of the alimentary canal in which the wind is generated; or pent up. When it is copiously generated in the flomach, and does not pass easily or readily out at the upper orifice, to be difgarded by eructation, it produces all the difgarding conquences which are attendant on great difension of that organ: in some instances great pain of the flomach is excited, either by the simple extension of the fibres, or by partial spasmic contractions; in others, especially in hysterical habits, the adjoining organs are considerably affected by the pressure of the diftended flomach; whereas great anxiety and oppression are felt in the chiel, from the impediment to the free motion of the lungs and of the heart; the respiration becomes laborious and dificult, with a sense of suffocation, and the heart intermits in its action, giving rise to intermission of the pulse, or is excited to violent palpitations. These symptoms are generally alleviated by the discharge of wind by eructation; this alleviation however, is only temporary; for the flates again accumulate and re-produces the same effets. The generation of air in the flomach, in lefs degrees, is an ordinary concomitant of indigestion; but it generally passes off readily. Some people, indeed, acquire a habit of voluntary eructation, which, however, is not healthy. For, as Dr. Darwin justly observes, "when people voluntarily eject the fixed air from their flomachs, the fermentation of the alimen goes on the faster; for floping the vessels which contain new wires, retards their fermentation, and opening them again accelerates it; hence where the digestion is impaired, and the flomach somewhat diftended with air, it is better to refrain than to encourage eructations, except the quantity makes it necessary." (Zoonomia, Clafs i. 3. 1.) It has been suggested, and we think not incorrectly, that in the repeated voluntary attempts to difpel wind from the flomach, which are often continued for some length of time, the atmospheric air is often actually flwatered, and the disagreeable fenstion of diffusion thus augmented.

When air passes from the lower orifice of the flomach into the intestines, or when, as is perhaps more common, it is generated from the fermentation or putrefactive changes of the alimentary matters in their course through the canal, other difgarding symptoms are produced. The flomach is filled with the fots from fermentation of an effe of neonferb, with a rumbling or gurgling noise in the belly, termed fomcrumus. This, however, is sometimes sufficently difgarding, especially from the drawing the attention of by-landers, and is not very uncommon in young women, about the age of puberty. "I attended a young lady about sixteen," says Dr. Darwin, "who was in other respects foble, whose bowels almost incessantly made a
As this noise never ceased a minute together for many hours in a day, it could not be produced by the uniform defeat of water, and, absent of air through it, but there must have been alternately a retrograde movement of a part of the bowel, which must again have pulled up the water above the air; or which might raise a part of the bowel, in which the fluid was lodged, alternately above and below another portion of it, as might happen in some of the curvatures of the smaller intestines, the air in which might be moved backward and forward as the air-bubble in a glass level. (Loc. cit.)

The colic, which is occasioned by flatulence, (the stinkily colic, or colica flatulenta,) arises from partial collections of air, probably pent up by partial epiphanic frictions, especially in the colon, or great gut. The distensions, in such cases as Hoffmann has remarked, are most frequently obvious in the right or left hypochondrium (under the short ribs), on account of the curvature of the bowel in those parts, by which the more ready passage of its contents is impeded; and such dilatations, he adds, have been mistaken by persons ignorant of anatomy, for tumours of the spleen. Large and painful tumours are also sometimes observed, above the spine of the right ilium, which are augmented by flatulent food. Hoffmann affirms their seat to be the head of the colon, which is capacious and mucular for the purpose of propelling the faces upwards, and which has been occasionally seen so much dilated, as to push forward the integuments, with considerable pain, and to be in danger of being ruptured. The nature of such tumours may be learnt from the relief to the pain and diminution of the swelling, which follow the emission of flatus, or the copious discharge of a tenacious matter, by vomiting or by follow. A great dilatation of the colon occasions very similar dilating symptoms, to those which arise from dilatation of the stomach, from the pressure produced on the surrounding organs. Hoffmann observes, that pains in the loins, internuinion of the pulse, cedematous swellings of the feet, &c. originate often in flatulent dilatations of the bowels, compriing the great vessels and nerves. (Hoffmann, Med. Rational, sect. 1. cap. v. § 57.)

See COLIC.

Sometimes the whole abdomen is enlarged by the general dilatation of the bowels with air, accompanied by colicification. When this dilatation has been of some duration, a degree of paralysis of the muscular fibres of the intestines is produced, their power in expelling the wind is lost, and the integuments of the abdomen become tense, like a drum; the patient becomes emaciated and tabid. This distension is called Tympanites; which see.

For the relief of flatulence, the radical cure, as we have already observed, can only be effected by curing the debility of the stomach and bowels; a number of medicines have been devised, from a very early period of time, especially such as are comprehended under the appellation of Carminatives, (which see.) There are generally substances possessing strong sensible qualities, which render them instantaneous dilatant to the nervous system; and by suddenly exciting the muscular coat of the stomach to action, enable it to overcome the dilatation, and disperse the distending gas. The aromatic vegetables, containing much essential oil, such as juniper berries, the seeds of anise, caraway, and coriander, the roots of ginger and zedoary, and the waters distilled from these, are among the most esteemed carminatives. To these may be added other stimulant and antispasmodic medicines; such as affo-
tides, and other strong smelling gums; volatile alkali; opium, &c. &c. Warm fomentation externally to the region of the stomach has been recommended by Dr. Darwin, and other external remedies were employed by Dr. W. Bytt, especially frictions on the region of the stomach, with prepara-
ments composed of the warm oil, such as the expressed oil of nutmeg, oil of musk, roasted and added the caju of large piddles to the belly, made with the stimulating gums and gum-assin. He considered rather and opinion, however, as the most effectual remedies for flatulence. Dr. Darwin recommends "the cores of black pepper swallowed whole after dinner, that its effects may be slower and more per-
manent," in the scrobogut of young women. We have freer them suspended by any subidity, taken into the stomach, as a piece of dry biscuit, which, by the way, the late Dr. Buchan considered "one of the best car-
minative medicines," and Eommend in all complaints of the stomach, arising from flatulence and indigestion. These dilatations are often particularly troublesome when the stomach is nearly empty, and perhaps the operation of a bilious. taken at such times is merely that of relieving this temporary vacancy, which may other light almost would effect.

As the proper digestion of the food is much aided by a regular motion and discharge of the excretion, a portion of it downwards, wherever the bowels are confined, particular care should be taken to obviate this tardiness of their action, by conjointing stimulant laxatives with the def-
pellers of wind. Hence pills, consisting of aloes, calody, or rhubarb, combined with affostrica, ginger, &c. may be ad-
vantagously administered. To these means the general rem-
dies for indigestion should be added, as well those which strengthen the constitution at large, as those which give vigour to the stomach in particular; such as are especially the aromatic bitsters, preparations of feb, and exercise. And the diet should be selected from those materials which do not readily pafs into the viscous or acetic fermentation, and which are easy of digestion; hence greens, peas, beans, and other similar vegetable matters should be avoided, as well as liquors which are in a state of active fermentation, and consequently defueling caloric air; and particular attention should be paid to moderation in eating and drinking, so that the digestive powers may not be oppressed and over-
come.

For, as we have already observed, when speaking of DIB, excess in quantity is, in general, much more pro-
ductive of injury, than any unwholesome quality in the articles of food which we use.
1. F. capitata. Juss. MSS. Flowers in aggregate corymbose heads.—(Erbilia bidensis; Linn. Nov. Gen. 1:10. Wild.; Sp. Pl. v. 3. 1741. See Erbilia.—Eupatorioides falsches folio trinervi, flore luteo, vulgo Contrabibra; Feuill. Pl. de Peron & Chili, 18. t. 14.)—Native of Chili, where it was gathered by Feuillee, who mentions its affording a fine yellow dye, if boiled in common water; and subsequently by Mr. Menzies, to whom we are obliged for a specimen in ripe fruit. It has been cultivated in the royal garden at Paris, whence we received a specimen in flower by favour of M. de Jussieu, marked with his own specific name as above. This is precisely the same as the Erbilia bidensis of the Linnaean herbarium, whose native country was never before ascertained.—The root is fibrous, and appears to be annual. Stirn from one to two feet high, erect, straight, angular, inflated, smooth, often purplish, solid, leathery, with several opposite, straight, spreading, forked branches. Leaves opposite, flaked, spreading, lanceolate, acute, three-nerved, hairy, borne on a leafy base. Footstalks dilated at the base, and clasping the stem. Flowers terminal, yellow, numerous, in a fort of compound corymbus, very ill-drawn by Feuillee. The ultimate flarchs are each a fort of compressed racemis, on which the flowers are arranged alternately, in a spiked manner, with a bractea under each, and several small flarks combine to form a dense level-topped head. All the parts of the inflorescence and flower are smooth, except a few hairs now and then at the edges of the principal flarks. When in fruit, the whole assumes a pale hue, the calyx becomes gibbous, containing rarely more than one grey, slender, obovat, nearly ribbed seed. The inflorescence of this plant greatly resembles that of Valeriana Cornucopiae, and some others of the same genus.

2. F. spicata. Juss. MSS. Flowers in compound spikes. Gathered by the unfortunate Dombey in Peru; see Doms. One of his specimens was given us by M. de Jussieu, with the same name we have adopted, and a very fine one was found, without any mark. In the herbarium of the younger Linnaeus. This species has altogether the figure of Sp. Scallii, but the stem is flabelliform, with many round, or slightly angular, roughish, leafy and flowery branches. Leaves opposite, flaked, lanceolate, narrow, smooth above; with three ribs, which are rough beneath; and a few shallow dilant furacera. Spikes very numerous, opposite, lateral and terminal, with innumerable little, yellow, crowded, suffuse, bracteated flowers, whose calix-leaves are fringed, roughish and very obtuse. Flowers about three. Seed shaped like the leaf, but smaller, blackish, and with scarcely more than four angles or ribs. The flavour of the plant is slightly bitter and aromatic.

FLAVIA CASSARINDIS, in Ancient Geography, a province of Britain, which extended over the whole breadth of the island where it is broadest, from the Land's End in Cornwall, to the South Foreland in Kent; and was bounded on the S. by the English channel, on the N. by the Bristol channel, the Severn, and the Thames. It comprehended the countries of the Damnoni, Dumetriges, Belgo, Atrebatia, Regni, and Camiis, which are now Cornwall, Devonshire, Dorsetshire, Somersetshire, Hampshire, Wilts, Berkshire, Surrey, Suffolk, and Kent. This province was not first established, but the countries comprised in it made a part of the one province in Britain, from the time when they were subdued, to the reign of the emperor Severus. When that emperor divided the Roman territories in Britain into two provinces, these countries
made a part of the southern one, and so continued until Constantine the Great formed them into a distinct province, which was called Flavia Caesariensis, from Flavius, one of the names of that emperor. The other four provinces were Britannia Prima, Britannia Secunda, Maxima Caesariensis, and Valentia. Britannia Prima was probably so named because it contained some of the countries which first submitted to the Romans, in this island. This province was bounded on the south by the Thames, on the east by the British ocean, on the north by the Humber, and on the west by the Severn; and comprehended the countries of the Dobuni, Cattuvelianni, Trinobantes, Iceni, and Coritani; which are now Gloucestershire, Oxfordshire, Buckinghamshire, Bedfordshire, Hertfordshire, Middlesex, Essex, Suffolk, Norfolk, Cambridgeshire, Huntingdonshire, Northamptonshire, Leicestershire, Rutlandshire, Lincolnshire, Nottinghamshire, and Derbyshire.

Britannia Secunda perhaps received that name, when Severus divided the Roman dominions in Britain into two provinces, of which this was the second. It was bounded on the south by the Bristol Channel and the Severn, on the east by St. George’s Channel, on the north by the Irish sea, and on the west by Britannia Prima. This province contained the countries of the Cornavii, Silures, Demetae, and Ordovices, which are now Warwickshire, Worcestershire, Staffordshire, Shropshire, Cheshire, Herefordshire, Radnorshire, Brecknockshire, Monmouthshire, Glamorganshire, Caernarvonshire, Pembroke-shire, Cardiganshire, Montgomeryshire, Merionethshire, Caernarvonshire, Denbighshire, and Flintshire. For an account of the other two provinces, see Maxima Caesariensis and Valentia.

FLAVIANO, St. A town of Naples, in Abruzzo Ultra, near the Adriatic; 12 miles N. E. of Parmo.

FLAVIANUS, in Geography, patriarch of Antioch in the fourth century, is distinguished for his zeal in opposing Arius. Upon the death of Meletius, he was elected his successor, in the year 381, by the suffrages of the council of Constantinople, notwithstanding Paulinus, the colleague of Meletius, was still living, and that Flavianus himself had formerly sworn not to consent to the election of any successor to Meletius during the life of Paulinus. His election caused a considerable schism in the Christian world. The western bishops declared themselves on the side of Paulinus, and the greater part of the eastern bishops defended the rights of Flavianus. The death of Paulinus, and the prudent conduct of Flavianus, put the latter in quiet possession of his situation. After this he signalized himself in defence of orthodoxy, and in persecuting the heretics; he entitled himself to the gratitude of the citizens of Antioch by his successful interruption on their behalf at the court of Constantinople, when they had incurred the emperor’s displeasure, and dreaded his resentment. For during the course of a popular tumult, occasioned by the imposition of a new tax, various outrages had been committed, and the statues of the emperor Theodosius and his empress were overthrown. The most exemplary vengeance was threatened, but, by the eloquent intercessions of the patriarch, pardon was obtained for the offenders. The address which he delivered on this occasion was said to have been composed by St. Chrysostom, who thought very highly of Flavianus, as one of the greatest ornaments of the church. Flavianus died in the year 424. He published some epistles and some homilies. 

FLAVIANUS, patriarch of Constantinople in the fifth century, was elected to that dignity in the year 447. An unfortunate misunderstanding took place between Flavianus and Chrysippus, the first chamberlain and favourite of the emperor, which terminated in the ruin of the patriarch. He was deposed and banished; and, unable to sustain the severities inflicted on him, died in 450, at Hysoppa in Lydia, the place of his exile. Flavianus was the author of "Two Letters" to pope Leo, which are extant in the fourth volume of the "Collectio Conciliorum”; and also of "A Declaration of Faith delivered to the Emperor Theodosius," More.

FLAVIGNAC, in Geography, a town of France, in the department of the Upper Vienne; 12 miles S.W. of Limoges.

FLAVIGNY, Valerian de, in Biography, a French ecclesiastic, was born at Laon early in the seventeenth century. He was admitted to the degree of doctor of divinity by the faculty of the Sorbonne in the year 1628, and shortly was made canon of Rheims. In the year 1632 he was nominated professor of the Hebrew language in the college-royal of France, and discharged the duties of that office with high reputation. In 1656 he became dean of the college-royal, and died at Paris in 1674, at an advanced age. He was esteemed very learned in theology and the oriental languages, but was distinguished by much violence of temper and a very bitter spirit, which he displayed on many occasions. In 1663 he lodged a formal complaint before the faculty of the Sorbonne, against a thesis that had been maintained by the jefuits of the college of Clermont, the object of which was to prove, that, as the doctrine of Copernicus was contrary to scripture, condemned by the Vatican, and anathematized by the inquisition of Rome; it was decidedly inconfident with the faith of the church, and ought not to be defended in France. M. Flavigny, in answer to this, attempted to prove that the theses went to violate the rights of the king and kingdom, and to set at nought the authority of parliament. He engaged in many other disputes, but his controversies relative to the Polyglott published by M. le Jay, and the purity of the Hebrew text, is his most important work. It is known by the title "Epitole de leptaphis Panificibus." More.

FLAVIGNY, in Geography, a town of France, in the department of the Côte d'Or, and chief place of a canton, in the district of Semur, placed on the Ozerain; 27 miles W.N.W. of Dijon. The place contains 1523 and the canton 12,392 inhabitants, on a territory of 356 kilometres, in 23 communes.

FLAVIOBRIGA, in Ancient Geography, Verme or Bersaco, a town and colony of Spain, in the Tarraconensis, situated on the coast, at the bottom of a small gulf, in the country of the Autiones; called also, according to Pliny, Ammanum Portus.

FLAVIONA, or Flavium, a town of Spain, in the Tarraconensis, in the territory of the Picthus, according to Ptolomy; situated on the coast of the country of the Castiliri; supposed to be the modern Ayxent, a town and college of Thrace, which, according to Pliny, succeeded the name of Zela, and not far from Kairon. It derived its name from Vulcius and Tauris, who were of the Flavian family.—Atho, a town of Asia, in Bithynia; called also C. I. Cesneria, and Caesarea—Altus, a town of Asia, in Cilicia, situated at the foot of mount Taurus, and near the source of the Cilicys; probably the Flavia of the Itinerary of Antoninus, who marks it on the route from Casm to Cappadocia to Anazarbe.

FLAVIUS, in Geography, patriarch of Constantinople, the immediate successor of Acacius, was raised to that high dignity, from the situation of the see of the church of St. Theodosius. He soon took part in a stratagem, which the superstition of Zeno furnished him with an opportunity of practising;
practising. The prince, on the death of Aetius, deposited on the altar of the great church a blank letter, filled with his own seal, and accompanied with a writing, in which he and the whole church bound themselves to choose such a person whose name should be found written within the blank letter. The church was shut up, and all the avenues carefully guarded by night and by day. Forty days fasting was enjoined, during which prayers were offered up to the Almighty, that he would be pleased to direct an angel to inscribe in the letter the name of the person most adapted to the office. Flavitas bribed the soldiers or their commander, broke the seal, and inscribed his own name. Such, however, was his renown for piety, that no suspicion of fraud fell upon him, and when it was found that his name had been written by an heavenly hand, he was with loud acclamations proclaimed bishop of Constantinople. His hypocrisy was of little avail, though it cheated the foolish emperor and his superfluous court, for he had no arts to ward off the hand of death, to whose summons he yielded in a few weeks after his advancement. The fraud was now discovered; the estate of Flavitas was confiscated, and the perfom-participating in the villany was condemned to die. Morevi.

PLAUTINO, Ital. a small, or octave flute.
PLAUNTO, Ital. a flute.
PLAW, at Sec, signifies a sudden gale of wind, otherwise called squall.
PLAX, in Botany. See LINUM.
PLAX, Carolina. See POLYPRENUM.
PLAX, Purging. See LINUM Cathartica.
PLAX, Toad. See LINARIA and ANTIRRHINUM.
PLAX, Baby-dread. See THESIUM.
PLAX, in Agriculture, is the name of a plant cultivated equally for the bark, or covering of its stalk, and its seed; the former being used in making linen cloth, and the latter for oil which is drawn from it by pressure, and for the refuse or cake. The stem of the plant, which is round and hollow, grows to the height of about two feet, and then divides into several branches. The leaves are terminated by blue flowers, confiding of five petals, and are succeeded by capsules divided within, into two cells, in each of which is enclosed a bright, finely, elongated seed. The leaves are long, narrow, sharp-pointed, and placed alternately along the stem and branches of the plant.

Soil. The most proper sort of soil for flax is a deep, free loam, such as is not liable to become too much charged with moisture, or too dry; but which has been rendered fine by tilth, such as those situated in a valley bordering upon water, or as is thrown up by rivers. If there be water at a small depth below the surface of the ground, it is thought, by some still better, as is the case in Zealand, which is remarkable for the fineness of its flax; and where the soil is deep and rather dry, with water almost every where, at the depth of a foot and a half, or two feet, underneath it. It is said to be owing to the want of this advantage, that the other provinces of Holland do not succeed equally well in the culture of this useful plant; but that this flax is also raised on high lands, if they have been well tilled and nourished, provided the leas are not very dry and unfriendly to the growth in that way.

It has been remarked, in the papers of the Dublin Agricultural Society, that moist loam soils yield much greater quantities of flax, and for better feed, than can be obtained from light lands; and that the feed secured from the former may, with proper care, be rendered full as good as any that is imported from Riga or Zeeland. M. du Hamel, however, thinks that strong land can hardly yield such fine flax as that which grows on lighter grounds. With due pulverization and preparation, there can be no doubt but that flax lands will afford excellent crops of good flax. It is seldom that either light sandy or gravelly soils answer well for crops of this kind. Land for flax should neither be in too great a state of fertility, or be too much exhausted, as in the former case the flax is liable to become too luxuriant, and the produce in consequence of it, of a coarse quality; while under the latter circumstance the quantity of produce is very small.

It has been stated by Mr. Donaldson, that flax is sown after all sorts of crops, but is found to succeed best on lands lately broken up from grasses. And that in Scotland, the most skilful cultivators of flax generally prefer lands from which only one crop of grain has been taken, after having been several years in pasture. When such lands have been limed or marked, immediately before being laid down to grass, the crop of flax seldom or never misgives, unless the lenso prove remarkably adverse to it. It succeeds in general better after green crops, than those of the grain kind.

Preparation. The land, in order to render it fit for the growth of this sort of crop, requires to be rendered perfectly fine and mellow, by being repeatedly ploughed over, and broken down by severe harrowings. Where grass is land to be broken up for this crop, it should be done in the autumn, and left exposed to the influence of the atmosphere, until the early part of the following year, when it should be well pulverized and broken down by heavy harrowing, then in the course of a week or two ploughed again, in which flax it may remain till the period of putting in the seed, when another light harrowing should be given, and the ploughing performed afterwards by a very light furrow. But in cases where the crop is sown after grain, or other crops that have the property of keeping the land clean from weeds, the first ploughing need not be given till January, when it may remain in that situation until it becomes pretty dry in the early spring, being then well reduced by good harrowing and rolling; and after continuing in that state about a fortnight, the seed may either be immediately put in, or another light ploughing and harrowing be performed.

Sec.—With regard to the choice of seed, the same writer states that, that which is of a bright brownish colour, oily to the feel, and at the same time weighty, is considered the best. Linseed, imported from various countries, is employed. That brought from Holland is however in the highest estimation, as it not only ripens sooner than any other that is imported, but also produces greater crops, and flax of that quality which best suits the chief manufactures of this country. American feed produces in common fine flax; but neither the quantity of flax, nor of the pods, provincially the "boils," which contain the seeds, is so large as the produce from Dutch linseed. The Riga feed yields a very coarse sort of flax, but a greater quantity of seeds than any other. It is common in some parts of Scotland to low feeds sowed from the crop preceding year, especially when the crop was raised from feed imported from Holland. The success of this practice is found to depend greatly on changing the seed from one sort of soil to another of an opposite nature; but the varying is the expense of purchasing that low feed, in place of what is newly imported from Holland, is so inconsiderable, and the risk of the crop misgiving, so much greater in the one case than in the other, that it is supposed these only who are ignorant of the consequences, or who are compelled from necessity, are chargeable with this act of ill-judged privity in the business.
The cultivators of flax in Ireland prefer the American feed for the lighter and more elevated exposed lands; but the Baltic or Dutch for those which are of a heavier quality. The feed of home produce is often sown for white flax in Yorkshire; but the Baltic feed is most commonly preferred where the soil is of a better kind; for the ensuing year, and one or two afterwards, it is seen to enrich as well as whiten the soil. But it is highly probable that if the feed which has been collected from the perfectly ripened flax of our own growth be made artificial, it will be equally productive in both the flax-y flax fibre and the quantity of feed, and the former be equally valuable for all the purposes of the manufacturer.

Propriety of Seed. — In respect to the quantity of seed used, it varies in different places according to the circumstances of the soil, the methods of sowing, and the use to which the crop is to be applied; but from two bushels to two bushels and a half, the English statute acre, is the ordinary allowance. In determining the proper quantity necessary for the acre, it is requisite to pay great attention to the condition of the land. When the land is rich and fertile, and the season favourable that it can be got thoroughly pulverized, if too much feed is sown the crop is in great danger of lodging; and when that happens, particularly before the pods are formed the flax proves considerably in quantities, and very inferior in quality. When cultivated in the drill mode at narrow distances, a much less quantity will be sufficient than in other cases; and where the intervals are large, scarcely one half the quantity is required. When the crops are intended for feed, in whatever manner the sowing is performed, much less will be necessary, than where flax is the main object of the grower.

Time of Sowing. — It may be observed, that this must depend much upon the soil and situation, but that the ordinary season of sowing flax feed is from the middle of March to the middle or end of April; but the last week of March, and the first ten days of April, are esteemed the best times; and, accordingly within these periods the greatest quantity of flax feed is sown in this country. In the county of York, where this sort of crop is grown on land broken up from grass, the feed is commonly sown before the second week in April, where it can possibly be done; while on such lands as have been in a previous state of tillage, the sowing is frequently deferred a week or ten days longer. Wherever it can be safely practiced, early sowing has the advantage of getting the flax plants to cover the surface of the land well, before they can run much risk of injury from the rilling of weeds, or the parching effects of heat.

In some of the southern counties of England, however, the husbandmen who raise flax sow part of their feed in September and October; so that the plants which spring from these remain of course in the ground all the winter; and this may be a judicious practice in these places, because plants which have not covered the earth well before the summer heats come on, are apt to be parched by the heat and drought which usually prevail in that season. They sow indeed again also in the spring; but the latter does not yield so large a crop; the flax, however, which it produces is more esteemed, because it is finer than that sown in autumn. M. du Hamel seems indeed to think, that the autumnal sowing yields the best feed; but, however that may be, in places where the winter is apt to be severe, and where the flax, which is but a tender plant, would in course be in danger of being destroyed during that season, almost all the flax is sown about the end of March, or in the beginning of April, as already stated.

It may be laid down as a general rule, that the land which is intended for flax crops should be broken to an exceeding fine tilth, in the way directed above, before the feed is set in; and that it should be enriched by some sort of manure suited to the quality of the soil. Then, when pasture lands are broken up, in order to their being broken with flax they must be well worn by the plough several times before they will be fit for producing Such crops, in the manner just described. To delay the expense of this culture, some other crops may be got; if the land in the mean time, especially of such kinds as require very light, or, and particularly of those which are remarkably benefited by frequent flinging of the earth while they grow, such as beans, peas, turnips, &c.; because these repeated flirings render the mould fine and loose, and help to kill the weeds, which would otherwise do great damage to the flax. It is asserted that the Livonians, when they clear wood land, burn the wood upon them, then plough them, and in this state prefer them to any other kind of soil for flax crops. If the land which is intended for flax be fine, great care should be taken not to work it when it is wet, for fear of knetting it; but it is often an excellent plan to work it deeply before winter, when dry, laying it up in very high ridges, in order that the winter frosts may the more effectually moulder and loosen its parts. In the month of February, where the land is not too wet, some very rotten dung should be laid on, and immediately covered over with the mould. The feed should afterwards, at the proper season, be sown, and harrowed in with a light or bush-harrow, so as not to bury it too deep. As this, when young, is a very tender plant, and is more easily injured and checked in its progress by weeds than any other that is usually cultivated in the field, it is indispensably necessary that the danger of injury in this way should be well guarded against, in order to save future trouble and expense.

Methods of Sowing. — Where the principal object of the grower is flax, the most general method of putting in the crops is that of sowing them broadcast over the surface of the land. In performing the operations, much care is necessary that the feed be distributed as evenly as possible over the ground, to prevent the plants rising in an unequal or tawdy manner. It should be afterwards covered in by regular harrowing, once or twice in the place, with a light common or bush-harrow, as just noticed, not covering it too deep.

But where the feed constitutes the chief intention of the cultivator, it is contended by some that the drill mode is preferable as requiring much less feed in sowing, and affording a much better and more abundant produce. Beaks, the irrigation, and weight of the feed render it extremely proper for being drilled, and the crops can be kept clean with greater facility.

In this method, the distances of the rows or drills should vary according to the circumstances of the soil, and the manner in which the crops are to be kept clean. Where the land is to be chiefly depended upon, narrow distances may be proper, as ten or twelve inches; but where the work is to be principally executed by the hand-beer or cultivator, larger intervals may be more desirable, as those of eighteen or twenty inches. Slight harrowing and rolling are sometimes afterwards necessary, especially the latter in dry seasons.

It has been observed that thick sown flax runs up in height, and produces fine leaf flax; but that when too thick this does not rise to such a height, but spreads out more, feeding off a greater number of side branches, which produce a great abundance of seed, which is much better filled, more
more plump and heavy than that which is produced from thick Iowa flax crops. Flax crops cultivated in this way are set too liable to be beaten down in bad weather, the flax being stronger and better fortified by the more free admixture of sun and air among them; and they are not so much exposed to danger in weeding or clearing the rows.

After-Culture of the Crop.—Where flax crops are grown in the broad-cultivated method, they are seldom much attended to afterwards: it is, however, highly useful and necessary that they should have one good hand-hoeing, or weeding, as soon as over the crop is sufficiently up; care being taken not to injure the plants by too much treading amongst them.

In the drill manner of fowing, the after-culture of the crops must be regulated by the distance of the rows; but they may in general be cleared from weeds, and kept in vigorous growth, by proper implements and horse labour.

The ground between the rows is mostly worked by a proper horse-hoe, cultivator, or small horse-hough, taking care that none of the mould is thrown against the rows; to prevent which, the intervals may be hoed with a triangular hand-hoe or proper number of rakes in it, and guided by two handles fixed behind. By these means the spaces are made to go deeper or shallower at pleasure; and if the intervals are cultivated with this instrument, beginning before the earth is become flaky, and while the weeds are small, the land may be kept very clean, and in fine tilth, at much less expense than by hand-hoeing: for one horse is sufficient for this work. A great deal may be done in a day; and by a frequent repetition of the hoeings, especially when the earth is dry, the weeds may be so effectually kept down, as never to rise to any height. But the rows must be weeded by hand.

Flax is sometimes damaged by insects, when it is about three or four inches high. There it is laid, may be destroyed by a flight of ground of foot, after which it is over the crop. At all events, this dressing will give vigour to the flax, though it may not kill the insects. If any weeds appear afterwards among the flax, as is almost always the case, they must be thoroughly rooted out; and that the flax may as little damaged as possible in the doing of this, the weeder should work as carefully as possible.

The finest flax is most liable to be laid, particularly in countries subject to flurries. To guard against this accident, some people run across their flax-fields flender poles fixed to flakes; but a better method is to run small ropes across the field, both lengthwise and breadthwise, where necessary, for these being fashened where they intersect one another, and supported by flakes at due distances, form a kind of net-work, which is proof against almost every accident that can happen from tempestuous weather. These practices are, however, both troublesome and expensive, and are seldom or ever necessary where the crops have not been grown too thick on the ground.

Pulling the Flax.—Opinions are divided in regard to the degree of ripeness at which it is best to pull flax crops. Some think it should be pulled whilst it is green, in order that its fibres may be the softer and finer. Others, with the same view, pull it up before its seeds are quite formed. And others, again, think that it should not be pulled till the capture which contain the seeds have begun to open; being of opinion that the fibres of green flax are too tender, and that they fall into tow. On the other hand, it is certain that the fibres of flax which has stood till it is very ripe are always firm and hard, that they are not easily separated from the seed, and that they do not bleach well. Here, therefore, as in most other cases, both extremes should be avoided; and it consequent seems most reasonable to think, that the proper period for pulling flax is when its flakes begin to turn from green to yellow, when its leaves begin to fall, and when its seeds begin to be of a brownish colour.

MR. DODDSON observes, that a crop of flax frequently grows fast, and runs out a great number of seede-bearing branches. When that is the case, the seeds, not the flax, ought to be the farmer's chief object; and the crop should be allowed to fall till the seeds are in a great measure perfect. But that when the crop thrives, and is likely to become more valuable for the flax than the seeds, it should be pulled from after the bloom drops off, and before the pods turn hard and sharp in the pits. Whenever the seed is the main object, the crop should be perfectly ripened, which is clearly shown by the points of the pods turning hard and sharp, and the capsules beginning to crack. It usually takes place towards the end of July, or beginning of the following month.

Where the object is the flax, the crop is pulled up by the roots, and placed in small parcels, usually termed 'beats,' upon the surface of the land, so as it may be as fully as possible exposed to the benefit of the sun. It is afterwards tied up, in order to be conveyed to the place where it is to undergo the process of watering.

In the work of pulling the flax, it is usual, when it is intended to save the seeds, to lay it in handfuls, partly across each other: the reason for which is, that the burrs of 'ripping' is thereby facilitated; as the ripplers, in place of having to separate each handful from the bundle, find it, by this simple precaution, already done to their hand.

It may be further observed, that although it is of much importance, yet it very seldom happens, that much attention is bestowed to separate the different sorts of flax from each other; in pulling the crops. It is perfectly ripened, which is clearly shown by the points of the pods turning hard and sharp, and the capsules beginning to crack. Therefore, when flax of various qualities is promiscuously mixed together in pulling, it is impossible to prevent some part of it from being lost in the after-management; a loss which might be avoided with a small share of attention, and some additional trouble when the crop is pulled. Those who rent flax-mills are often blamed for embroilment; but, there is reason to believe, very unjustly. Because the crop of a particular part of a field yields a such a quantity of flax from one mill, it does not follow that the manager of another mill should return an equal quantity from the same space, probably, of very inferior land. It is certain, in very many cases, that the attention of flax-farmers to the above very necessary precaution is the cause, why crops of flax often turn out of the little value, and is the principal reason why the proportion of tow or inferior flax so often exceeds, in ordinary seasons, that of superior quality; the millers and hecklers being obliged, in the course of their operations, owing to the mixed state in which they receive the crop from the growers.
FLAX.

grower, to reduce the quality of the whole to a lower standard than there would be any occasion for, were the different qualities sorted, and put into their hands in that state.

As the flax is pulled, when for feed, it is, as has been observed above, laid together by handfuls, with the feed ends turned to the fourth. These handfuls should neither be quite in a line with each other, nor directly across, but a little slanting upwards, so that the air may easily pass through them. Some, instead of this method, tie the handfuls of flax loosely at the top, then spread out their roots, and thus set several of them together upright upon their roots. In either of these ways the flax is generally left twelve or fourteen days in the field to dry it. This drying is certainly not necessary for the rippling, because the ripple will separate the capsules from the flax as effectually before it has been dried as it will afterwards; and if it be done with a view to ripen the feed, it should be considered, that the flax will be more hurt by the longer time of steeping, which will become necessary in consequence of this drying, than the feed can be benefited; because the more the substance or membrane which connects the fibres to the seed is dried, the greater must be the degree of putrefaction necessary to loosen and destroy the cohesion of this connecting medium or membrane; the finer parts of the flax itself must necessarily be destroyed by this degree of putrefaction; and if the putrefaction does not arise to such a degree as to destroy the cohesion of this substance or membrane, the fibres of the flax will adhere so strongly to the seed, that the force necessary in scattering will prove equally detrimental to the flax. The practice adopted in some parts of Brittany seems therefore much more rational, which is, to ripple the flax after it has lain in the air two or three days; but even one day will be sufficient if the weather is dry. In fact, it is the best method to do it as soon as possible after the flax has been pulled.

Rippling the Seed.—In order to ripple, or force off the feed-capsules of the flax, which is the next operation, a large cloth should be spread on a convenient spot of ground, with the ripple placed in the middle of it. This is a sort of comb, consisting of fix, eight, or ten long triangular teeth, let upon a base, having the angles approaching pretty near each other, by which the parts containing the feed are removed from the flax. In performing the bufincox, the pods containing the seeds are forced from the flax by means of this iron-comb, which is called a ripple, and which is firmly fixed on a beam of wood, on the ends of which two persons sit, who, by pulling the feed-ends of the flax repeatedly through between the teeth of this comb, execute the operation in a very complete manner, and with great dispatch.

After the flax has been rippled, the seeds and pods thereby obtained should be spread out thinly upon a cloth in the sun to dry and harden. Those seeds which separate from the pods of their own accord are the fullest and ripest, and should therefore be kept apart for fowling, in cafe the precaution of raking some flax purposely for feed has not been attended to. The pods or capsules are then broken open, either by lightly treading, or by thrashing, in order to get out the remaining feed, the whole of which, as well as the former, should be carefully sifted, winnowed, and cleaned from dirt and chaffy matter. When the feed is laid up, which should be immediately done, it must be frequently stirred and ventilated, to prevent its heating.

This second sort of feed affords a considerable profit by the oil which it yields, and also by being used when broken for fattening of cattle. The cakes of linseed, after the oil has been pressed out of them, are likewise found to be useful for this last purpose, though they are thought by some to render the fat of cattle yellow; for which reason it is advised not to give it them till within a few weeks before the b. alks are to be killed. They are likewise of great utility as a manure, but from the expense can seldom be employed in that way with advantage. See Oil-Cake.

It has been remarked by the author of the "Prefert State of Husbandry in Great Britain," that those who bestow most attention on the cultivation of flax in Scotland, generally ripple off the seed, even when there is no intention of faving it; as it is found, when flax is put into water without taking off the pods, the water soon becomes putrid, in consequence of which the flax is greatly injured. This imperfectly ripened seed is improper for being town, but may be expressed for the oil. But when it is proposed to fave the seeds of flax, the pods are carried home from the field as soon as they are separated from the flax; and either laid on cloths, and exposed to be dried by the influence of the sun; or they are spread on barn-floors and turned two or three times a day, till they are so dry that the seeds can be easily threshed out in the ordinary way. This is the method adopted in Scotland. But in Dorsetshire they allow the flax to be rippled and after it has been pulled, till the pods become so dry, that the seeds can be threshed out with a flack; which is done on a board, or log of wood, placed in the field for the purpose. It is likewise the practice with some expert flax growers, where the chief object is the feed, to set it up, after being tied up into sheaves, in the manner of corn, and, when thus rendered perfectly dry, to flack it until the spring following: in which time, by placing the tops of the sheaves so as to incline towards each other, and making use of a roller, the feed is readily forced out. It is supposed that in this mode more time is allowed in the after management of the produce.

It may be stated, that the quantity of feed produced on the statute acre is generally from six to eight, but sometimes as high as ten or twelve bushels; and that the price depends in a great measure on that of foreign feed imported; as, when sold to oil-makers, it is generally about one-half of that of Dutch feed, sold for the purpose of bowling. The price of home-cultivated linseed is considerably advanced of late in some of the southern and eastern counties of the kingdom, in proportion to what it is in those of the northern, owing to the circumstances of its being much used as food for fattening cattle. The average price of the linseed cultivated in the kingdom at large cannot, it is supposed, be rated higher than from three to four shillings the bushel. It has, however, lately been considerably higher.

Watering.—This is the next operation that becomes necessary with this sort of produce. The intention of this process, is that of inducing the separation of the flaky material, by exciting a flight degree of fermentation in the substance which attaches to it the smell of the plant. It is accomplished in two ways, namely, by steeping the flax in water; and exposing it to the action and influence of the atmosphere. The former is the most common and safest method; the latter being less certain and exact in producing the necessary changes. The first mode is termed water-setting, and the last air-setting.

In water-setting, when the flax has been cleared from the feed, it is loosely tied up into small bundles, and put into pools or ponds of soft stagnant water, where it is suffered to continue several days, according to the natural warmth of the water. As soft clear stagnant water has been...
FLAX.

been found by long experience to be superior for this purpose to any other, where that cannot be obtained without art, a pit or canal may be formed adjoining a river or stream, whence water can be readily brought. This pit or canal is filled with water for some time (a week or two) before it be prepared to pull the flax: by this means the water acquires a greater degree of warmth than river-water pozzolans, and which contributes greatly to facilitate the object. Farmers have in view in immersing green flax in water, namely, to make the hale or flaky fibrous part easily and completely from the boon or reed.

With respect to the period that flax ought to remain in the water, it depends on various circumstances; as the state of ripeness in which it was pulled, the quality and temperature of the water, &c. The most certain rule by which to judge when flax is sufficiently watered is, when the boon becomes brittle, and the hale separates easily from it. The method of depositing the flax in the water is in general that, after having it tied in small bundles, often at both ends, of placing it in a sort of square bed, the bundles being laid lengthways and crossways of each other, so as to bind firmly together, the whole is kept down by having a part of the bundles stuck in it. Some, however, instead of this mode, have the small bundles set in a erect position, the tops of every layer, except the lowest, being upwards; and in place of keeping them down by the application of heavy weights, the flood or earth, treading the whole down occasionally, once or twice at first in the course of the day, so as to keep the whole below the surface of the water, as, where the contrary happens, the flax is greatly injured by being rendered black. The first is, most probably, the best mode of management.

When the flax has remained the proper length of time in these pits, it is taken out by means of a tool called a drag, and deposited in a directed manner on the sides or banks of them, in order to its becoming in some measure dry, and in a state for being spread out on the grass.

With regard to dew-reeling, although it is in general the practice, where flax is cultivated in this country, to immerse it in water for some time after it is pulled, yet in Dorsetshire, and the neighbourhood, it is seldom done. There the flax is allowed to arrive at that state in which the hale parts separate most easily from the boon or reed. By a more gradual process, that of ripening or producing the necessary purification, by the action and influence of the dew, which is nothing more than exposing the flax to the influence of the weather, thinly spread out upon a grass field for a longer period than is necessary, when the operation of watering has been previously performed. When the flax has been so long exposed as to be judged sufficient for effecting the separation of the hale, nothing more is requisite than putting it up in parcels, or bundles, in order to its being broken and feathed.

Drying.—After reeling the flax, where the watering method is pursued, the only other operation which properly falls under the farmer's attention is drying it. For this purpose it is commonly spread very thin on the ground, and in regular rows; the one being made to over-lap the other a few inches, with a view of preventing, as much as possible, its being torn up and scattered by gales of wind. Old grass-ground, where the herbage does not grow to any great height, is the best for the purpose; as, when the grass or weeds spring up so as to cover the flax, it is frequently rotted, or at least greatly injured thereby.

Flax is allowed to remain on the ground, being occasionally turned, till, by repeated trials, it is found that the boon has become very brittle; so that on being broken, and rubbed between the hands, it easily and freely parts from the hale. It is then taken up, a dry day being chosen for the purpose; and, being bound in sheaves, is either sent directly to the mill, which is the usual practice in the northern districts, or broken and feathed, in the manner they do hemp, by a machine or tool contrived for that use.

But before these operations are capable of being performed, it is necessary that the flax should be exposed to the heat of the sun, by placing it against a wall or paling, in a sloping direction, or to the gentle heat of a fire, by putting it over hurdles, or by introducing it into an oven, heated by the refuse flax. The heat in any way should be very moderate, and regulated in an equal manner. And in either case the flax should only be suffered to remain just long enough to dispel any dampness that it may have acquired. The sun is, however, always to be preferred where it can be had.

With respect to the produce, there is scarcely any crop that is more variable than that of flax in the quantity and quality. From twenty to seventy stone of fourteen pounds each have been produced from an acre of land; but from forty to fifty stone may be considered a medium crop. The expense of the cultivation, and management of this crop afterwards, cannot be estimated on the average at less than from nine to twelve or fifteen pounds the acre, where flax is the object.

It has been calculated in these ways in a northern and southern district of the kingdom, before the late great advance in the price of labour.

£ 1 a
FLAX.

In Scotland, where the flax is often held before it is pulled, the usual price was formerly from six to ten pounds the statute acre.

The produce and value of the seed has been shewn above.

It seems, on the whole, not improbable but that flax crops may be grown in many situations with advantage.

It is usual for farmers in different parts of Scotland, who rent lands in the vicinity of large towns or villages, to let fields to the inhabitants, for the purpose of raising flax; which is supplied by some the most advantageous mode of any that can be adopted in cultivating the crop. The rents in these cases are mostly fixed at from 3l. 10s. to 4l. the statute acre, according to the quality of the land, the farmer constantly undertaking to cultivate the land in a proper manner. The same practice, with a little variation, is also established in some parts of England; the farmer rents or lets the land to a person who is denominated a middle-man, or flax-jobber, and whose business it is to perform all the various operations after the feed is sown; which, as in the former case, is always furnished by the renter, the farmer having nothing more to do than to plough and harrow the ground.

When not grown upon newly broken upland, flax may succeed turnips and potatoes with great propriety. The seed is usually called "linseed," which see. See also OIL.

FLAX-DRESILING, denotes the various operations which are necessary for bringing flax into a state of preparation proper for being formed into cloth or other articles. These are very different, and require different sorts of implements and machinery, in order to their being properly performed. Flax, for the purpose of being formed into cambrie, fine lawn, thread, and lace, is drested in a rather different manner to that which is commonly employed. It is not fletched so thoroughly as common flax, which from the fechting proceeds to the heckle, and from that to the spinner: whereas this fine flax, after a rough-fechting, is scraped and cleaned with a blunt knife upon the workman's knee, covered with his leather apron; from the knife it proceeds to the spinner, who, with a brush made for the purpose, straightens and drests each parcel, just before he begins to spin it.

And in the Swedish Transactions for the year 1747, a method is given of preparing flax in such a manner, as to resemble cotton in whiteness and softness, as well as in coherence. For this purpose, a little sea-water is directed to be put into an iron pot, or an untinned copper kettle, and a mixture of equal parts of broth-ashes and quick-line stirred upon it; a small bundle of flax is to be then opened and spread upon the surface, and covered with more of the mixture, and the stratification continued till the vessel is sufficiently filled. The whole is then to be boiled with sea-water for ten hours, fresh quantities of water being occasionally supplied in proportion to the evaporation; that the flax matter may never become dry. The boiled flax is to be immediately washed in the sea, by a little at a time, in a basket, with a smooth stick at first, while hot; and, when grown cold enough to be borne by the hands, it must be well rubbed, washed with soap, laid to bleach, and turned and watered every day for some time. Repetitions of the washing with soap expedite the bleaching; after which the flax is to be beat, and again well washed; when dry, it is to be worked and carded in the same manner as common cotton, and pressed between two boards for forty-eight hours. It is now fully prepared and fit for use. It lores in this process nearly one-half its weight, which, however, is abundantly compensated by the improvement made in its quality, and its fitness for the finest purposes.

FLAX-BRACE, a hand-instrument, or machine, which was originally, and for many ages, chiefly employed in breaking and separating the boon or core from the flax, which is the cuticle or bark of the flax. In performing this business, the flax being held in the left hand, across the three under teeth, or swords of the brake, shown at A, Plate (Flax) Agriculture, fig. 1, and as, fig. 2: the upper teeth or swords B, fig. 1, and b, fig. 2, are then, with the right-hand, quickly and often forced down upon the flax, which is artfully shifted and turned with the left hand, in order that it may be fully and completely broken in its whole length.

FLAX FOOT-BRACE, an implement or machine of the brake kind, invented in Scotland, by which flax is broken and scutched with much greater expedition than by the hand-instrument just described; and in a more gentle and safe manner than by the flax-mill. By this contrivance, the boon or flax is well broken, and the flapping brake given as with the fechter, while the machine is moved by the foot. The treadle is of considerable length, on which account it is put in motion with great facility, and affixed in it by means of a fly. The flutchers are fixed upon the rim of a fly-wheel. But though these machines may be highly useful where mills turned by water cannot be established, they are probably much inferior in point of expedition, and the economy of labour. A brake of this kind is represented, in different views, at figs. 3 and 4, in which is shown, by A, the three under-brake teeth, or swords, seventeen inches long, three inches deep, one and a quarter inch thick at the back, and a quarter-of an inch at the fore-part or edge.

B, the edges, two and three quarters of an inch asunder at the end next the guide B, and two inches asunder at the other end.

C displays the two upper teeth, about an inch shorter than the under teeth; and

D represents the brake-mallet, about thirty-three pounds English weight.

E is a compound foot-treadle, which is eight feet four inches between the fulera F, raised at F eight inches above the ground, (or rather five inches higher than the flaxen of the workman); E is two feet four inches between the fulera G, and is raised at G eighteen inches above the ground; that is, fifteen inches higher than the flaxen of the workman.

H, the fword, or upright timber-rod, which turns the wheel by the treadle-crank.

I, the treadle-crank, of seven and a half inches radius.

K, the fly-wheel, four and a half feet diameter, above sixty pounds English weight. As here represented, it is beat on cast-iron, but it may also be made of timber.

L, braia cords orbufles.

m M, the lifting crank; M is fixed firm upon the axle of the fly, while the crank m about eight inches radius, plays freely round the axle. In position first, M begins to take round the crank (which by the lever K pulls up the mallet); when it comes to position second, the mallet is again at liberty, and by its weight pulls up the crank (smaller than the fixed pieces move) into position third.

It may be observed that the treadle-crank is advanced about one-eighth part of the circle before the lifting crank.

n, a small pulley which turns easily round on the end of the crank, and to which a rope is fixed.
The filamentous parts of different vegetables have been employed in different countries for the same mechanic uses as hemp and flax among us. Putrefaction, and in some degree alkaline luxiva, destroy the pulp or bulky matter, and leave the tough filaments entire. By curiously putrefying the leaf of a plant in water, we obtain the fine flexible fibres which constituted the basts of the ribs and minute veins, and which form, as it were, a skeleton of the leaf. In Madagascar different kinds of cloth are prepared from the filaments of the bark of certain trees belied in strong ley; and some of these cloths are very fine, and approach to the softness of silk, but in durability come short of cotton; others are coarser and stronger, and last three as long as cotton: and of these filaments they make sails and cordage to their vessels. The filaments of nettles are sometimes used for like purposes even in France; and for Hans Sloane relates, in one of his letters to Mr. Ray, that he has been informed by several, that muffin and calico, and most of the Indian cloths, are made of nettles.

A strong kind of cloth is said to be prepared in some of the provinces of Sweden of hop-flax; and in the Transactions of the Swedish Academy for 1750, we have an account of an experiment relating to this subject: a quantity of the flax was gathered in autumn, which was equal in bulk to a quantity of flax, sufficient to yield a pound after preparation. The flax was put into water, and kept covered with it during the winter. In March they were taken out, dried in a stove, and dressed as flax. The prepared filaments weighed nearly a pound, and proved fine, soft, and white: they were spun and woven into five cloths of fine strong cloth. Unlefs the flax are fully rotted, which will take much longer time than flax, the woody part will not separate, and the cloth will prove neither white nor fine. See Dr. Lewis's notes to Newmann's Chemistry, p. 428, 429.

FLAY-CRAKE, in Agriculture, a provincial term, which is frequently applied to the scare-crow employed to keep rooks from new-town lands.

FLAYL. See FLAIL.

FLEA, Pulex. in Natural History, a genus of the order of insects of the roundish compressed figure, with two eyes; six feet, formed for leaping, and filiform antennae; the mouth is bent downwards, and conceals a small sting or piercer. The generation of this familiar vermin affords something very curious, first discovered by Sig. Dacincto Cellone. See PULEX.

Fleas bring forth eggs, or nits, which they deposit on animals that afford them a proper food; these eggs being very round and smooth, ulteriorly slip straight down; unless detained by the piles, or other inequalities of the cloaths, hairs, &c.

Of these eggs are hatched white worms, of a shining pearl colour, which feed on the finely furthance of the cuticle, the downy matter gathered in the piles of cloaths, or other the like furthance.

In a fortnight they come to a tolerable size, and are very lively and active; and, if at any time disturbed, they suddenly roll themselves into a kind of ball. Soon after this, they come to creep, after the manner of fireworms, with a very swift motion. When arrived at their size, they hide themselves as possible, and spin a filken thread out of their mouth, wherewith they form themselves a small round bag, or cafe, white within as paper, but without always dirty, and fouled with dust. Here, after a fortnight's rest, the animalcule bursts out, transformed into a perfect flea; leaving its exuviae in the bag.

While it remains in the bag it is milk white, till the second day before its eruption; when it becomes coloured, grows hard, and gains strength; so that, upon its first delivery, it springs nimbly away. (Phil. Trans. N. 239.)

The flea, when examined by the microscope, affords a very pleasing object. It is covered all over with back, hard and shelly scales, or plates, which are curiously jointed, and folded one over another in such a manner, as to comply with all the nimble motions of the creature. These fleas are all curiously polished, and are built about the edges with short spikes in a very beautiful and regular order. Its neck is finely arched, and much resembles the tail of a lobster; the head also is very extraordinary; for from the front part of it there proceed the two fore-legs, and between these is placed the piercer or sucker, with which it penetrates the skin to get its food.

Its eyes are very large and beautiful, and it has two short horns or feelers. It has four other legs joined all at the breast. When it leaps, it twists short one within another, and then exerting their spring all at the same instant, they carry the creature to a surprising distance. The legs have several joints, and are very hairy, and terminate in two long and hooked sharp claws.

The piercer or sucker of the flea is lodged between its fore-legs, and includes a couple of darts or lancets, which, after the piercer has made an entrance, are thrust farther into the skin to make the blood flow from the adjacent parts, and occasion that red round spot, with a hole in the centre of it, vulgarly called a flea-bite.

This piercer, its sheath opening sideway, and the two lancets within it, are very difficult to be seen, unless the two fore-legs, between which they are hid, be cut off close to the head: for the flea rarely puts out its piercer, except at the time of feeding, but keeps it folded inwards; and the belt way of seeing it is by cutting off first the head, and then the fore-legs, and then it is usually seen thrust out in convulsions.

By keeping fleas in a glass tube corked up at both ends, but to as to admit fresh air, their several actions may be observed, and particularly their way of coupling, which is performed tail to tail; the female, which is much the larger, standing over the male; they may also be thus seen to lay their eggs, not all at once, but ten or twelve in a day for several days successively, which eggs will be afterwards found to hatch successively in the same order. The flea may easily be deflected in a drop of water, and by this means the stomach and bowels, with their peristaltic motion, may be observed very plainly, as also their teats and penis, with the veins and arteries, though minute beyond all conception. Mr. Leeuwinkloek affirms also, that he has seen innumerable animalcules, shaped like serpents, in the fermen mufculum of a flea. Baker's Micros. p. 191, and 194.

Flea is also an infect which often does great mischief to crops of the hop kind. See Hops.

Flea-bane, in Botany. See Conyza.

Flea-bane, the common name of a plant of the weed kind, which is perennial, and common in pasture lands. It has a round, bending, solid, heavy stem. The leaves are oblong, sharp-pointed, wrinkled, downy, and embrace the stalk, on which they grow very thickly, without any regularity. It has yellow flowers, radiated and inclinato in a flower-cup, composed of narrow scales like bristles. And it has sometimes the name of fleawort. See Tachonanthus. fleawort, Pityriam. See Plantago.
FLEA-wort. See Flea-hone.

FLEA-hone. colour of a horse: is white, spotted all over with dark reddish spots.

FLEA. A common name, sometimes applied to a wattle hurdle, or kind of gate, which by negligent farmers is occasionally set up in the gaps of their hedge-fences. See Hurdle.

FLEAM. A small instrument of pure steel, composed of two or three moveable lancets, for bleeding a horse, or the like.

A case of fleas, as it is called by farriers, comprehends six sorts of instruments: two hooked ones, called drawers, and used for cleaning wounds; a pinknife, a sharp pointed lancet for making incisions; and two fлеамs, one sharp, and the other broad pointed: these last are somewhat like the point of a lancet, fixed in a flat handle, only no longer than is just necessary to open the vein.

There are many surgeons in Germany who bleed, or perform the operation of phthisotomy with this instrument, which they use in this manner: they hold one finger upon the end of it, which serves as a handle, and applying the point to the vein they are to strike, strike upon the back over the point with one of the fingers of the other hand, opening the vein much as farriers bleed horses. Others use a spring fleam, something like a single point of the fearfully instrument used in cupping; and others employ a sort of instrument in form of a dart; but as the position and size of the veins is different, in different subjects, no instrument will ever be found so useful as the common lancet of a proper size.

FLECHA, Matthew, in Biography, a Spanish Carmelite Monk, born at Prades, a small town in Catalonia; he was Maestro di Cappella to the Emperor Charles V. Amongst many other works in Spanish and French, he published "Divinarianum complutuum Psalmon," "Sectionem Brevem," and a "Salve Regina," together with a book of Motets at Prague, 1581; and died in 1604. in the Benedictine's College at Salzona, a large town in the State of Catalonia.

FLECHA, La, in Geography, a town of France, and principal place of a district, in the department of the Sarthe, seated in a pleasant valley watered by the Loire; 21 miles S.S.W. of Le Mans. N. lat. 47° 42'. E. long. 0° 1'. The place contains 5,699, and the canton 15,453 inhabitants, on a territory of 255 kilometres in 22 communes. In 1603, a college of Jesuits was founded here, by Henry IV., for the descendants of nobility only: the centre is converted into a town-hall, and the wings have been rebuilt as a seminary for the education of youth.

FLECHE, the name of a small work used in Fortification, having two equal faces, generally standing at an angle of about 85° or 90°, perhaps rather more, and deriving its designation from the French word fleche, meaning an arrow, to the head of which it bears much resemblance. This work is generally constructed along the front of the glacis, before the re-entering and salient places of arms: it confines only of a parapet, forming a faibant angle. The length of the faces may be from 20 to 25 toises, and the height of the work may be 8 feet; communicating with the covert way by means of a cut through the body of the glacis in a direct line: so that, by means of traverses, the defenders may make one or more flanks, and prevent their assailants from making any lodgement within the fleche, or in any degree commanding the place of arms before which it may stand.

FLECHIER, Esprit, in Biography, a French prelate, was born at Pernes, in the county of Avignon, in the year 1632. Though his parents were but of low rank, they contrived to give him a good education; and he made a rapid progress in the different branches of literature. At an early age, he was appointed professor of rhetoric in the college belonging to his order at Narbonne. In this situation he was called on to deliver, before the fletes of Languedoc, a funeral oration for Claude de Retè, archbishop of Narbonne. His discourse was received with raptures; and the success of this first attempt at such composition indicated the road which would lead him to celebrity. Some circumstances arose which induced him to try his fortune at Paris, where he was defers of distinguishing himself as a poet; but he not only failed in his expectation of a patron, but was obliged to drudge in the most subordinate duties of education to obtain a scanty livelihood. He was afterwards appointed preceptor to the son of M. de Cramart, counsellor of State, and remained some time in that situation; but his natural talents, with so much success, that he ranks next to Boffet. Of Flechier's orations, that for the great Turenne is the most celebrated. In 1673, he was chosen one of the forty members of the French academy; and in 1679 he published his "History of the Emperor Theodosius the Great," which was drawn up for the instruction of the dauphin, as a model of a pious and Christian monarch. After this he published "The Life of Cardinal Ximenes," in which he seems to have forgotten the character of this man as an intriguing politician. In 1685, Flechier was nominated by Lewis XIV. to the bishopric of Lavaur, on which occasion the sovereign paid him the highest compliment: "I have," says he, "made you wait some time for a place which you have long desired, but I was unwilling sooner to deprive myself of the pleasure of hearing you." Two years afterwards he exchanged the see of Lavaur for that of Nîmes, but not without great reluctance; though in a pecuniary point of view he was much benefited by the translation. Nîmes abounded with protestants, and the edict of Nantes had been just revoked. The persecutions which had followed that revocation had produced a crowd of martyrs, though it had added very few, if any, real converts to the catholic religion. In these circumstances, Flechier was considered as peculiarly qualified by his learning, eloquence, and zeal, to preside over that see. His moderation gained him the esteem of the protestants, who, in their retaliations on cruel persecutors, always held his dwelling in reverence. He was eminent for benevolence; and, during the scarcity in 1709, his charities were very great, and equally divided between the protestants and papists. He was free from pride, but never at a loss to chastise those who were ready to lock down upon him on account of his low origin. Some time before his death he had a dream, which he regarded as a preface of his approaching dissolution. He accordingly ordered a sculptor to attend with some designs for his tomb: he selected the most simple, being anxious that after his death there should be nothing ostentatious erected to his memory. When he bad made his choice, he said to the artist, "Begin your work without delay, for there is no time to lose." He died shortly afterwards, in the year 1710, lamented, says d'Alembert, by the catholiques, and deeply regretted by the protestants; and leaving to his brethren a worthy model of zeal and charity, simplicity and eloquence.
of any works, which, in the year 1782, were collected and published at Nîmes, in ten volumes octavo. Of his funeral orations, d’Alembert says, “their style is not only pure and correct, but full of sweetness and eloquence. They were truly pathetic; but this property became still more sensible, when the orations were pronounced by the author. His fiery action, and his flow and somewhat feeble voice, brought the hearers into a disposition of symptomatic sorrow: the soul felt itself gradually penetrated by the simple expressions of the sentiment, and the ear by the soft cadence of the periods. Hence he was sometimes obliged to make a pause in the pulpit, that he might leave a free course to plaudits, not of the tumultuous kind which refound at our profane spectacles, but expressed by that general and modest murmuring which eloquence, even in our temples, from an audience deeply moved; a kind of involuntary enthusiasm, which not even the futility of the places can repress.” Morell. Gen. Biog.

FLECKED, in Rural Economy, a term signifying pied, or streaked with different colours, as is often the case with cattle.

FLECKERAC, or FLECKERAN, in Geography, an island near the coast of Norway, in the North sea. Between the island and the continent is a famous harbour, which may be entered or quitted by the same wind. In the 17th century a fortress was built for its defence, so that the largest fleet may lie in it secure from storms or enemies. N. lat. 58° 1'. E. long. 59° 18'.

FLEDWITE, or FLIGHT-WHITE, in our Ancient Laws, a discharge, or freedom, from amercements: when one, having been an outlawed fugitive, comes to the peace of our lord and king, on his own accord, or with licence. Rathal.

Others rather take it to denote a muf't or fine, set upon a fugitive to be restored to the king's peace.

FLEECE, the name of the woolly covering thorn from off the body of the sheep, and rolled up in a long round form. Fleeces are of different weights and sizes, according to the breed of sheep. See Wool, and Sheep.

Fleece, the Golden, is famous among the ancient writers. It was this that the Argonauts, under the command of Jason, went in pursuit of to Colchis, a province of Asia, now called Mingrelia.

The mystery of the golden fleece is variously explained; either of the profit of the wool-trade to Colchis; or of the gold that they commonly gather there, with fleeces, in the rivers. Arthub. Diff. p. 223. See Argonauts.

Fleece, Order of the Golden. See Golden Fleece.

FLEECY HOSIERY, a kind of manufacture of modern invention and use, consisting of fine fleeces of wool interwoven into cotton pieces of the common flocking texture. The process of this manufacture may be thus described. Having twisted silk, cotton, yarn, &c. in the common flocking-frame, let the work be begun as in the common hophobia; and when a few courses are wrought in the usual method, in order to add a coating, draw the frame over the arch, and then hang wool or jersey, raw or spun, upon the beards of the needles, and slide the frame off their beards upon their frames, till it comes exactly under the ribs of the fawkens; then link the jacks and fawkens, and bring forward the frame, till the wool or jersey is drawn under the beards of the needles; and having done this, draw the frame over the arch, and place a thread of spun materials upon the needle, and proceed in finishing the course in the usual way of manufacturing hophobia with spun materials. The article thus manufactured has, on the one side, the appearance of common hophobia, and on the other side the appearance of raw wool.

FLEET, a number of vessels, going in company, whether on a design of war, or commerce.

In times of peace merchants ships go in fleets, for their mutual aid and assistance: in times of war, besides this security, they likewise procure convos of men of war; either to escort them to the places whither they are bound, or only a part of the way, to a certain point or latitude, beyond which they are judged out of danger of privates, &c.

The admirals of his majesty's fleet are classed into three squadrons, viz. the red, white, and blue. When any of these officers are invested with the command of a squadron, or detachment of men of war, the particular ships are distinguished by the colours of their respective squadron; the union is common to them all, and in those of the red squadron it is displayed on a red field; on a white for those of the white squadron, and on a blue field for the blue squadron.

A fleet, whatsoever be the number of ships of which it consists, is usually divided into three squadrons; and these again, when the ships are numerous, into three divisions, distinguished by a particular flag or pendant, and usually commanded by a general officer. The admiral, or principal officer, commands the centre; the vice-admiral, or second in command, superintends the van-guard; and the operations in the rear are directed by the rear-admiral, or officer next in rank. The most convenient order of a fleet, proceeding on a voyage, is that in which it is ranged into three lines or columns, each of which is parallel to a line close-hauled, according to the tack on which the line of battle is designed to be formed. The fleet being thus more inclosed, will more readily observe the signals, and with greater ease form itself into the line of battle, which see. See also Engagement.

The Spanish fleet went against England by Philip II., consists of a thousand vessels. In the East there have been fleets seen of three thousand vessels.

Merchant fleets generally take their denomination from the place to which they are bound; as the Turkey fleet, East India fleet, &c.

The Spanish call simply the fleet or flota, a certain number of vessels, belonging partly to the king, and partly to merchants, sent every year to Vera Cruz, a port of New Spain.

The flota consists of the captain, admiral, and patach or pinnace, which go on the king's account; and about sixteen ships, from four hundred to a thousand tons, belonging to particular persons. They are all so heavy laden, both going and coming, that they have much ado to defend themselves when attacked. The fleet puts out from Cadiz about the month of August, and makes it eighteen or twenty months before its return.

The fleet sent annually from the same port to Peru, they call the galloons.

When the two fleets put out together, they go in company as far as the Antilles, where they separate; the galloons for Carthagena and Porto Bello; and the flota for Vera Cruz; at their return they join at the Havana.

Of the two fleets the galloons are the most richly laden; not but the cargo of the flota is also very considerable.

Fleet, is also a famous prison in London, thus called from the river Fleet, on the border whereof it once stood.

To this prison persons are usually committed for contempt of the king and his laws; or upon absolute command of the king, or some of his courts, particularly that of chancery; and lastly, for debt.
FLEET, in Geography, a river in Kirkcudbright-shire, in Scotland, is navigable from Murray's falls in Wigtown bay, into which it enters by a wide mouth, called 'Fleet bay'; up to Gatehouse bridge, N. lat. 56° 35', W. long. 1° 47'.

Also, a river of England, in Darlington, navigable for barges from Portland Road at Pallante-House near Abbotthorpe, at the head of that remarkable ridge of pebbles and sand called Caulc bank. Also, a river of Nottinghamshire, which runs into the Trent. 8 miles S. of Newark.

FLEETING, in Sea Language, is the act of changing the situation of a tackle, when the blocks are drawn together; or what is called block and block by fairs. The use of fleeting is to replace the mechanical powers into a state of action, and the operation is nearly similar to that of winding up a clock of watch.

FLEETWOOD, William, in Biography, a learned English prelate, was born in the Tower of London, in the year 1596. He was initiated in clerical learning at Eton, from whence he was elected to King's college in the university of Cambridge. He took orders about the time of the Revolution, and became distinguished for the excellence of his pulpit talents. He soon obtained the honour of being chaplain to the king, and some other valuable preferment. He was appointed rector of St. Austin, and immediately, lecturer at St. Dunstan's, Fleet-street, where his sermons attracted great crowds of hearers. In the year 1651, he published an useful introduction to the knowledge of antiquities, entitled "Inscriptionum Antiquarum Sylloge, in duas Partes distributa," &c. octavo. The first part containing remarkable pagan inscriptions, collected from Gruter, Reinisch, and other writers; and the second containing of ancient Christian monuments; the whole illustrated with short notes, which were partly original, and partly selected from other writers. This work was well received, and contributed not a little to maintain the high reputation which the author had already acquired during his residence at the university. Mr. Fleetwood was next known as a theological writer. Of his works under this character, the principal was published in 1701, under the title of "An Essay on Miracles," which is reckoned a very ingenious performance, and was pronounced, by Mr. Farmer, as abounding in excellent reflections. A short time before, king William's decease, Mr. Fleetwood was nominated by his majesty to a canonry of Windsor; but, as the grant had not passed the great seal before the king's demise, the house of commons addressed queen Anne to allow that dignity upon their chaplain. She, however, attentive to the late king's wish, confirmed the grant in favour of Mr. Fleetwood, and also appointed him her own chaplain. About the year 1705, he resigned his rectory and lecturership, and retired to a small living which he had in the neighbourhood of Eton. He indulged his inclination for privacy, and applied much of his time to the study of church history and antiquities. In 1707 he published a work, entitled "Chronicon Precliormii," or "An Account of English Gold and Silver Money, the Price of Corn, and other Commodities, and of Stipends, Salaries, Wages, &c. in England, for six hundred Years last past." In the following year he was appointed, without his request, and even without his knowledge, to succeed bishop Beveridge in the see of St. Asaph. At this period, party rage and animosities ran very high, and no where more so than in the diocese of St. Asaph; but so high was the reputation of the new prelate, so great his prudence and address, so amiable and conciliating his manners, and so unbiased and exemplary his life and conduct, that he not only cleared all indecent and disreputable treatment, but secured the reverence and affection of his clergy, who almost all diffused from him in principle. The queen now frequently attended the sermons of her bishop, many of which were made public at his desire. He likewise constantly attended his place in the house of lords, where he conducted himself with dignity and spirit, maintaining his independence; and he was invariably governed in his votes by a regard to what he considered to be the true interests of his country. In his first episcopal visitation, he delivered and published a charge, which has been generally regarded as one of the most perfect performances of that kind. This was early in 1710; and towards the close of that year a change in the ministry took place, and new principles became triumphant at court. From these the bishop was very averse, and nothing could induce him to give his support to the measures of the new ministry, which he conceived to be equally prejudicial to the glory of the queen and the true interest of the nation. In the year 1711-12, he was appointed to preach before the house of Lords; but by some means it was known that the discourse which he had prepared was very hostile to the sentiments of ministers, and they accordingly adjourned the house beyond the day on which it was to have been delivered. The bishop determined to print what he was prevented from preaching, and published it under the title of "A Sermon preached on Fast-day, Jan. 16, 1711-12, against such as delight in War, by a Divine of the Church of England." In the political part of this discourse, the bishop spake his mind with the utmost freedom, relative to what he judged to be the disgraceful and ruinous measures of administration; which so exasperated them that they resolved to lose no opportunity of repenting the infilt, as they deemed it. He next engaged in the controversy respecting lay-baptism, excited by Mr. Dodwell and others. In 1712, the bishop published four sermons, which he had formerly preached with great applause on the deaths of queen Mary, the Duke of Gloucester, and king William, and on the accession of queen Anne. In his preface he assigned the reasons for their publication at this particular period, and made some severe animadversions on the fashionable politics of the day. It was now determined to crush the bishop. With this view, ministers carried in the house of commons a motion that the objonuable work should be burned by the hands of the common hangman: to which it was replied, "the fire is certainly a conclusive, but not a convincing argument; it will destroy any book, but it refutes none." In 1713, bishop Fleetwood published, without his name, "The Life and Miracles of St. Wenefred, with her Litanies, and some Historical Observations made thereon." He undertook this work to counteract the attempts of papist emulators, who made use of it to induce to their faith the weak and silly among the crowds who repaired for the benefit of the waters to the well of Holywell, which was in his diocese. On the accession of the house of Hanover, Dr. Fleetwood was translated to the see of Ely; which new and unexpected dignity he received only to spur him on to be more diligent in the discharge of those duties which belonged to the episcopal office. His indefatigable labours are said to have worn him immunities, which produced a gradual decay, under which he sunk at Tottenhall, in Middlesex, whether he had removed for the benefit of the air. This happened in 1723, when the worthy bishop had attained his sixty seventh year. He had ever maintained an excellent character, and was a bright pattern of innocence of life, integrity of heart, and sanctity of manners. Beng. Brit.

FLEGIS, in Geography, a small island in the gulf of Engla; 8 miles E. of England.

FLEICHER, John Christopher, in Biography, a
very celebrated instrument-maker of Hamburg, at the beginning of the last century. He had harpsichords from 60, 70, and 100, to 1000 dollars each. His theorbo and other lutes were in the greatest request; and in all his instruments the imitative stops were ingenious, and the mechanism excellent.

FLEISCHER, M., a Brunswick composer of great merit, in 1723, whose church music, comic operas, and harpsichord pieces, are all written in an elegant and pleasing style.

FLEMEN, a term in Surgery, having two different significations, viz. a tumour near the ankles, and the hardened surfaces which occur on the hands and feet. Flemen (quinque flagmen) is said to be derived from fleas, to incline downwards.

FLEMENFRIT, Flemenfrith, or Flemishfrith, in our Old Writers, signifies the receiving or relieving of a fugitive or outlaw.

FLEESWITE. FLEISCHER, received in settlement of his haberd in the church of Leyden, and His haberd in the church of Amsterdam. In the course of a few years, he accepted of an invitation as pastor of a Scotch church in Lothbury, London. Here he expected to become more extensively useful as a minister of the gospel; he was moreover urged to make the exchange by King William, who often advised with him on the concerns of his own country. So great was his modesty, that he requested he might at all times be called to court with the utmost privacy. His great learning and talents procured him much respect abroad, and also in this country, where he was greatly esteemed by churchmen and dissenters, as well as by those belonging to the Scotch presbyterian ministry. He was on terms of friendship with the archbishop of Canterbury; and was chosen one of the preachers of the lecture, instituted by the merchants of London, at Sotterly-hall, every Tuesday. From his early years he was eminently devout; and he was firmly attached to the British monarchy and constitution. He died in 1716. He published several works; but that by which he was chiefly known is entitled "Chirnology, a Discourse concerning Christ." This excited much attention in the early part of the French revolution, on account of the striking coincidence between the author's interpretation of the fourth vial in the book of Revelation, and the events which were taking place at that period. Gen. Biog.

FLEEMING, Caleb, was born at Nottingham in the year 1698, and, while very young, he discovered an uncommon taste for literature, and employed every leisure moment in improving his mind, in which he had the assistance of a learned and liberal divine of his native town, who took the care of a small number of pupils. He continued at Nottingham some years, engaged in a mercantile employment, and then removed to London. He became intimate with Mr. Holt, afterwards one of the tutors at Warrington, who assisted and encouraged him in those studies which enabled him afterwards to embark in the work of the Christian ministry. His abilities and acquisitions had attracted the notice of Dr. Thomas, bishop of Winchester, who was desirous of making provision for him in the established church. A living was offered him in Cumberland, and Dr. Thomas benevolently proposed advancing a sufficient sum of money to defray the expenses of his journey and removal to so great a distance. His scruples upon the subject of conformity prevented him from accepting this liberal and very handsome offer; but he never ceased to acknowledge with sentiments of unfeigned gratitude the kindness of the worthy prelate. Nothing but a sense of right, and an ardent love of the truth, could have led him to decline the offered introduction to the national church; for he, at that time, had a wife and several children, and was almost destitute of every resource to provide for their wants. In forming his determination, he was encouraged by the magnanimity of his wife, who assisted him. He was ready to undergo any privations, and suffer any hardships, rather than accept of influence at the expense of his integrity and peace. From this moment he resolved to engage in the work of the ministry among the protestant dissenters, and was, after an interval of some years, chosen pastor of a congregation in Barb and exemplify, London. Here he continued in office till the year 1752, in which he was chosen assistant to the celebrated Dr. Potter at Pinner-hall, whom in a short time he succeeded in the pastoral office. The duties of which he discharged with exemplary diligence, until he became incapacitated for public service by the infirmities of age. He died in the year 1759, in the eighty-first year of his age. He was the author of numerous publications on important and interesting topics, relating to morals, the cause of Christianity, and of civil and religious liberty. The titles of many of these are given in the General Biography. He was an able and judicious defender of the truth of divine revelation, and a close and diligent inquirer into its doctrines. He was led to renounce what are called the orthodox tenets of established systems, and to embrace the simple unitarian creed. He was a steady and resolute upholder of the rights of conscience, and of private judgment; and considered the interposition of human power in matters of religion as the principal source of the corruptions of Christianity. His piety was cheerful and rational; his character and manners upright and exemplary; and his private and public virtues such as rendered him the object of warm esteem among those who enjoyed his acquaintance.

FLEMING, in Geography, a county of Kentucky in America, bounded N. by Mafon, S.E. by Virginia, S.W. and W. by Montgomery: it is mountainous, and watered by several streams which fall into Sandy and Licking rivers; it contains 4,903 inhabitants, of whom 240 are slaves. The chief town of this county is Flemingsburgh, containing 123 people, and a post-office.

FLEMINGIANS, or FLANDRIANS, in Ecclesiastical History, a sect of rigid Anabaptists, who acquired this name in the sixteenth century, because most of them were natives of Flanders, by way of distinction from the Waterlanders. In consequence of some dissensions among the Flemings, relating to the treatment of excommunicated persons, they were divided into two sects, distinguished by the appellations of Flandrians and Frierders, who differed from each other in their manners and discipline. Many of these in process of time came over to the moderate community of the Waterlanders; but those who remained separate are still known by the name of the old Flemings, or Flandrians, but they are comparatively few in number. These maintain the opinion of Manno, with respect to the incarnation of Christ, alleging, that his body was produced by the creating power of the Holy Ghost, and not derived from his mother Mary.

FLEMING, natives of Flanders, a colony of whom were established in South Wales by Henry 1, in order to strengthen
Agriculture, and they and receive their patronage of them, but from true notions of policy; with a view of increasing, by such an accession of useful inhabitants, the wealth and strength of his kingdom. Many of them were planted by William Rufus in the waste lands of Northumberland, and about Carlisle; and others were dispersed all over England, and began by their multitude to give some uneasiness, which Henry removed, and availing himself of them to still greater advantage, he sent them all to settle in South Wales; where he gave them the district about Tenby and Haverfordwell, in which their polity remain to this day. They were very industrious, and, at the same time, very valiant; skillful in husbandry, manufactures, and commerce, and equally expert in the use of arms: so that they answered all ends which can be proposed in planting a colony, cultivation of lands, improvement of trade, and defence of the country. William of Malmesbury speaks of them as a strong barrier, which restrained the Welsh in those regions from inflicting the English territories: and certainly such a plantation was a more effectual security than any fortress or bulwark. This colony was further strengthened by Henry II., who allowed some of the Flemish mercenaries, whom, in the first year of his reign, he banished out of England, to go to their countrymen established in Pembroke, and settle among them. This proved in the event a very politic measure; for this reinforcement of brave and veteran soldiers was sufficient to defend the Flemish colony, and a cessation of hostilities on the part of the Welsh soon followed that event. This colony was attacked in the year 1164, and their country ravaged by Rhus ap Gryffyth of Dynevor.

Flemings. If the Natives of Flanders and the Netherlands were not the inventors of counterpoint, many proofs are extant of their having successfully cultivated it at a very early period. Almost all the elder great contrapuntists, of whose works there are many remains, such as Ockeghem, Jucquin du Pres, Adrian Willaert, &c. were Flemings; as the most curious specimens of early counterpoint, among the printed music in the Museums, there is a collection of masses in four parts, the first that issued from the press after the invention of printing. They consist of the first and third part of the masses which Jucquin composed for the pope's chapel, during the pontificate of Sextus the Fourth, who reigned from 1471 to 1514; the masses of Pierre de la Rue, sometimes called Petrus Platensis, a set of masses by Anthony de Foven or Feun, Robert de Foven, and Pierzon. The masses of John Mouton; ditto of different composers, ("Miffie diversorum Autorum," &c.) Obrecht, Phil. Baffron, Brunel, Gafpar, and de la Rue.

All these were printed by Ottavius Petruccio da Fossembronc. He first published the masses de la Rue at Venice, 1503, and in 1508 those by different authors. In 1513, removing to Fossembronc, in the Ecclesiastical State, he obtained a patent from Leo the Tenth in behalf of his invention of types, for the sole printing of figurative song, ("Cantus Figurarum,"") and pieces for the organ, ("Or ganorum Intabolaturarum,"') during the term of twenty years. This patent is signed by the learned cardinal Llemback, Leo's secretary.

The masses are followed in this collection by the second, third, and fourth sets of Latin motets, in four or five parts, called "Motetti della Corona," from the figure of a crown stamped on the title page. The words of these excellent compositions consist of short portions of Scripture, and hymns of the Roman church, set by Jucquin, Carpentras, Mouton, Adrian Willaert, Contantius Festa, and other great masters of the same period: they were all printed at Fossembronc, in 1519 by Petruccio, and published with the same patent as the masses.

The only Italian composer amongst these is Contantius Festa, but there is so much of that grace in his melody, clearness and facility in his harmony, as have always been the distinctive characteristics of masters of the highest class in his country, that we can hardly think a genius so highly polished flood alone among such a number of foreigners at this early period; or that such regular compositions, and learned and ingenious contrivances, could be attained by the gigantic stride of any one musician, however superior his genius may have been to that of his predecessors.

FLEMMINGTON, in Geography, a small post-town of New Jersey, in Hunterdon county, about 6 miles N.E. of Amwell or Delaware river; 53 miles N.E. by N. from Philadelphia. It has a post-office and about 12 compact houses.

FLEMISH, or the FLEMISH TONGUE, is that which we otherwise called Low Dutch, to distinguish it from the German, whereas it is a corruption, and a kind of dialect. See Flemish Bibles.

The Flemish is the language used throughout the provinces of the Netherlands. It differs considerably from the Walloon, which is a corrupt French.

Flemish Brick. See Bricks.

FLEMISH Husbandry, in Agriculture, a name sometimes applied to that sort which was introduced from the Low Countries, and which consisted in the combining of the green crop system, with that of corn. It is supposed to have been practised there at an early period. See Husbandry.

Flemish School of Engravers. See Netherlands.

FLEMMING, Richard, in Biography, an English prelate, who flourished in the fifteenth century, and who was founder of Lincoln college, Oxford. He was born at Crofton, in the county of Lincoln. He finished his studies at the University college, Oxford; and was, in 1420, collated to a prebend in the cathedral church of York; and in the next year, he had the honour of being one of the proctors of the university. He now espoused warmly the cause of Wickliff, and, by his zeal, induced others to join in the same business. Some preference in the existing church induced him to change sides; and he became more violent in defence of what he had been in the habit of holding to contempt as gross corruptions, than he had been in the cause of reform. He obtained the friendship of Henry V., and was promoted, in 1420, to the bishopric of Lincoln. After this he was sent deputy to the council of Constance, where he obtained great applause by an eloquent speech delivered in the presence of pope Martin V., in vindication of his country against the calumnies and aspersions of the French, Spanish, and Scottish prelates. He was now probably appointed chamberlain to the pope; and, on his return, to exhibit his zeal, in subterranean to the decree of the crusade of Constance, he caused Wickliff's bones to be dug up and burnt. The see of York being vacant, the pope, by his own authority, translated Dr. Flemming from Lincoln to that archbishops; but the king put in his veto, and the disappointed prelate was obliged to be contented with Lincoln. After this he formed the design of founding a college, accordingly as a seminary for divines to write, preach, and dispute.
against Wickliff. Before he had made much progress in the building, he died at Sleaford, in 1430-31; leaving, however, sufficient money and effects in the hands of trustees to complete the undertaking. Biog. Brit.

FLEN, in Geography, a town of Sweden, in Sodermanland; 22 miles N.W. of Nykoping.

FLENSBO, a sea-port town of Denmark, situated on the eastern coast of the duchy of Slesvig, in a gulf of the Baltic, called “Fleensborgvick,” which extends about 18 miles inland, and forms a good harbour, so that the large vessels are unloaded at the quay, and secured from all winds by surrounding hills. It is the capital of a district, and one of the handomest and most commercial towns in the duchy; 22 miles N. of Slesvig. N. lat. 54° 47'. E. long. 9° 27'.

FLE'RON, a town of France, in the department of the Oise, and chief place of a canton in the district of Lesd. The place contains 950, and the canton 15,412 inhabitants, on a territory of 130 kilometres in 23 communes.

FLEsberg, a town of Norway, in the province of Agderhus; 36 miles W. of Christiania.

FLESH, in Anatomy, is understood to denote only the muscular substance of an animal body, although in common language it forms to include all the soft parts of the frame, except the skin. Yet it is used sometimes more loosely by the old anatomists, who speak of muscular flesh, glandular flesh, &c.

FLESH, in Rural Economy, the fine healthy fibrous matter that constitutes the principal value of domestic animals. The nature and properties of flesh are of great importance to the breeding and grazing farmers, in respect to the feeding and fattening of their animals. Such breeds as do not possessed perfectly good flesh should not be encouraged either in sheep flock or in cattle.

FleSs, also used in Theology, in speaking of the mysteries of the incarnation and eucharist.

The word was made flesh, Verbum caro factum est. The Romanists hold, that the bread in the sacrament of the supper is turned into the real flesh of Jesus Christ. See Transubstantiation.

FLESH, Fungous. See Fungus.

Flesh is sometimes also used for botanists for the soft pulpy substance of any fruit, included between the outer rind or skin, and the seeds, or done; or for that part of a root, fruit, &c. fit to be eaten.

Flesh-eater. See Carnation.

FEsh bay, in Geography, a bay of the Indian seas, on the coast of Africa. N. lat. 34° 35'. W. long. 22° 20'.

FLESHY, Carnosis, in Botanical Phytology, is used to express any more than ordinary degree of thickened or juicy skins in such parts as are naturally in some degree pulpy, as leaves. Witness the whole tribe of succulent plants, comprehending the genera of Aloe, Grifolia, Mammillaria, Sedum, &c. all which have folia carnosia, flabby, or very pulpy, leaves. It is also applied to fruits usually dry or juicy, when they happen, contrary to their general nature, to be pulpy, as the cape in Cerbera apoidea, and the receptacle of the seeds in the Strawberry; but in these last instances the word fructus, expressing a fruit allaining the nature of a berry, is more proper. Several species of Euphorbia, Peganomum, &c. have flabby items; and a great number of perennial plants, few annual ones, have flabby roots. In all such cases, the part is more durable, more tenacious of life, and less dependent on contingencies than it might otherwise be. The roots of some grasses, as Pileum pratense, though naturally flabby, become flabby, when they are exposed to occasional privations of food or moisture, by which they become more independent of such accidents in future.

Fleshy Roots, in Gardening, are all such as are constituted of a large mass of pulpy matter, whether in a laminated form, or the contrary. See Root.

FLESK, in Geography, a river of Ireland, in the county of Kerry, which flows into Lough Leane, better known as the lake of Killarney.

FLETEUS, in Ichthyology, a name used by some authors for the common flounder; the polar flounders of most writers. See Plenerpeye Ploca.

FLLET-Milk, in Rural Economy, such milk as has been skimmed, or had the cream taken off from it. This sort of milk is sometimes employed in forming a poor kind of cheese, termed skim-milk-cheese.

Fleta, in Biography. It is not a little singular that this, which is the title to one of our early law-books, should almost uniformly have been noticed as the name of a writer on law, and that by him cited in the title. It is probably Blackstone, in his Commentaries on the laws of England, speaking of the legal period, which commenced in the time of Edward I., when enumerating the great law writers of that reign, mentions Britton, Fleta, and Hougham, as eminently conspicuous. The commentary under the title Fleta was evidently written at the reign of Edward in 1540.

But Nichollson, in his invaluable work, "The Historical library," observes, that the writer is unknown; that it was some person resident in the Fleet, and who thence adopted the name of the place as a title for his work. Yet Morey says the authors of it were some lawyers, who wrote it in the prison of the Fleet, where they had been confined for the crime of concussion, the particular nature of which has been discussed at large by the learned Selden. Grand Dict. Hist.

Fletcher, Giles, brother of Richard, bishop of London, was born in Kent, and educated at Eton school, whence, in 1565, he was elected king's scholar at Cambridge. He obtained at the university the character of an accomplished gentleman and an excellent poet, and after he had taken the preliminary degrees, he took that of doctor of laws in 1581. He was employed by queen Elizabeth as commissioneer in Scotland, Germany, and the Low Countries, and in 1588 was sent ambassador to the Emperor Theodore Ivanovich, with the charge of re-establishing the commercial concerns of the Russian company, which had fallen into decay. His reception at first was very unfavourable, but he at length succeeded in concluding an advantageous treaty, by which the former privileges of the company were renewed and confirmed. After his return, in 1591, he published an account "Of the Ruffe Commonwealth," which contains many curious and authentic particulars of that country, then little known to the rest of Europe. The freedom of certain remarks and strictures in the book caused it to be suppressed, through fear of giving offence to the reigning prince, but it is to be found in Hakluyt's collection. After this he was made secretary to the city of London, a matter of request, and treasurer of St. Paul's church.

Fletcher, John, a dramatic writer, son of Richard Fletcher, bishop of London, was born in Northamptonshire in 1570, and received his education at Cambridge. It does not appear that he followed any profession except that of a poet, in which capacity he was the insepable companion of Beaumont. He died of the plague in 1625, and was buried in the church of St. Mary Overy. Several of the plays of Beaumont and Fletcher were published during their lives, and various editions have been given of them in a collective form. The ten volumes edited by Theobald, Symonds, and Seward.
Seward, in 1751; and the same number published by Colman in 1778, a e ecleemed the most correct. The poetical powers of Fletcher are advantageously displayed in a piece which was certainly his own unaided composition, entitled, "The Peculiar Stephenresa," a dramatic pastoral on the model of the Italian. "It poifsibly," says an able critic, "many beauties, and has been honour'd with a chaste imitation of some of its passages by Milton in his Comus." Its plot, however, is defective and unpleasing, to which may be attributed its unfavourable reception on the stage."—BLO.

FLETCHER, PHEINEAS, son of GILES, was educated at Eton school, and from thence he was elected to King's College, Cambridge, in 1600. In 1621 he obtained the liviry of Holgate, in Norfolk, on which he appears to have passed the greater part of his mature life. Little more is known of this person but that he was addicted to poetical composition at a very early period. His principal works are "The Purple Island," "Peculiar Elogues," and "Miscellanies," all printed together at Cambridge in 1633. An edition of his Peculiar Elogues, with some of his Miscellanies, was published at Edinburgh in 1784; and all his poetical compositions have been received into Dr. Anderson's collection. He wrote a book in prose, entitled "De Literatis Antiquae Britanniae."—BLO.

FLETCHER, ANDREW, son of Sir Robert Fletcher of Saltoun, in Scotland, was born in 1673. Being left fatherless while he was a child, he was placed under the tuition of Dr. Gilbert Burnet, then rector of Saltoun, from whom he imbibed the learning, piety, and attachment to the principles of a free government, by which that eminent prelate was distinguished. He spent some years of his youth in foreign travel, and first appeared as a public character in the station of a commissioner for East Lothian in the Scotch parliament. He became so distinguished by his opposition to the arbitrary measures of the court, that he thought it advisable to withdraw to Holland, and upon being cited to appear by a summons from the lords of the council, which it was known he could not obey, he was outlawed, and his estate confiscated. In 1683 he came over to England to aitift, with his friend Mr. Baille of Jerivwood, in the congratulations held among the friends of liberty in England and Scotland, to concert measures for their common security; and by his prudence and address he avoided giving any pretext to the ministry for his apprehension. He returned to the continent, and in 1688 engaged in the enterprise of the duke of Monmouth. He landed in the west of England, but was obliged to quit the country again on account of a difpute which he had with a rude, vulgar, and violent man, whom he shot dead. From England he embarked for, and landed in Spain; he afterwards passed into Hungary, where he engaged in the war with the Turks, and distinguished himself by his valour and skill. The interest which he took in the fate of his country soon brought him back to join in the conferences which were held among the Scotch refugees in Holland, for the purpose of effecting a revolution. When that event took place, he returned to Scotland, and resumed the posifion of his estate. He was a member of the convention for the settlement of the new government in Scotland, and in all his political conduct he shewed himself the zealous affeter of the liberties of the people, without any regard to party distinction, and free from all views of his own interest. In 1698 he printed "A Discourse of Government with Relation to Militia," also "Two Discourses concerning the Affairs of Scotland." In one of these he suggests a plan for providing for the poor by domestic slavery, which, to lay the least of it, comes with a very ill grace from one so zealously attached to the cause of liberty as Mr. Fletcher. When a bill was brought into the parliament of Scotland for a propfly to the crown, in 1763, he moved, that previously to this or to any other bullions, the house should consider what acts were necessary to secure their religion and liberties in case of the queen's death, and he proposed various limitations of the prerogative, which were received in the "Act of Security," p. 6 through his exertions into a law, but not followed by the subsequent union. Of this last measure he was a zealous opposer, and made many speeches on the subject; but it was not a matter to be decided by eloquence, or else that of Fletcher, which was more nervous and correct than that of any other speaker in the Scotch parliament, enforced by his known patriotism would have had much weight. He died at London in 1716. His publications, and some of his speeches, were collected in one volume by the author, entitled, "The Political Works of Andrew Fletcher, Esquire." As a writer he possessed great power: his style was periphrastic, elegant, and energetic, and his mind was enlarged by acquaintance with the best authors, ancient and modern, and by every species of knowledge which forms the politician. "He was," says one of his biographers, "a true friend, but an irreconcilable enemy; would have his life readily to serve his country, and would not do a base thing to save it. His thoughts are large as to religion, and could never be brought within the bounds of any sect, nor will he be under the distinction of whig or Tory, saying these names are only used to cloak the knavery of both parties."—Hume.

FLETCHER, in Geography, a township of America, in Franklin county, Vermont, containing 200 inhabitants, having Cambridge on the S. E. and Georgia on the W.

FLETCHER'S Noo, a cape of America, on the coast of Main. N. lat. 43° 25', W. long 70° 29'.

FLETZ, or Flötz, among German miners, a term of high antiquity, generally denoting a layer of any kind of rock, the position of which approaches the horizontal line. The word, thus applied, being vague and insignificant, it would fearlessly claim our notice in this work, but for the more fixed and scientific meaning it conveys in the compounds "Flötzen Mountains" (Flöz Gebirge), and "Flötz-rocks" (Flöz-gelber-arten), which terms, as proceeding from the country which may properly be called the cradle of mineralogy and geology, are now inserted into the technical definitions of most European languages. We too (in the succeeding article) have adopted the prefix "flötz," in preference to "secondary," which latter, (not to mention other objections against it,) cannot be adopted by those who, with Mr. Werner, admit a formation of rocks, intermediate between the primitive and secondary rocks of other geologists.

With regard to the spelling here proposed, it is to be observed that, although "fletz" with a diphthong may be conformable to the rules of modern German orthography, yet the ancient mode of spelling the word is "flötz," and this we prefer, partly because the sound of the letter ë, as pronounced by the Germans, is foreign to the English language, and partly because the old spelling and pronunciation (which latter is still heard in several parts of Germany) are more correct, as they approach nearer those of other words, which in various dead and modern languages equally convey the idea of a horizontal even plane, such as natio, latit, fluit, plat, flot, etc.

Flötzen Mountains, Flötzer-Rocks; Flöz-Gebirge, Flötz-gebirge-arten. Germany. The mountains and rocks to which these names are given by the German school of geology, are obviously of much more recent origin than those called primitive (see Rocks, Primitive). They bear a more diffusely
From the alluvial, the fletz rocks are distinguished by all those positive and negative characters that bespeak an earlier origin, being the result of a general revolution that extended over the whole surface of the globe; while the former can, without any gratuitous assumption, be considered as partial formations produced by the drift of all of the others: they have originated, as it were, under the eye of the geologist, who discovers in their later substance, in the compounds of loam, marle, &c., the remains of substances known to him, as belonging to the present creation, and swept together by partial inundations, by overflows of rivers, &c. (See Rocks, Alluvial). From the primitive, the fletz mountains are in general easily distinguishable: for while the former, (such as the Hartz, the Saxon Erzgebirge, a great part of the Fichtelgebirge, &c.) usually tower to a majestic height, divided up to their summits by ravines and chains, the fletz mountains are generally of a less bold and steep aspect, and run along in more uniformly undulated ranges. Viewed on a large scale the fletz-rocks are much more compound than the primitive; but they appear much less so, and often of a perfectly homogeneous nature, when viewed in small masses. Though the fletz are already seen to occur in the primitive rocks, yet this formation owes its principal character to the siliceous and argillaceous earths, (from granite to clay-lime); while calcareous with argillaceous earth, appear to be the leading features in the composition of fletz-rocks. Very characteristic of these rocks are the petrifications with which they abound, and which decrease in number as the fletz approaches the primitive formation, where they are no longer observed. These petrifications consist in parts of vegetables, and shells of various marine animals, most of the prototypes of which no longer exist; and frequently one particular species occupies a stratum throughout a considerable tract of country, while the adjoining stratum is floored with a species totally different from, and unmixt with the others. Bituminous fossils, of rare and ambiguous occurrence in primitive rocks, have their principal occurrences in fletz mountains. Thus coal, so frequent in the comparatively new formations, can scarcely be traced higher than to the oldest sand-lime, where it becomes infrequent and dispersed. But as a feature of the mountain under consideration, it is a stratification, marked by many peculiarities not observable in other formations. The fletz generally run parallel with one another; their position, though sometimes feebly deviating from the horizontal, is often visibly inclined; they accompany the sides of primitive mountains, either partially, or they surround them; while the summit of the latter, projecting over the overcomposing fletz-rocks, will often make the superficial observer suppose to see a primitive rock superincumbent on a more recent formation. Thus, for instance, we have the Schweiterleng, an old porphyry mountain, near Wettin, in the district of Halle, rising in the inclined of an infolded mass out of the surrounding fletz strata. It has been said above that fletz mountains are less rapidly rising, and it may be added that they do not generally attain any considerable height, if we except some of those belonging to the cliffs which Mr. Werner calls the newest fletz-trapp formation, comprising basalt, wacke, &c., rocks, some of which, by other geologists, are classed with the genuine volcanic productions. If, however, the fletz mountains can be said in general to possess many characters that keep them distinct from the primitive, this is not strictly applicable to all of them; for there is a small series of rocks of an ambiguous nature, which, being often intermediate between the two formations, and participating of the characters of both, have frequently embarrassed the framers of geological arrangement, being formed by Mr. Werner into a particular class, under the name Übergangsgebirge, (see Transition Mountains); a distinction which is not admitted by Mr. Voigt and others.

As the ideas which the two last mentioned geologists entertain relative to the origin of the fletz mountains have regulated their classification of the rocks belonging to that and the transition formation, it will be proper, before we proceed, to give a short outline of their respective theories, as far as they relate to the subject under consideration. Werner accounts for the difference that subsists between the rocks of his three first classes of the aqueous formation, from the oldest granite down to the newest fletz-lime, by the gradual diminution of the water on the surface of the earth. At that period, when the earth was in a chaotic state, and entirely encompassed by the ocean, which contained its first matter, the primitive mountains were formed by the laws of crystallization. As the volume of the water gradually diminished, and dry land took its appearance, in that, when the earth pafted into an inhabitable state, a series of rocks originated, which participate, in some measure, of the nature of the primitive, at the same time that they display the first traces of remains of simple organic bodies that inhabited the sea, and of mechanical deposition, which could take place only near the surface of the water. The increase of these mechanical depositions corresponded to the diminishing level of the ocean, from the transition to the more recent periods, each of which furnished the successive fletz-litha with their peculiar contingents of organic bodies, most of which remain only as petrifications. It is in this manner that the celebrated professor of Freiberg assigns to all the known rocks their respective places in his arrangement, the whole forming an uninterrupted series from the granite to the youngest of the alluvial mountains. There is, however, another and essential difference of rocks allied to those of the fletz formation, and which, (being superimposed promiscuously on other formations, from the primitive to the most recent,) is kept separate by Werner, as one of the subordinations of their class; to this belong basalt, the kindred wacke, porphyry-lime, amygdaloid, and other rocks enumerated by Werner as members of the fletz-trapp formation. The whole of this is supposed by him to owe its origin to a posterior deluge, or a sudden rising and retiring of water, and is considered as the newest member of the fletz formation.

Mr. Voigt, who has given a classification of rocks, though he rejects the transition period adopted by Mr. Werner, still divides the fletz rocks into those of older, and those of newer formation. As his ideas on this subject are but little known to the English reader, we shall here give a short sketch of his theory, omitted under the article Earth. His hypothesis is, that in its primordial state, our planet was entirely encompassed by water, in which, without having either mountains or valleys, it floated like the yolk in the albumen of the egg. Of the substances that composed the earth in this state of submission, some were apt to undergo fer-
fermentation, to ignite, to give out elastic vapours and gases, and to produce explosions. It was by these energies that masses were raised from the bottom of the ocean towards its surface, where they formed islands, which afterwards constituted the principal ranges of primary mountains. The body of water displaced by these elevated masses filled up the space the latter originally occupied; and this diminution of the water was the cause of the appearance of an additional portion of dry land. Of the detritus of these primary mountains, and by the deposition of mineral substances, still divided or floating in the ocean, the flëtz mountains were produced, which formed layers surrounding the original islands.

As according to this theory (which the reader will observe is not unlike that of Lazzaro Moro), no considerable time intervened between the formation of the primary and flëtz mountains; it is no matter of surprise that the newest of the former should show considerable affinity to the oldest of the latter formation; and that intermediate kinds of rocks should have been formed, which appear of an ambiguous origin only when viewed out of connection with the rest.

But, though our author does not admit transition rocks in the sense in which this word is taken by some geologists, he nevertheless thinks that there are flëtz rocks, that, strictly speaking, might be referred to the primary; namely, such flëtz of lime and sand-flëtz, that, according to his theory, were raised at the same time with the primary mountains on which they were deposited at the bottom of the sea. To this division belong those flëtz which are sometimes observed in such places, which, from their elevation, cannot be supposed to have been reached by the water when the regular flëtz rocks were deposited. Thus, for instance, we see on the primitive granite mountains of the Hartz, not far from Clausthal, a calcareous rock called the Hüttengesteine, which constitutes a reef almost entirely made up of corals, which prove its having been formed at the bottom of the ocean. Not less remarkable in this respect is the Hanskühlcn-burg, a huge sand-flëtz rock, on the high Bruchberg, one of the Hartz mountains, at an elevation which precludes the idea of its having been produced at the same time with the younger flëtz-sand-flëtz, from which it differs also in its external characters. In the same manner, our author refers to the older flëtz rocks those flëtz that are met with on the declivities and in the chains of high primitive mountains, at a greater elevation than the younger flëtz formation reaches; and which were deposited soon after the summits of the primitive mountains were raised above the surface of the ocean. The first of Voigt's older flëtz-rocks is what he calls the old sand-flëtz, the fame which has been above alluded to, and which is totally different from that of Werner, as we shall see hereafter. The old sand-flëtz of Voigt is of a much rougher nature than the common flëtz sand-flëtz, and always occurs in very elevated situations.

2. The principal coal formations, confided by Werner as of much later date. The geognostic relation of this interesting inflammable substance, much as it has been written on it, is still involved in obscurity; more recent observations appear, however, to be in favour of Voigt's ideas respecting it.

3. Slate-clay (Schieferthon) nearly of the same age with coal and its sand-flëtz, it being found alternating with these latter, and in general occurring under similar circumstances. In this rock are found the most perfect impressions of vegetables which the earth produced in its primordial state, wholly belonging to the animalculeous and terraceous, the former of which required nothing for their growth but water, the latter nothing but naked rocks.

4. The sand-stone, as Mr. Voigt calls it, of yellowish, and sometimes orange-grey colour, coarse grain, considerable hardness, and a multitude of petrifications. It never occurs distinctly stratified, but generally as infiltrated amorphous masses and rocks in more elevated situations. The highest masses are seen at Reichen in the forest of Thuringia, where they rest on high porphyry mountains; and lower down it frequently accompanies those mountains in grotesque groups of mafly rocks. Lasso has described the same kind of lime-flëtz in his work on the Hartz mountains. Some kinds of rocks, described by pupils of Werner, as transition lime-flëtz, appear to be the same with the oldest lime-flëtz of Voigt.

From what has been said, (and what remains to be said under the article Transition-Rocks), it appears that, however the followers of different geological systems may be agreed with regard to the nature of primitive and flëtz mountains in general, their opinion will be found to diverge at a few points where adjoining distinct formations, by mutually borrowing of each other geognostic and orceognostic characters, battle disimilification, and cause the orients to draw lines of demarcation that are more or less derived from hypothetical propositions.

In order to illustrate the different flëtz of the flëtz formation more generally acknowledged as such, we shall call a view over the tract of country extending in an eastern direction, from the foret mountains of Thuringia to the Hartz, and enumerate them in the order in which they succeed each other, according to the observations of Mr. Voigt. This successive, however, should not be supposed to prove exactly the fame in all parts of the world: the fact is, that often entire flëtz, especially subordinate ones, are wanting without being supplied by others, and sometimes flëtz are substituted in their room that are foreign to other countries, such as the salt rock-salt flëtz in Hungary, Poland, the chalk in England, &c.

The flëtz, which almost without interruption fill up the space between the two above-mentioned ranges of mountains, whose distance from each other is about twenty-two miles, are the following:

The old red sand-flëtz of Werner, called by the miners of Germany, das rothe Tödt-legendne (i.e. the red dead or barren rock). It occupies the lowest situation of all the newer flëtz rocks. In the Hartz it reds on grey-wacke, one of the transition rocks of Werner, but referred by Voigt to the primitive. (See Grey Wacke.) Where this sand-flëtz hawks out it appears in pretty high mountains, and often covers considerable tracts of sand, as, for instance, at Eifenach, Eisleben in Mansfield, &c. It is often difficult to distinguish it from the newer sand-flëtz, when not viewed in its connection with the formations that accompany it (See Sand-stone); but in general it is much harder, and of a coarser grain than the latter, often appearing as conglomerate; and its colour is usually brick and ochreous red, from which its name is derived; but is also found grey. The coarsest grained often alternates with fine grained varieties, in layers of various thicknesses. Mr. Jäsmann intimates that, if the observations lately made in Germany by Karlken, Buch, and others, are correct, much of the red sand-flëtz of England will be found to belong to this old sand-flëtz formation. This flëtz, in the above-mentioned tract of country, is regularly followed by

Biminusius Marl-Flëtz, for the description of which, see Marl-Flëtz, Biminusius.

The most distinct line is drawn between this and the preceding flëtz. It bears evident marks of being deposited on the old red sand-flëtz from a calm and undisturbed fluid. Impressions of fishes are frequently seen in it, but none of vegetables. It is rich in metals, especially copper ore, whereas
whence the appellation copper slate gneiss; sometimes the metalic veins, those of copper and silver, penetrate through the bituminous slate, and form the surface of the old fan-shaped stratum underneath, which thus becomes metalliciferous. (See Sand and Ore.) The bituminous slate is classed by Werner under his first lime-stone formation, as is likewise the Zechstein, which rests on the preceding. This is a coarse splinterly, alb-grey compact lime-stone (in some places it approaches the nature of undated marble); it does not pass over into the adjoining slates, but is separated from them by a marked line. It contains neither bitumen nor metals, nor impregnations of fishes as the bituminous marl-stone. This stratum, and the two following, are wanting in some parts of the forest of Thuringia, but their places are supplied by a bed of yellowish-brown lime-stone, accompanied by considerable beds of brown iron-stone, and containing a great quantity of the petrifaction called Ammonia gryphus. The zech-stein is succeeded, upwards, by a stratum of Gyppum, called the first flint-gypsum by Werner. It is composed of granular and compact gyppum, of a white and grey colour, often variegated and veined, penetrated by bitumens, and containing fossiliferous gyppum, flint-stone, &c.; but petrifactions are seldom found in it. See GYPSUM, Compacted, Granular.

By what chemical combination it happened that the zechstein-stratum, being a carbonate of lime, was immediately succeeded by a combination of lime with sulphuric acid, is a question not easily to be answered; but the circumstance is the more striking, as this petrifaction is immediately succeeded by another carbonate, called Silt-stone. a stratum confused by Werner as subordinate to his first flint gyppum (See SILT-STONE.) On this rests another, Sand-stone, which appears to belong to the variegated or second sand-stone formation, as characterized by Werner. Its colour is partly yellowish-white, partly light grey-brown and red. This is succeeded by another stratum of Gyppum, being the second flint-gypsum, which, though in some parts of Thuringia it assumes considerable thickness, is entirely wanting in others, as for instance in the principality of Fulda. But a more constant attendant on the last-mentioned sand-stone is the superimposed stratum of Clay, mostly of a brown-red colour, often intermixed with other tints, such as light mountain-green and blueish-grey. Mr. Voigt observes, that most rivers of Thuringia, Franconia, and Hesse have cut their way through the flint lime-stone, through this reddish clay and the gyppum (where they met with it) down to the last-mentioned sand-stone; and in most low grounds and valleys of these countries, the arable land consists almost entirely of that clay, which, though unfavourable to vegetation in its pure state, becomes the most fertile soil when mixed with sand, gyppum, and lime, as is the case in the neighbourhood of Erfurt, and in several other parts of Thuringia.

The common clay belongs partly to the alluvial, partly to the flint formation, and principally to that sub-division of the latter called the newest flint trap formation by the Wernerian school. The uppermost stratum, and the most considerable next to sand-stone, is Flint lime-stone. Like the sand-stone, and almost all other rocks of the flint formation, it is composed of several strata, each constituting a different variety of compact lime-stone. Those of Thuringia, according to Mr. Voigt, are, 1. A compact lime-stone of yellowish-white or blueish-grey colour, of even and earthy texture, wrought as a marble at Weimar. Except cornua ammonis, few petrifactions are found in it; but often indigene, vermilion, and carboniferous elevations are discovered on the planes of its principal fracture. 2. A faint alb-grey lime-stone, entirely composed of small petrified pebbles, and called by the provincial name of toad-eye. 3. A faint alb-grey splinterly lime-stone, with here and there some petrifaction, and also containing nodules of green flint, which, however, on account of its fracture not being conchoidal, does not answer the purpose of making ground-shells. (See Flint, Gun-Flint.) 4. Compact lime-stone, apparently composed of irregularly cubic fragments, into which it separates on being struck upon; it is by far the most common variety in those parts. 5. Lamellar lime-stone, &c. into thin layers; only found in the vicinity of Jena by professor Voigt. These five layers, constituting the above flint-lime-stone strata, follow each other, though in irregular succession. The whole formation corresponds with that of the second flint or flint-lime-stone of Werner, so called from containing a great number of petrified shells, but formed by other materials; though in the upper of the beds alb-grey petrifactions of flint, crabs, vermiculites, &c. are frequently met with. It is in this lime-stone that most caverns are found containing remains of land animals. Various distinct lime-stone formations are probably included in this; but the observations of well-informed travellers on this subject are as yet too scanty and imperfect to be turned to account by the geologist.

The principal of these formations being illustrated by the above series of strata in Thuringia, we shall here add a few words on those that are not found in that district. First, with regard to the second of Werner's formation it is to be observed, that in several countries a stratum of porous grey lime-stone is found subordinate to it, called rauch wood, which is wanting in that part of Thuringia; and the same is the case with roe-stone, confused as subordinate to the fourth of Werner's formations, and of which considerable strata are seen in other countries, though it does not appear to constitute an independent formation. The seventh formation, being the third flint sand-stone, is represented by the commentators on Werner's arrangement as a very extensive one; but its geognostic relations do not appear to be sufficiently determined. It is supposed to be of much newer origin than the other preceding sand-stone formations; it exhibits many traces of coal; is constantly of a white colour, and as negative characters are given its not containing any clay-galls, or gyppum, its not alternating with sandstone flits, or ros-stone. The hills formed by this sand-stone have a peculiar appearance: they are conical and steep, and exhibit in the variously slipped and arranged masses of which they are composed, a striking scene. "One of the most striking appearances of this kind," says Mr. Jackson, "is at Andenbuch in Bavaria, where we observe numberless cones, pyramids, and pillars, sometimes isolated, sometimes joined together, and from two to three hundred feet high, spreading over a conflagrable tract of country. In other places, caverns or grottos appear, from which there issue many flames, that give rise to waterfalls, and thus increase the beauty of this striking scene. These caverns are wide at the mouth, but become very narrow towards their further extremity, and are generally very short. This form flows, that
that they owe their existence to external agents, particularly water. A more near examination discovers, that the forms of the strata of the different isolated masses correspond to each other, which render it probable that all these cones, pyramids, and pillars, have been formerly united, and that the pendent parts of fissures have given rise to this diffusion, which has been afterwards increased by the action of the air, and by the water carrying away the softer or more loosely aggregated parts of the hard stone, and having the harder parts in these various forms. A similar appearance of faulted strata occurs near Tuns; and, from its striking resemblance to turns, is described as the remains of a great city, by some travellers who saw it at a distance. In the land of the Namequas in southern Africa, and on the banks of the Weiga, there are similar appearances. This formation passes through Saxony, Silesia, and Bohemia, and is wrapped around almost the whole of the Rieben-Gebirge.

An excellent characteristic of this land-fissure formation, as it appears in Bohemia, we prefix from the able pen of Dr. Rehbein.

Another formation, not in the above series of Thuringian fletz rocks, nor, indeed, abundantly met with in any part of Germany, is of particular interest. It is found only in connection with the fletz-syenites; and in the territory of Sames of Upper Austria may be considered as subordinate to the first fletz-limite, the principal formation of that country. It is a kind of clay, somewhat accompanied by beds of clay called by Humboldt 

*Schlacke,* which is a variety but little understood; we shall here add Buch's description of that occurring at Halländ, Ichbel, &c. in the just-mentioned Austrian territory. Its colour is smoke-grey, and it also occurs greyish-black and greyish-white, more seldom reddish-brown and tilled. It is perfectly dull, but always mixed with minute glimmering felsine particles; fracture fine earthy, and in large pieces, list conchoidal; fragments indeterminate angular. It is perfectly opaque, does not fail, is soft, approaching to very soft, rather oecile, and not particularly heavy. This kind is light ash-grey. This clay is said to become of a darker colour when exposed to the air, which is the more singular, as, according to Humboldt's experiments, it eagers about the oxygen of the atmosphere. It is quite penetrable by salt; and the small angular fragments, approaching more or less to the cubic form, are often found coated with a crust of felsine particles. Rock-felt is generally found in large masses, in low parts between mountains, or at the foot, such as in Transylvania; though very deposition of it also occur in high situations, such as at the foot of the elevated range of mountains which, to the north-west from Tibet, encompass Caucasion; a situation equally elevated with a great part of the European Alps. For a more detailed account of this interesting formation, see the article Rock Salt.

The flatz of Werners's fletz formations, that of chalk, is but little understood with regard to its geognostic relation: all we know is, that its occurrence in low situations on the sea coast, where it forms high and rugged cliffs, and its earthy aspect, b-ipsak its more recent origin. In England it occurs in considerable strata, in many cliffs and high mountains. We do not know much of its occurrence in Germany; it is, however, said to be found at Luneburg, alternating with thin strata of chalk. Chalk contains no metals except iron ores, and few petroleum have been found in it; but the nodules of flint imbedded in this rock are almost characteristic of it. See Flint.

As to the eleventh or independent coal formation, we have already occasion to mention it as one of Mr. Voigt's Vol. XIV.

older fletz rocks. We shall here add a few words on Mr. Werner's coal formation in general. According to E. Werner, who gives us an exposition of the Wernerian system, the coal-mounts (Kohlengebirge) are to be divided into four distinct formations: to the oldest belong the coal strata occurring in fletz lime-stone, as, for instance, the foot of the Besseberg, near Kripten, on the Tummers. Younger than this, but of the same age with one of the newer sandstone formations, is the independent coal formation of still more recent origin is the coal which is subordinate to the trap formation: and the newest of all is that contained in alluvial mountains. Mr. Janson, as the other hand, informs us that Werner has attested three distinct coal formations, without including the beds of coal found in sand-stone and lime-stone formations, which latter, he says, are in general of no importance. According to this new arrangement, therefore, the independent coal formation is the oldest; the second is of the newest fletz-trap formation; and the third, that which occurs in alluvial land. Again, according to later accounts, it is understood that Mr. Werner has adopted another arrangement of that formation which, according to Kriek, is that of the Kriefel, who makes the sandstone coal formation dependent on the older sandstone, and of the lime-stone subordinate to the fletz, or Alpine lime-stone. From these frequent changes it would appear that the history of the different formations of coal and their relative age are still involved in considerable darkness. What is known with certainty amounts, we suppose, to this, that coal is of early as well as of late formation; the former is found under the older sandstone, sometimes even reposing on primitive rocks; the latter, on the newer sandstone in the vicinity of the rocks that belong to Werner's younger fletz trap formation. We are happy to find that Mr. Janson has promised to publish the results of his observations on the relation in which these formations of coal stand to the other fletz rocks; and, indeed, many doubts remain to be cleared up respecting the determination of this point, as well as of many others intimately connected with the natural history of those important mineral deposits.

The last of Werner's fletz formations is called the new coal trap formation, comprising principally those enigmatic masses, known by the names of flitte, wacken, and amygdaloid rocks, which, though they contain no organic remains, cannot be ranked with the primitive, since they rest both on these and the fletz mountains; rocks which are considered by many geologists as the principal products of volcanic agency, but which, according to Werner, are the results of a deposit of the waters at a more recent period than that in which the other fletz rocks were formed. Besides the just-mentioned, the following rocks are referred to this formation: green-stone, grey-stone, pitch-stone, compact feldspar, obsidian, pumice, and those that are mechanical deposits, viz. gravel, sand, bituminous wood, brown coal, clay, and trap-nels; in which articles we refer our readers, as we have to the article Trap.

For further remarks on the subject of fletz strata, and on the order in which they succeed each other in different parts of the world, see Strata.

Not unconnected with the history of the strata of mountains, are the remarkable appearances observed by travelers under the precipices of Alpine peaks, &c. They are disturbances that have happened to the strata, after being ridged by vertical fissures; the separate sides of the fissures, which are generally filled up, do not longer correspond, the strata of the one being either above or below those of the other.
those of the other side, with which they were connected before the disturbance took place. See the articles Slip and Vein.

FLEUKAN, FlOOKAN, in Mining, denotes rubble and unconsolidated earth contained between the sides of strata vertically divided by a failure and detached. See Slip and Vein.

FLEUR-D-LESIS, FLEURETTE', FLOUROAN, and Fleury, in Heraldry. See FOERY.

FLEURENCE, in Geography, a town of France, in the department of the Gers, and chief place of a canton, in the district of Leilour, seated on the Gers; 4 miles S. of Leilour. N. lat. 42° 51'. E. long. 0° 15'. The place contains 3,621, and the canton 12,159 inhabitants, on a territory of 3,500,000, in 22 communes.

FLEURIEU, Cape, a cape on the W. coast of North America, so called by Perouse. It is supposed to be the same with that which captain Dixon called Cape Cox. N. lat. 51° 45'. W. long. 128° 55'.

FLEURIS, a term in French Myth, now obsolete. It implied florid counterpart, such as is not noted again, but compounded of notes of different value and proportion as to measure. It likewise implied the graces or ornaments of a melody when too simple. See Broderies, Doubles, Variations, and Passages.

FLEURUS, or FlOORUS, in Geography, a village of France, in the department of the Sambre and Meuse, remarkable for having been the place near which three battles were fought, viz. the first August 1, 1622, the second between the allies and the French, and the third between the Austrians and the French, in June 1754, in which the former were defeated with great loss: 6 miles N. E. of Charleroy.

FLEURY, ANDREW-HERCULES, in Biography, cardinal and prime minister of France, was born in 1537. He was educated at Paris in the Jesuits' college, and became, at a proper age, canon of Montpelier, and doctor of the Sorbonne. Possessing an agreeable person, and those manners that never fail to recommend a man at court, he obtained the poet of almoner to the queen, and afterwards to the king. In 1608, he was nominated to the bishopric of Frejus, when Lewis XIV. paid him a high compliment; "He that made you wait a long time," said the monarch, "but you have so many friends, that I was deficient you should be obliged for your advancement to no one but myself." Fleury, however, was not always pleased with his promotion, the diocese was in a distant and disagreeable country, and he became disgusted, probably, for the want of that kind of society which was conformable to his wishes. In a letter to a friend he subcribed himself, "Fleury, by divine indignation, bishop of Frejus." He nevertheless held the see many years, and on one occasion, when the allies under the duke of Savoy and prince Eugene made an invasion into France, the bishop, by his prudent conduct and engaging manners, saved his city and its neighbourhood from pillage, and pacified the generals to be contented with a moderate contribution. He was nominated by the will of Lewis XIV. preceptor to his successor, the young king, with whom he so completely ingratiated himself, as to inspire him with a profound esteem and attachment. Nor was he less anxious to pay his court to the monarch Villeroi, the king's governor, and to the regent the duke of Orleans, by the most respectful demeanor. The regent would have conferred upon him the archbishopric of Rheims, but he refused that splendid promotion, dreading, perhaps, that it might be a pretext for removing him from the person of the king. At the death of the regent, it was through his recommendation that the duke of Bourbon was appointed prime minister, though in truth it was Fleury who governed, by means of the influence which he possessed over the king's mind. This was put to the trial, when, the duke, urged by his mistrels, attempted to exclude the bishop from his private consultations with the king. Fleury immediately retired, and wrote to his sovereign a letter filled with expressions of tenderness and regret, the effect of which was such, that it was impossible to pacify the king, till he was recalled and restored to his place. From this time Fleury became chief minister, without aiming the title and apparent functions which pointed out the premier. He was created cardinal in 1736, and at the age of seventy-three devoted the remains of his life, which had hitherto challenged the public esteem, to the ungrateful toils that attend ministerial power, and at a period when the most ambitious are ready to seek reposes, he avowedly entered the lists of fame. The spirit of his administration was economy in the public revenue, and the preservation of peace. The pacific disposition of this great man corresponded with the immediate welfare of France, and he quietly left the kingdom to repair its losses, and to enrich itself by an advantageous and extensive commerce, without making any innovations. This tranquil and enterprising disposition was not calculated to gain the respect of a nation like the French, who have ever been more defirous of being thought great, than anxious to be really prosperous. Peace the cardinal could not always attain, but he terminated in three years the war of 1733 with the emperor Charles VI., and obtained for France the important acquisition of Lorraine. In the year 1741, Frederic III., king of Prussia, laid claim to four duchies in Silesia; he suddenly entered that country, defeated the Austrians near Malitz, and occupied the whole of the duchy. This victory was the signal for war to France; but Fleury, now in his eighty-fifth year, was but little inclined to relinquish the pacific system that he adored, but he was overwhelmed by the impetuosity of the marquis and chevalier de Bercy, who represented to Lewis that the period was now arrived of finally breaking the power of the house of Austria, and relieving that kingdom from its ruins; and that so favourable an opportunity never again would offer of raising the elector of Bavaria to the imperial throne. The monarch assented, and cardinal Fleury, tottering on the brink of the grave, yet still desirous of keeping his power, functioned with his name an enterprize he had never approved, and confounded to prefigure over a people whose counsels he was not permitted to direct. This war embittered the close of his life, which, however, by habitual temperance and natural cheerfulness, was protracted to nearly his ninetieth year. He died in 1743, and was buried in the church of the Louvre at the king's expence. In private life he was simple and modest, content with a moderate income, and remote equally from avarice and ostentation. MORERI. Histoire de France.

FLEURY, CLAUDE, was born at Paris in the year 1640. His father was an esteemed advocate, and he intended his son for the same profession. Claude, indeed, was admitted an advocate of the parliament of Paris in the year 1658, and from this period, for the next nine years, he diligently applied himself to the study of jurisprudence, and the belles lettres; after this he determined to embrace the ecclesiastical state. To forward himself in this new career, he attended the conferences which the celebrated Bossuet held at his house on the scriptures, and on subjects of religion and literature. During his interviews with this excell-
excellent man he translated his well-known work, entitled, "The Explication of the Catholic Doctrine." He soon acquired a high character for abilities and literature, while he was equally the object of respect for his piety and virtues. In the year 1651, he was chosen preceptor to the princes of Conti, and afterwards enamored the same character with respect to the count de Vermandois, the favorite natural son of Lewis XIV. In the year 1689, the king fixed upon him the illustrious prelate to be associated with the great Feron in the education of his legitimate offspring, and made him sub-preceptor to his grandsons, the dukes of Burgundy, Anjou, and Berry. In the year 1696, he was admitted a member of the French academy, at the meetings of which he ascribed often as his other duties and engagements would permit. He had not been overlooked by the king in church preferment; but being a very disinterested man, he was content with comparatively small emolument, and sought nothing for himself till the priory of Argenteuil became vacant, which, from its proximity to the king's residence, was a most desirable retreat for study with the reach of desirable sources of information. This benevolence the abbé Fleury obtained from the king without difficulty; at the same time he resigned an abbacy into the sovereign's hands which he had held before. In his retreat at Argenteuil he continued till the year 1712, when he was drawn from it by the death of Orleans, the regent of the kingdom, after the death of Lewis XIV. to occupy the place of confidant to the young king. His own infirmities, and the intrigues of the Jesuits, obliged him to resign his office in the year 1722, and in the following year he died, leaving behind him a character estimable for extensive learning, firm and nice integrity, true modesty and candour, great purity and simplicity of manners, and ardent and unalloyed piety. He was author of numerous works of merit, but his most considerable and important, the fruit of thirty years study, was his Ecclesiastical History, in 20 vols. 12mo., of which the first was published in the year 1691, and the last in the year previously to his death. This work has been published in England, in seven volumes. It contains the history of the Christian church, from the earliest times to the council of Constance in 1414; his facts are collected with great industry and impartiality from the best authorities, and they are, in general, combined in a simple and unornamented style. Morel. Hist. de France.

FLEURY, in Geography, a town of France, in the department of the Loire; 2 miles N. of Orleans. Also, a town of France, in the department of the Loire; 4 miles N.W. of St. Pol.

FLEWS, in Rural Economy, a name sometimes provincially applied to the phlemes employed in bleeding cattle.

FLEXIBLE, in Physics, is applied to bodies that are capable of being bent, or changed from their natural form and direction. A body is not capable of being inflected or bent, unless the whole thereof be at rest. In bending a body, it constitutes, as it were, two levers; and the point it is to be bent is a fulcrum. Hence, as the moving power, the farther it is from the fulcrum, it acquires a greater force; the nearer the flexible body is, the easier it is bent.

FLEXION, in Anatomy, the act of bending, or the attitude into which any part of the body is brought by the action of the flexor muscles. When the parts composing an articulation are so situated with respect to each other, as to form one straight line, the joint is said to be extended; when they are moved so as to form an angle with each other it is bent. Some joints, as those of the hip, knee, and elbow, admit of being bent only in one direction; and from this bent attitude, they can be moved in the opposite course only so far as to bring the two parts of the limb into the same straight line. In other cases, as at the wrist, motion is almost equally free in both directions, from the attitude in which the limb describes a straight line. Yet here the term flexion is confined to one of these motions; and the other is called extension, although the joint is not then straight.

FLEXTOR, a name given to those muscles, particularly of the wrist, fingers, and toes, which have the office of bending those organs; they are the antagonists of the extensors.

FLEXTOR brevis minimi digiti manus; flexor proprius; flextor palmaris Alb; capro-metacarpian. This is sometimes wanting, and in all cases it is a very small muscle. It arises from the annular ligament and os uncinatus, is situated at the side of the adductor minimi digitii, and inserted in company with it into the outer and anterior part of the last phalanx of the little finger. It is covered by the skin, and covered by the palmaris brevis, and covers the adductor oss metacarpi minimi digitii. It will bend the first phalanx of the little finger on the metacarpus.

FLEXTOR brevis minimi digitii pedis; palmaris minor of Winning; tarso phalangien du petit orteil. This muscle, situated within the adductor minimi digitii, has an elongated form, and is thicker in the middle than at the two extremities. It is attached, by means of aponeurotic fibres, to the under surface of the radial extremity of the last metatarsal bone, and to the first of the peroneus magnus. Advancing forwards, it first increases in size, and then diminishes again, and is fixed to the metatarsal extremity of the first phalanx of the little toe, adhering closely to the joint. It is covered by the adductor, and by the palmar fascia; while its superior surface corresponds to the last metatarsal bone, and to the interosseous muscle of the little toe. It bends the little toe on the metatarsus.

FLEXTOR Carpi radialis brevis; Flextor, Carpi radialis longus. See Carpi.

FLEXTOR, Carpi radialis brevis. See Carpi.

FLEXTOR brevis pollicis manus; thenar of Winning; carpophalangien; is a short muscle belonging to the ball of the thumb, and placed within the opponens pollicis. It has two origins, one from the annular ligament and os trapezium, the other from the os magnum and the third metacarpal bone. The two fleshy portions of which it consists run parallel to the metacarpal bone of the thumb, and unite at the opposite end, still leaving a channel between them for the tendon of the flextor longus. It is inserted into the two fleshy bars of the thumb, being connected to the abductor and adductor muscles of this organ. The adductor pollicis, the skin, the tendons of the flextor longus, that of the flextor profundus, and the two first lumbricales, cover this muscle externally. It covers the first metacarpal bone, the tendon of the flextor carpi radialis, and the first interosseus. This muscle will bend the articulation between the metacarpal bone and the first phalanx of the thumb; and it will also draw the metacarpal bone towards the carpus.

FLEXTOR brevis pollicis pedis; flextor brevis pollicis pedis; thenar; tarso-phalangien du pouce; a short and thick muscle,implead behind, and bifurcated in front, and placed on the inferior surface of the first metatarsal bone. It arises by a flattened, but clearly marked tendon, from the under surface of the os cunis and two of the cuneiform bones, and the ligaments which join them. It is also attached to the plantar fascia, where that covers the flextor brevis digitorum
FLEXOR.

The flat fibres, collected into a thick fasciculus, marked below with a groove for the tendon of the flexor longus, proceed forwards to the great toe, and are inserted in two divisions. The inner and largest, closely connected to the abductor, is fixed with it by tendinous fibres to the internal fascioid bone, and to the corresponding extremity of the first phalanx. The external, which is thinner, is fixed to the external fascioid bone. Both are directly attached to the synovial membrane of the articulation, which joins the great toe to the first metatarsal bone. Its upper surface is covered by the deltoid of the humerus, and then from the corresponding ligament, and from the coronoid processes of the ulna, by short aponeurotic fibres; 2dly, from a septum which separates it from the flexor carpi ulnaris; 3dly, by tendinous fibres from a considerable portion of the front edge of the radius, between the supinator brevis and the flexor pollicis longus; 4thly, from septa which separate it from the flexor carpi radialis and palmaris longus. From the origin just enumerated, a thin portion of muscular fibres is produced; but the muscle grows thicker towards its middle, runs in a direction parallel to the bones of the fore-arm, and divides into four flat fibrous portions, corresponding to the four fingers; of which, the two belonging to the middle fingers are the most superficial, and those of the fore and little fingers the most deeply seated; the latter is the smallest. These end in tendons proportioned to their bulk; which are completely disengaged from the muscular fibres at the annular ligament. The four tendons, connected together in the manner which will be presently explained, pass in the deep channel formed by the annular ligament, in front of the tendons of the profundus, separate as they proceed, and continue their course towards the fingers under the palmar fascia. They become broader and thinner, enter the tendinous sheath of the fingers, and each presents, at the commencement of the sheath, a concavity adapted to the corresponding tendon of the flexor profundus. As the tendon passes over the first phalanx, it divides into two portions, which separate to allow the passage of the tendon of the profundus, then unite together behind that tendon, so as to form a channel, with its concavity in front, lodging the tendon of the profundus; and afterwards separate again to be implanted, distinctly from each other, in the lateral and anterior margins of the second phalanx.

Thus each tendon is first concave posteriorly, where it lies on the tendon of the profundus; then presents a large flat for the passage of the latter; and afterwards concave anteriorly, from the two sides of the flat uniting below, and then ends by a double inflexion in the front.

On the fore-arm, the posterior surface of this muscle is in contact with the profundus, the flexor longus pollicis, and the median nerve; while its anterior surface is covered by the pronator teres, flexor carpi radialis, palmaris longus, and the fascia of the fore-arm. It covers the profundus and lumbricales of the hand, and is covered by the annular ligament and palmar fascia. In the fibrous sheath of the fingers, it is placed first between the sheath and the tendon of the profundus, and lower down between the latter and the bone.

FLEXOR digitorum profundus; profundus, Alb.; flexor perforans; cubito-tarsionis; flexor superficial profund. This muscle is situated in the fore-arm, under the former, which it very much resembles. It is thick, flattened, elongated in its form, flatly above, and tendinous below. It arises, 1st, from the aponeurosis extended from the flexor carpi ulnaris to the ulna, and from the inner surface of that bone in one-third of its length; 2dly, from the anterior surface of the bone for three-fourths of its length, next to the elbow, and from the corresponding portion of the interosseous ligament, by aponeurotic fibres. Smaller at its origin, it twines in the middle, and diminishes again, dividing into four more or less distinct portions, terminated by four tendons, which are at first concealed by the flat fibres, but become entirely disengaged at the annular ligament, where they are closely connected by cellular substance. They pass in the deep channel of the ligament, behind those of the flexor pollicis, to pass as they proceed into the hand, give origin to the lumbricales, enter the tendinous sheaths, perforate the tendons of the flexor pollicis, and lie in the channels formed on the anterior surfaces of the first phalanges. Each tendon terminates in a slightly flattened form, by an insertion in the anterior surface of the little phalanx.

In the fore-arm this muscle is covered by the flexor carpi radialis, the flexor sublimis, the median and ulnar nerves, and the radial artery; and it covers the surface of the ulna, the interosseous ligament, and the pronator quadratus. The bones of the carpus and metacarpus, and the interosseous muscles, lie behind it in the hand; and the lumbricales and tendons of the sublimis are before it. In the fingers, its tendons lie on the bones, being covered by the tendons of the sublimis and the fibrous sheaths. It is furnished with certain synovial membranes, common to it with the preceding muscle.

The annular synovial Membrane.—On cutting the annular ligament of the hand, and lifting up the subjacent packet of tendons, we observe a cavity terminated by a cul-de-sac above and below, and formed by a membrane, which envelops the tendons of the flexor sublimus and profundus of the flexor longus pollicis, and the median nerve; and which is spread over the surface of the annular ligament and the carpal ligaments. This membrane connects all the parts into one fasciculus, lends numerous folds between them, is very soft and yielding, but contains a little synovia, that a doubt may be entertained whether it should properly be regarded as a synovial membrane. Yet its office and use are exactly the same as those of the bursa mucoce; it enables the tendons to play easily in the channel of the annular ligament. The latter expands the tendons in their proper situation; they would otherwise start up from the wrist when the hand is bent on the fore-arm, and describe the chord of an arc formed by the fore-arm, wrist, and hand.

Synovial Membranes and fibrous Sheaths of the Fingers.—These membranes are expanded on the tendons of the two flexor muscles just described, and on a canal containing them, formed partly of bone, and partly of a strong fibrous substance. The anterior concave surface of the phalanges, and the front of their articulations, form the bony portion of the canal. The fibrous part is a dense strong layer, attached to the sides of the bony channel, and terminating below by a connection to the flexor profundus. Thus the cavity ends in a cul-de-sac. The sheath is very thick and strong
FLEXOR.

strong at the middle of the first and second phalanges, and composed of semicircular fibres of cartilaginous funnels; the flexor profundus is thinner, and composed of decussating fibres. A synovial membrane lines this cavity, and is reflected at its commencement over the tendons, so as to form here a cul-de-sac. The tendons are completely covered by this sheath, being lubricated, as well as the containing cavity, by a synovial fluid: there are, however, one or two slender vascular threads going from the sheath to the tendon. The use of this sheath is the same with that of the annular ligament, viz., to confine the tendons in their situation. When it is divided in the dead subject, and the muscles are drawn so as to bend the fingers, the tendons immediately start up from the bones. As they move considerably within the canal during the motions of the fingers, the necessity of the parts being lubricated by synovia is obvious.

No similar apparatus belongs to the extensor muscles of the fingers; because these members cannot be moved in that direction beyond the point at which they form straight lines with the hand, and their extensor tendons do not consequently admit of displacement; which would be prevented too by the attachment of the lumbricales and interossei to these tendons. At the wrist the extensor tendons are confined as well as the flexors; because the hand can be moved in this direction beyond the straight line, and the tendons would be subject to start from the bones.

The lumbricales muscles are small, slender, and elongated muscular fibres, so named from a comparison to earthworms. Their number is four, and they are designated by numerical epiteths, counting from the thumb to the little finger. They are placed in the palm of the hand, and derive their origin from the tendons of the profundus. The first arises from the anterior and radial side of the first tendon, and the succeeding ones from the bifurcations of the tendons, so that each of the latter has an attachment to two tendons. They accompany the tendons towards the fingers; are small at first, then grow larger, and afterwards contract again, and end at the first phalanx in small flattened tendons. These turn round the articulation, which joins the metacarpus to the phalanges, and go towards the back of the fingers. The expanded tendons are connected to the intersosseus, and are joined by a broad surface to the edge of the extensor tendons. They then run along the side of the fingers, and terminate by an insertion at the back of the joint of the first phalanx. The first lumbrical runs along the radial side of the first, the second along the anteroposterior side of the second, the third along the ulnar side of the same tendon, and the fourth along the lateral side of the last finger. The middle or the ring-finger may have a lumbrical on each side, and then the little finger alone. They are covered by the flexor sublimis, the palmar fascia, the digital nerves and vessels, and lie upon the intersosseous muscles. In the fingers their tendon covers the phalanges, and is covered by the skin.

The flexor sublimis and profundus, and the lumbricales, are muscles of the three joints of the fingers: the first bending the middle joint; the second, the joint; and the third, the joint that which connects the metacarpus to the first phalanges. When the two tendons have produced their effect upon the articulations to which they belong, they have the further power of bending the first joint, concurring in this office with the lumbricales. Since the latter muscles turn round the first joints, and run afterwards along the back of the phalanges, being confined in their situations by their connection to the extensor tendons, they will extend the second and third joints, although they are moved in the palm of the hand; for their peculiar course alters the direction of the force. It is necessary, in order to the flexion of the first joints by the lumbricales, that the flexor profundus should be in action; that its tendons may be fixed, so as to afford a firm point, to which the lumbricales may move the fingers. Hence, where all the three joints are bent, as in clenching the fist, in grasping a fickle, &c., the middle and last are bent first, and afterwards the first. The lumbricales, however, may be bent, while the others are kept straight; but this requires a painful effort. Here, the flexor profundus is put in action, and the extensor commissus also contracts, to prevent the fingers from being bent. By feeding in the fore-arm, we can ascertain that both the flexors and extensors are exerted on this occasion, and the effort is attended with considerable pain. Thus a fixed point is produced for the action of the lumbricales.

The sublimis and profundus, after bending the fingers, or if the fingers are kept extended, will concave more powerfully, with the flexors of the carpus, in bending the wrist. As they arise chiefly from the inner side of the fore-arm, they will also cooperate in turning the palm towards the ground, or producing the slate of pronation. Inasmuch as any of their fibres are derived from the humerus, they will have the power of bending the elbow joint. We cannot avoid noticing, even on the most superficial examination, the great superiority in bulk of the flexors over their antagonists, the extensors of the fingers. The sublimis or profundus alone contains twice or three times as many fibres as the extensor commissus; and this disproportion becomes still more striking, when we observe that the internal condyle, from which the flexor muscles arise, is very prominent, so as to give them a mechanical advantage in their action. The bending of the fingers is employed on many occasions, which require great muscular forces: the lifting of heavy weights is an example of this kind; where the ring of a weight is grasped by the fingers, and the weight elevated, it is entirely supported by these muscles. Now any individual can easily lift, in this way, from fifty to a hundred pounds and upwards, by his little finger only. In seizing and holding bodies firmly great power is required, on occasions which are constantly occurring, not merely among the laborious parts of the community, but also in those who do not depend for support on their personal exertions. In the latter, indeed, the fact is more obvious: the act of rowing, the handling of cables, the use of the hammer, the scythe, and similar instruments, all exemplify the great importance of the flexors of the fingers. No effects of any analogous description are produced by the extensors: they move the fingers, in the course of their work, but it is the flexors that make the work.
FLEXOR.

Hefty fibres descend obliquely on each side to a tendon, concealed in the substance of the muscle at first, but soon appearing superficially at the back of the muscle. The fibres of the second origin continue to enter the tendon as low as the ankle; but those of the first cease higher up in the leg. The tendon passes in a superficial groove behind the internal malleolus, separated by a fibrous septum from that of the tibialis politicus; and then passes behind the astragalus, turning afterwards horizontally forwards in the sole of the foot. It now turns rather outwards; passes under the tendon of the flexor longus politicus pedis, to which it is connected by a small tendinous chord; then becomes considerably broader and flattened, and flows the markings of a division into four portions. Here it divides into four tendons, which proceed towards the four smaller toes, entering with the corresponding portions of the flexor brevis into the tendinous sheaths of the toes, passing in the slips of those tendons, and inserted into the lower and posterior part of the first phalanges. The respective positions, the insertions, and the fibrous sheaths of these tendons are analogous to those of the flexor sublimis and profundus in the fingers; to the description of which the reader is referred.

In the leg this muscle is covered by the soleus, the facia of the leg, the posterior tibial artery and nerve; and it covers the tibia and the tibialis politicus. The tendon reflected behind the ankle, at its entrance into the sole, is contained in a fibrous sheath attached successively to the groove at the back of the tibia, to the malleolus lateralis, the astragalus, and front of the os calcis. On situating this caudal, we find it lined by a distinct synovial membrane, lubricated with a mucous fluid, and reflected over the tendon above and below to as to form two cul-de-sacs. The deepened muscles of the foot, and particularly the flexor accessorius, lie over the tendon in the sole. The adductors of the great and little toes, the plantar nerves, and the flexor brevis, are under it.

The flexor accessorius, or maffa carneus sylvi, is a thin, flattened, and rather square portion of muscle, situated under the tarsus, and above the preceding tendon. There is nothing analogous to it in the profundus of the hand. It arises, by aponeurotic fibres, from the inferior and internal surface of the os calcis; these proceed horizontally forwards parallel to each other. The muscle is inserted, either by hefty fibres or by a tendon, into the upper and outer surface of the flexor longus, where it expands previously to the division into its four tendons. It is interposed between the under surface of the tarsus and the tendon of the flexor longus.

The lumbricales pedis arise from the tendons of the flexor longus in the foot, as those of the hand do from the profundus. Their number, size, figure, and course correspond very much to those of the lumbricales manus. They are inserted, at the roots of the toes, into the metatarsal extremities of the first phalanges, attaching a thin production to the extensor tendons.

The flexor longus will bend the last joints of the toes, and afterwards the middle and first articulations. In the latter effect it is assisted by the lumbricales, which at the same time will give a flight degree of lateral motion. The toes being bent, or kept straight by the extensors, the foot will be carried back upon the leg by the flexor longus, in which case it assists the muscles of the calf. It will also aid these muscles in elevating the leg, and through it the whole body, while the foot rests on the ground; it acts therefore when we stand on our toes, as well as in the office of progression. When it bends the toes, or extends the foot upon the leg, it draws them at the same time inwards, so that the sole faces backwards and inwards, in consequence of its tendon going behind the internal malleolus. This effect is counteracted by the flexor accessorius, which draws the tendon outwards; and the toes are consequently bent without any obliquity to either side. Its action, when the body is erect and supported by the feet, fixes the sole to the ground; and by bending the front of the foot accommodates the organ to inequalities of surface. When the foot is firmly fixed to the ground, the flexor longus may draw the leg backwards upon the foot; in this way it will restore the legs to their upright bearing upon the astragalus, when the knees have been bent forwards.

Flexor longus politicus manus; radio-fons-onguien; grand fléchisseur du pouce; is a peculiar and separate flexor of the thumb, placed on the surface of the radius, and on the same level, in the fore-arm, with the flexor profundus digitorum. It has an elongated form, and is flattened at the sides. It arises from the anterior surface of the radius, commencing in a narrow pointed form just below the tubercle, and continued as far as the origin of the pronator quadratus; being also attached to a small part of the interosseous ligament. Sometimes a small fasciculus joins it from the coronoid process of the ulna. From this origin the fibres descend in an oblique direction, and terminate in a tendon lying on the front of the muscle, and passing with the flexors of the fingers, to which it is united by the synovial membrane already described, under the annular ligament of the carpus. It then turns outwards, palms between the two portions of the flexor brevis politicus, and between the two interosseous bones; it is continued over the first phalax of the thumb, and is inserted in the root of the second, being previously marked by an impression dividing it superficially into two portions. In the fore-arm, the flexor sublimis, flexor carpi radialis, supinator longus, and radial artery and nerve lie on this muscle, which covers the surface of the radius, a little of the interosseous ligament, and the pronator quadratus. In the hand, it occupies first the radial side of the channel formed by the annular ligament, and then is surrounded by the two portions of the flexor brevis politicus; being afterwards contained in a fibrous sheath. The latter is fixed to the two edges of the first phalanx of the thumb, and to the whole surface of the second, where it is continuous with the insertion of the tendon, and, together with the concavity of the bone, forms a complete canal including the tendon. It is lined by a synovial membrane, reflected at the commencement of the canal over the tendon, so as to form a cul de sac. It will bend the left joint of the thumb towards the palm of the hand; and afterwards also articulate with its metacarpal bone with the carpus. Further, it may assist in bending the wrist on the fore-arm.

Flexor longus politicus pedis; flexor longus politicus; grand fléchisseur du gros orteil. The great toe, like the thumb, has a separate long flexor, which is a thick and strong muscle, lying on the back of the fihula, and covered by the muscles of the calf. On the outside, it arises from a kind of septum placed between it and the peroneus longus and brevis; on the inside, from a more distinct tendinous production separating it from the tibialis politicus and the flexor longus digitorum; between these points, from the two inferior thirds of the back of the fihula, to which the above-mentioned sefpa are also attached. It has above a thin and pointed form, but grows considerably thicker as it descends; becoming thinner again below. A middle tendon receives the muscular fibres, appearing at the back part of the muscle, from which it is completely disengaged at the ankle. It goes behind that joint, and then turns horizontally forwards in the sole of the foot; palms over the flexor longus digitorum, being connected
connected to it by a portion of tendon, continues its course along the inner side of the foot, between the two portions of the flexor brevis pollicis, and afterwards between the two fasiform bones of the great toe. Here it generally expands, then proceeds in a narrowed form, under the first phalanx of the great toe, and is inserted into the under and back part of the second phalanx. In the leg, this muscle is covered by the soleus and by the fascia of the leg; and covers the fibula and tibialis posticus.

It then lies upon the back of the tibia, and is confined to the aflatagulus and os calcis by a fibrous sheath, lined with a synovial membrane. On the first phalanx of the great toe it is contained also in a sheath with a synovial lining. This muscle has the same uses with respect to the great toe and foot, as the flexor longus digitorum has in regard to the other toes. See the account of the action of that muscle.

*Flexor brevis digitorum pedis*; *flexor perforatus or sublimis*; calcaneo-lousongien. This muscle is placed in the middle of the sole, and is one of the superficial muscles of the foot. It is moderately thick, of an elongated form, and possessing four tendons in front. It arises from the os calcis, on the sides from two septa, which separate it from the abductors of the great and little toe, and below from the plantar fascia; proceeds in a straight direction to the end of the metatarsus; and divides into four portions which give origin to four tendons. The latter pass in the intervals of the double insertions of the plantar fascia, and enter the fibrous sheaths of the toes. At first they are concave above, to receive the tendons of the flexor longus, then they are divided for the passage of the latter, unite again, and afterwards separate to be attached by means of dilute portions to the edges of the second phalanges.

The edges of this muscle correspond to the abductors of the great and little toes; its inferior surface is covered by the plantar fascia; and the superior by the flexor accessorius, tendons of the flexor longus, plantares, and plantar nerves and vessels. By bending the toes, this muscle renders the inferior surface of the foot concave, and thus enables it to accommodate itself to uneven ground, and in a manner to grasp such unequal surfaces. This effect is much limited in the human subject by the practice of wearing shoes. By drawing the toes downwards, it tends to fix the foot to the ground.

*Flexores primi internodi digitorum*; a name given by some of the older anatomists to the lumbricales.

*Flexor secundi internodi digitorum*; is a name by which the flexor sublimis of the hand, and the flexor brevis of the foot, have been described. The flexor profundus of the hand, and the flexor brevis of the foot, have been called *flexores tertii internodi digitorum.*

*Flexor primi internodi pollicis*; is the opponens.

*Flexor secundi internodi pollicis*; is the flexor brevis.

*Flexor tertii internodi pollicis*; is the flexor longus.

*Flexor primi et secundi syllis pollicis* of Cowper, includes the adductor, opponens, and flexor brevis.

**Plexuosus Caralis**, in Botany, a zigzag stem. See Caralis, n. 3.

**Flexure, or Flexion**, in Geometry, is used to signify that a curve is both concave and convex, with respect to a given right line, or a fixed point. And the point which limits the concavity and convexity is called the point of contrary flexure. See Degradation of Curves.

Also the method of finding the points of the contrary flexure, see *Inflection.*

**Fliedethrift**, or more truly *Slidethrift*, is the game we now call *bowel-board.* It is otherwise called *flower-ground,* and is mentioned in the statute 33 Hen. VIII. cap. 9.

**Flied, or Fly**, that part of the mariner's compass on which the thirty-two winds are drawn, and over which the needle is placed, and fastened underneath.

**Flied, or Fly,** in Geography, a river or channel, which runs from the Zuyder Lee, near the coast of Friesland, into the German ocean, between the island of Schelling and Veleland.

**Flied's Bay,** a bay on the W. coast of Africa. S. lat. 14° 50'.

**Flies,** a river of Lufatia, which runs into the Spree, near Luben.

**Flight,** the act of a bird in flying; or the manner, duration, &c. thereof. See *Flying.*

The feathers of birds are admirably contrived, and fitted for the cafe and convenience of flight. See *Feathers.*

Almost every kind of bird has its particular flight: the eagle's flight is the highest; the flight of the sparrow-hawk and vulture are noble, and are fit for high enterprise and combat. The flight of some birds is low, weak, transient, and as they call it, *terra a terra*; the flight of the partridge and pheasant is but of short continuance; that of the dove is laboured; that of the sparrow undulatory, &c.

The augurs pretended to foretell future events from the flight of birds.

**Flight, in Rural Economy,** a young brood of different sorts of birds, as pigeons, &c.

**Flight.** In melting the lead ore in the works at Mendip, there is a substance which flies away in the smoke, which they call the flight.

They find it sweetish upon their lips if their faces happen to be in the way of the smoke, which they avoid as much as possible. This, falling on the graces, kills cattle that feed thereon; and, being gathered, and carried home, kills rats and mice in their houses; that which falls on the said they gather, and melt upon a flag hearth, into flot, and feed-lea.

**Flight, Caupon's,** in some Cussons, is a compas of ground, such as a capon might fly over, due to the eldest born of several brothers, in making partition of the father's effects with them, where there is no principal maner in a lordship. It is usually estimated by a bow-shot.

**Flight of a Stair-case,** See *Stair-case.*

**Flight, in Heraldry,** See *Vol.*

**Flight of an Army,** Were it impossible for each individual of an army to be sufficiently impressed with the terrible consequences of "taking to flight," such as occurrence would be extremely uncommon. Whatever may be the dangers of opposing an enemy front to front, they certainly fall very short of those inseparable from that disasters of which, while it disperses the whole, subjects each to be massacred in detail. Very fortunately for the British service, and with the most heart. It pride do we declare it, very, very few instances could be adduced wherein our soldiers have so far lost sight of subordination, or been so far overcome by panic, as to induce them to adopt this ruinous conduct. That they have been led very improperly into such situations as to render their valour and discipline of no avail, cannot be denied; but even under such disheartening circumstances their exertions have kept pace with surrounding difficulties, and taught their enemies to respect them, even when compelled to surrender at discretion.

The flight of an army is usually attended with great carnage, and with the total loss of its artillery, ammunition, baggage, flotes, treasure, &c. This rarely happens when the discomfiture is unconnected with the precipitate abandonment of positions, and of the ordnance; in this latter

*calp*
F L I G H T.

cafe, the reserve commonly offers an asylum to the defeated corps, enabling them at least to retire, if not to make head against their partners. The French, in their usual mode of vanishing over blemishes in their conduct, and of reconcing, at least to themselves, the errors of their generals, as well as the misconduct of their fieldiers, never admit the affection that their troops were "put to flight," but with much figurae observe, that "they made a precipitate retreat." This is something on a par with the defiance made by a gentleman, when having been insulted rather abruptly, was found lying in the mud; but denied having been thrown. Oh, no, "he had only dismounted, to get a better foot."

In that neat little volume, "The Packet Gunner," published by captain Ralph Willett Adye, of the Royal Artillery, is the following maxim, which cannot be too affidiously circulated, not only amongst artillers, but amongst every class of fieldiers. He says, "never abandon your guns till the last extremity. The last discharges are the most destructive; they may be your salvation, and crown you with glory."

**Flight of a Shot or a Shell.** Referring ourselves for an ample dissertation on the flight of projectiles in general, under the head of *trajectory* (which see), we take the opportunity of offering some remarks regarding those very erroneous opinions which are, in many instances, prevalent regarding the line in which a shot proceeds from the mouth of the cannon to that object towards which it is directed.

The term *point-blanc* has been greatly misunderstood. It originated in the practice among the French artillers, of firing at a *white* centre within various concentric circles of black; whereas we commonly make the centre of a target black; designating it "the bull's-eye." Therefore, when a piece was laid for the centre of the target, it was supposed to be exactly horizontal, so far as related to the line of the chance; the target being only eight feet in its whole height, which corresponded with the average height of a man on a middle-sized horse; the centre of the *point-blanc* (or white spot) was then about as high from the ground, supposing the intermediate distance to be level, as the muzzle of the gun.

Now it was found, that with the proper service-charge, a gun would at a certain distance throw the shot to the height of the *point-blanc*, and, if correctly "laid," that it would strike with exactness thereon. This gave rise to the opinion, that the shot proceeded to that distance in a direct line, after which it began to form an angle downwards. That such an error should maintain its ground while science was only in the womb of time, may not be extraordinary; but that any man who has either observed the practice, or considered the theory, should for a moment attempt to uphold so false a position, must appear absolutely wonderful. Were no such opinions extant, we should not have expended one drop of ink towards explaining the real flight of a shot, and to remove the vulgar error of what are called *point-blanc* ranges, being rectilinear.

In confuting the popular opinion on this subject, we must observe that, exclusive of the perpetual tendency of all bodies in motion, (from whatever impetus) to deviate according to the rules of gravity, (which fee), certain circumstances, particularly relating to artillery, seem to combine for the purpose of giving an acescending direction to all shots impelled by the action of gunpowder. We are to consider, that every piece of ordnance, when discharged, rises from the ground in proportion to the quantity of gunpowder used, and to the weight of metal, of the carriage, &c. in opposing ratios. This alone would probably give some determination upwards to the shot at the moment of its quitting the piece, and when the air, opposed to the expanding flame, fo forcibly occasions the piece to recoil; but if we call to mind, that that flame being to much lighter than the atmosphere, must instantly be forced upwards thereby, (especially as the concussio upon the foil below would add to such tendencies), we may at once find sufficient cause for the ascent of a shot at the moment it quits the cannon; for both will, with the action of the cannon and the rarefaction of the air at such a distance, whereby a rapid and strong current of aecio is given, tend to cause some departure from a horizontal direction.

The fact lies in a nut-shell; for, unless when following the line of gravity, which is every where locally perpendicular, and of course always points to the centre of that globe we inhabit, nobody can maintain a rectilinear motion; there will always be a tendency to gravitation. This being admitted, it follows, that in order to arrive at a certain level, at a certain distance, an elevation must, either naturally or artificially, be given, whereby the line of flight will be found to describe that unequal curve called a *parabola*, (which fee). Every boy that flings a sling, or throws up a cricket-ball, must be convinced of the truth of our position. The fact may, however, be more certified to the eye, by placing rather behind a cannon (the greater its bore the better) and at about an angle of 25° from the line of fire, when the flight of the shot will be seen to give a curve upwards.

With respect to shells, their lines of flight are exactly on the same principles, but their altitudes being considerably greater in proportion than their baees, the parabolic curve generated assumes a different figure. It should be particularly noticed, that, for the sake of giving effect to the fuses driven into shells, the ordinary periods of flight for particular ranges, i.e. distances horizontally, together with the charges of powder, and the angle of elevation, (usually 45°) are to be carefully noted. If the powder were all of equal strength, the fuses all exactly similar, and equally well driven, or filled, the weight of the atmosphere always the same, and the angle of elevation ever fixed immovable, the lengths of fuses for particular ranges might be always determined; as it is, we fee that considerable variation often takes place even with the same powder, the same gun, the same temperature, and, in fact, with every thing perfectly similar, to all appearance. Observing that the more prosnated the line of flight, the greater the force with which a shell will fall, shall submit the following table of ranges made with sea-service iron mortars, at 45° upon a horizontal plane.

The great increase of velocity gained by the heavier charges must be apparent; in the first instance the time of flight is 13 seconds to about 680 yards of horizontal distance, which gives only 50 yards for each second; whereas the latter charges gain on the preceding ones so rapidly, as to give 400 yards in every added second. From this we see, that, unless fired at an improper elevation, mortars cannot be used with their greatest effect, unless so far removed from their object, as to admit of their being charged as high as the metal will bear.

FLINT, in the Mans, is the fiery and obfinate action of an unruly horse.

To fling like a cow is to raise only one leg, and give a blow with it.

To fling or kick with the hind legs, see YERKING.

FLINGING, among Birds. See Bowling.

FLINK, GYPSY, in Geography, a painter of history and portraits. He was born at Cleves in 1616. Early in his youth he exhibited a strong inclination to painting, from which neither the desire of his father that he should pursue a mercantile occupation, the influence of his friends, nor the prospect of making a fortune, could divert him. He was therefore placed under Lambert Jacobs. With him, at the same time, Barker also studied under Jacobs, and the emulation which exalted between these two greatly advanced their progress in the art, but Flink outstripped his companion considerably. He afterwards entered in the school of Rembrandt, and imitated the works of that extraordinary man with great success, and his pictures are now frequently sold as the productions of his master.

He very soon rose into high repute, and was almost constantly employed in painting the portraits of distinguished personages, although his genius inclined him to paint historical subjects, and several of his performances in that style were admired for the goodness of the design and the beauty of their colouring. He died in the year 1660, at the age of 44, very much regretted. After his death his collection of prints and drawings were sold for twelve thousand florins.

FLINT, in Geography, a small borough town in the hundred of Colchill, and capital of the shire to which it gives the appellation. Though almost defirite of trade, it is conveniently situated upon the river Dee; distant from London 204 miles, and 12 W.N.W. of Chelten. This place was formerly fortified, having been surrounded by a double fosse and vallum, and, during the struggle of Cambria for her independence, was celebrated for its strong calfe, begun by king Henry II., but not completed till the time of Edward I. This fortress stands upon an isolated hill in a low marsh, which is occasionally overflowed by the tide. Aniently the efluary of the Dee laved the walls, and a communication was formed between the cale and the advanced works, called the barbacum, by means of a bridge; but the channel of the river is now at some distance. The structure is formed of a reddish grit-ctone from quarries in the vicinity. The form is a right-angled parallelogram, having three of its angles defended by polygonal towers, some remains of which are still standing, including an area within the walls of about an acre. At the south-east is a detached tower of angular construction. It is of a circular form, consisting of two concentric arches, leaving a space between for a gallery eight feet broad; the diameter of the inner circle is twenty feet. In this castle the unfortunate Richard II. took shelter, on his arrival from Ireland; when, quitting it, he was seized by the duke of Lancaster, and carried prisoner to Chelten. During the civil wars it was garrisoned for the king, but surrendered to general Myton in 1646.

FLINT is a corporate town, governed by a mayor, two bailiffs, and other inferior officers; and, in conjunction with Rhuddlan, Overton, Cheeryws, and Caergwrile, sends one member to parliament. The voters are such as pay foot and lot in the respective places, and the returning officer is the mayor of Flint. The church, which is a chapel of ease to Northop, is a mean looking building, having for a steeple a boarded turret. In 1783 a new county gaol was erected upon the plan of one previously built at Ruthin; although the affizes are regularly held at Mold. In the summer featon Flint is frequented as a bathing place, but the marshy nature of the coast, over which the sea at high tides flows, renders the bathing inconvenient, and the air rather insalubrious. Though privileged as a market town, the market has been long discontinued. By the returns made to parliament in 1801, the number of houses was 159, and inhabitants 1169.

A wood in the vicinity of Flint is celebrated, in the annals of history, for having been the scene of many a singular conflict, and as ominous to the English cause. Here Henry II. was twice defeated in one campaign, losing not only his principal officers, among whom were included many of the nobility, but the king himself was frequently in imminent danger of being killed, and narrowly escaped being taken. Penmaen's Tour in North Wales. Skrine's Tour.

FLINT, a considérable river of America, in Georgia, which rises in the country of the Creek Indians, and pursueth first a south, and then a south-west course, joins the Appalachian, at its entrance into Florida. The territory adjoining this river affords a rich soil capable of profitable cultivation, and offering an uninterrupted navigation to the bay of Mexico and Atlantic ocean, and thence to the West India islands, and other parts of the world. On this river is a number of villages belonging to the Creek Indians.—Allo, a small town, about 25 miles long, in the Genesee country, in New York, which runs N.N.E. into Canadarqua creek.—Alloa, a river of Jamaica, which runs into the sea, seven miles W. of Montego bay.

FLINT Island, an island in the gulf of St. Lawrence, near the east coast of the island of Cape Breton. N. lat. 45° 10'. W. long. 59° 40'.

The first, one of the most remarkable of the flinteous flowers, has frequently been confounded with other hard flowers of the same class: the quality it possesses in an eminent degree of giving spurs with the file, and the popular denomination it has thence derived among almost all nations, have been the principal causes of this confusion, which may easily be avoided by a proper attention to its more distinguishing characters. It is, however, to be confessed, that, in some cases, its diagnosis is rendered uncertain by its too great affinity to Horn em and Flint flints (see those articles,) and by its gradual transition into those kindred flowers.

Its colour is chiefly gray, of which yellowish, blueish, and smoke-grey, are the more usual shades, and these pass, the latter into greenish-black, the former into all the well known tints of yellow, reed, and reddish-brown, that approach it, to the carnelian. It is sometimes found perfectly black.
FLINT.

and also displaying several of the just-mentioned colours in strips, zones, and spots.

Flint occurs massive, in angular pieces of various size, in globular boulders, frequently tapering at one end, (the petrified melons of Mount Carmel, vulgarly so called, belong to this variety); also in knobbled, branching, amorphous, perforated pieces, and as hollow balls filled with various substances. (See Grose.) Besides these forms, it sometimes assumes the form of crystals, which however do not belong to it, as some writers have supposed, but are formations from calcareous spar it derives the double three-sided pyramid, as also the five-sided prism terminated by three planes; and it has been likewise observed in crystals formed after the form of lenticular borax or calcite. It is also frequently observed, (contrary to what we know of hornstone) in extraneous external shapes, as petrifactions of species of echinus, madrepora, coralline, &c. Surface little glistering, and of various degrees of smoothness, often coated by, and passing into, a white or yellowish-white crust, of which we shall say more hereafter. Fracture conchoidal, never perfectly pithity; internal surface but little glistering, or dull, of an almost imperceptibly fine grain. Fragments sometimes tabular, very sharp-edged, and more or less translucent in proportion to the lighter or deeper colours of the stone. It is easily frangible. Its hardness appears to be in a ratio with the depth of its colours: in general it will scratch quartz.

Specific gravity, according to Gellert, 2.581; Blumenbach 2.594; Gmelin 2.999. To these physical characters of flint we may add the one afforded by its phosphorescence, and the peculiar smell, which are manifested when two pieces are rubbed together.

Flint is infusible before the blow-pipe without addition, but loses its colour and becomes opaque. By the intense heat excited by a stream of oxygen gas, Mr. Lharmann found it to melt into a white glistering quartz-like globule.

Its constituent parts are,

Flint is met with in most parts of Europe, particularly in the north of France, in England, Saxony, Tyrol, Poldavia, &c. Norway seems to be deflitate of flint, as it is of chalk; also in Sweden it is scarce. In Denmark it is principally at Vordeborg and Taxo, in the island of Seeland, that some chalk-hills with imbedded flints are found; and more copiously in the remarkable Stevens-Klint. It occurs but seldom in primitive mountains, and when found there, only in veins, as, for instance, in the Saxony Erzgebirge. Its principal geographical situation is in the Switz-mountain, where it occurs chiefly in common compact lime-flint or in chalk; in the sand-flint formation, where it is also met with in the flake of those conglomerates vulgarly called Puddingstone. See this article.

Though the formation of flints is a subject which has engaged the attention of many naturalists, yet but few opinions have been broached respecting it that will at all stand the test of closer investigation. The theory which explains their origin by a metamorphosis of one earth into another, though it may appear absurd to the chemist who is unable to produce the same changes in his laboratory, has notwithstanding its able and celebrated defenders. Some have endeavoured to prove that the argillaceous, others, that the calcareous earth, underwent this conversion into flint. Buffon was an advocate for the argillaceous origin of this stone; and the observations of Pallas appeared to corroborate the opinion of the French naturalist; for he found that the Ephemera borax, which abounds in the Molus, had in some places perforated the clayey bottom of this river with innumerable tubes closely joined; and in the adjacent fields pieces of perfect flint frequently occurred that were placed precisely in the same manner as the clay, from which they were not found to differ in any respect but in fracture and hardness. In the same manner he states that, in the small river Sungbir, near Woldenmire, black, globular, rolled masses occur, which, on being broken, exhibit, from their circumference to the central part, a gradual transition from red clay and clay-stone into what he considers as perfect flint. With all deference, however, to the great merits of this excellent observer, we cannot but fee in his account one of those frequent cases in which the hard flints of the siliceous clays (and clay flint and Jasper belong to it) have been mistaken for real flint merely by reason of their giving copious sparks with steel; for this appears to be the character on which Pallas has chiefly founded his diagnosis of the stone he describes.

According to other geologists, it is lime-flint, and principally chalk, which have undergone a transformation into flint—an opinion which Wallerius endeavoured to support both by geographical and chemical facts, and which was followed by Linnaeus himself. Also Gillet-Lamont and Girod-Chantres, from observations they respectively made in various parts of France, were induced to consider flint as a mere modification of chalk. The principal ground on which this hypothesis appears to rest is the geographical relationship that subsists between the strata of chalk and of flints, together with the intimate union of the boulders of flint and their white earthy crust; both these substances being to completely incorporated with one another, as to preclude the possibility of there being in the lime which each may be considered as perfectly distinct from the other. This latter reason, though specious, may, however, lose much of its force by future analysis of that white earthy substance. To us it appears that most of the boulders of flint, such as they are found embedded in chalk, are but seldom familiar with a coating throughout calcareous: it seems to be comprised of a twofold crust, viz. an outer chalky one, originating from the matrix of the stone; and an inner one passing over into the outer, and, by reason of the thinness of colour, not distinguishable by the eye. This inner crust matures no effervescence with acids; it appears to be fleshy, and may perhaps be properly looked upon as the result of incipient decomposition; especially if it be considered that flints with uncoated surface, by a long exposure to the influence of moisture and other atmospheric agents, have been known to acquire another thin coating (but not calcareous,) with lols of weight.

Many geologists of the present day, who consider the idea of a transmutation of the calcareous into siliceous earth as unworthy the advanced state of modern chemistry, at the same time that they are unwilling to have recourse to floods and other revolutionary agents for rolling fragments of flint into boulders, and dispersing them in the regular manner in which they are now found, have adopted, from the hypotheses of infiltration by means of a siliceous fluid; others, that of a forcible injection of melted flint into cavities previously existing in the calcareous strata. But either of these
FLINT.

theories is open to objection; and, indeed, the same objections appear to apply to both. It is difficult to account for the strange predilection the flinty fluid (whether its fluidity proceeded from water or fire) has manifested for flint lime-bone, particularly for chalk; while other flint and primitive rocks, several of which must be supposed to have been equally exposed to it, remained perfectly untouched. Nor is it much easier to conceive how that suppoed fluid can have found its way into so many approxi-mate, but perfectly distinct, hollows in the chalk, without more or less penetrating the intermediate parts, or leaving traces of mafles that were connected with the nodules as they now appear; not to mention the improbability that so many both contiguous vacuities (especially those that must be suppose to have been the moulds for the frequently occurring tabular expansions of flint) should not have yielded to the pressure of the superincumbent stratum. As, moreover, these hypotheses are silent respecting the origin of this flinty maf, (although a substance is different in its appearance from common flint,) another theory of the generation of the nodules of flint has been proposed, which, however, is not likely to meet with any followers among those geologists, whose exalted ideas of the present state of chemical knowledge lead them to suppose that the refult of their analytical and synthetical processes must of necessity, in all cases, square with those great operations that, with her ample means, and affihed by a long series of ages, have been accomplished by Nature in the vast laboratory of the earth. We allude to the hypothesis, according to which all flint, whether it be found in nodules or as flat tabular plates, originates from the bed of a stratum of marine gelatinous animals, which perished by some revolution, and were buried in their shells. The internal aspect of the nodules, and their being almost constantly found imbedded in flint lime-bone, which, by molt geologists, is allowed to owe its existence to shells and other calcaneous coverings of tender animals, seems fball to have suggested this new idea; which, if range as it appears, may be allowed to have as much plausibility as any of the former; especia11y as it may be adapted equally well to the sytem of an igneous, and to that of an aquatic origin of terrestrial bodies. Mr. Patrin is of opinion, that when the chalk was deposited at the bottom of the sea, in those strata which we now see, it met, on other strata already existing, a vast number of marine bodies, shells, madreporas, &c. while others were carried along with the precipitating chalk itself, such as medusas, &c. whose soft and gelatinous bodies, while they occupy much space, contain but little subiubility. When all these marine animals were buried in the chalk, and their decomposition took place, those of a confidence merely gelatinous, left in their matrix an empty space, nearly equal to the space they occupied when alive: their subiubility, alone in a state of fluidity, was absorbed by the porous foids of the cavity; and by the combination of this animal fluid with the chalk, these foids were, by some unknown agent, converted into flint. In this manner Mr. Patrin accounts for the generation of nodules that are either hollow or filled up with chalk; which latter may have been depofed there by means of some aperture, or may have penetrated through the flint entifel, when full in a state of fottifes. As to thole nodules, the central part of which is of a more perfectly flinty nature than that nearer the circumference, they were, according to the fame author, formed of marine animals of more confidence or solidil; and it is in these particularly that velites of animal organization are found. The more confident part of the body of these animals produced the more perfect flint, such as we see it in fuch solid nodules; while the fluid which escaped from the body, by the effects of decomposition, formed the external layers of the nucleus, which, being mixed with the substance of the chalk, became fels perfect flint, the further it removed from the central part. According to this explanation, the fult imperfect part of a nodule of flint would be that, which, in its original situation, occupied the lowest place, and towards which the fluid which escaped from the more solid nucleus must naturally have taken its direction. This, however, is never found to be the case; nor has Mr. Patrin endeavoured to account for this circumstance. What appears to be much in favour of this explanation is, that the whole body of echinii in their fells has been found converted into flint; and Gillet-Laumont has frequently observed that those echinii, which he met with in the chalk strata of Monfreul-fur-Mer, were furnished with a flinty appendage filling from their mouths, and which appears to have been the animal subiubility converted into a flint slate by decomposition. The fame circumstance is not feldom observed in bivalve fells, whose gelatinous inhabitants have been found in a perfectly fuble clarity; while the fells themselves had retained their original calcaneous nature, and were partly converted into flint. In cases where the gelatinous marine bodies were in such abundance that no intermediate space was left for the deposition of chalk, the flint has been formed into large mafles and plate of considerable extent. Dr. Darwin's ideas on this subject are nearly the fame, and modified only by his adopting a different theory for explaining the conversion of the gelatinous animals into flint. He conjectures that the nodules of flint found in chalk-beds have gained their form, as well as their dark colour, from the fells of the shell-fish from which they had their origin, but which have been so completely fuble by heat, or heat and water, as to obliterate all velites of the shell; in the fame manner as (according to the doctor's opinion) the nodules of agate and onyx were produced from parts of vegetables, but which had been so completely fuble as to obliterate all marks of their organization.

A remarkable circumstance, relating to the geological history of flint, should not be passed over unnoticed in this place: it is that Sir Henry Englefield has observed in the neighbourhood of Carli brook, and in other parts of the Isle of Wight, an immense number of nodules of flint, all of which, though not removed out of their places, and retaining perfectly their original shape, were more or less tufted or flattered. Some few were only split into large pieces, but the greater part were broken into small fragments, and some absolutely reduced to impalpable powder. The chalk strata in which they were imbedded had an inclination of at least 67 degrees, and perpendicular lines traversed the whole. Sir Harry conjectures, "that when the tremendous convulsion took place which sunk them to the situation in which they now appear, (at which time the channel which separates the Isle of Wight from the main land was perhaps formed,) the flata of chalk, in the act of subfidence, had a tendency to slide on each other; and this would have exerted most fublefully where, from the inclination of the strata, the cohesion of the parts of the chalk was the weakest. This motion, or rather flipt of so enormous a weight, might in an instant shatter the flints, though their edges fheep the incipient motion; for the flints, though crude to powder, are not displaced, which must have been the case had the bed flipt horizontally." This theory appears to us very unsatisfactory, though we are not prepared to give a better. The advocates for the 1st mode of flint decay,
FLINT.

perhaps, be inclined to account for the phenomenon by an accidental sudden cooling of the flinty masses.

We conclude this article by adding a few words on the use to which flint is applied, some of which are of considerable importance. The one derived from its giving copious sparks with fleck is the most ancient and generally known; but the art of cutting or rather breaking this flint into regularly shaped gun-flints is of more modern date, and was not practised till a considerable time after the invention of fire-arms. The mode of making gun-flints has for a long time been involved in fable and mystery: the most absurd and contradictory accounts having been given of it by various authors; and it was not till lately that we have been made fully acquainted (by Hacquet of Vienna, and by Dolomieu) with the simple manner in which the flints are manufactured in Galicia and in France, where they constitute an important article of trade. (See Gun-Flint.) The art of squaring and chipping flint was practiced long before that of making gun-flints; and as this latter requires exactly the fame management and the same tools, the former cannot properly be called a loft art, though, on account of the expensiveness of such square pieces of flint, if employed for constructing walls and covering roofs, it is not much practiced. The north wall of the Bridewell at Norwich, mentioned in a letter of Mr. Baker, in the 43d volume of the Philosophical Transactions, was built of flints, "squared to such a nicety, that the thin edge of a knife could not be interposed between the joints without a great deal of difficulty." And we learn from a note to that letter, that the gate of the Austin friars at Canterbury, the gate of St. John's abbey at Colchester, and the gate near Whitehall, Welfinnder, are executed in the same talle; and the platform on the top of the Royal observatory at Paris, which is paved with flint after the same manner, is adduced as a proof that the French have in some measure recovered the art. Flint is also often employed in the manufacturing of glafs, small, porcelain; and some of its lighter colored and striped varieties are made use of for ornamental purposes. They take an excellent polish, and are not unfrequently manufactured into snuff-boxes, &c.

FLINT. The history of this fossil presents a labyrinth of blunders and confusion. On one hand it has been described under the names of well defined Wernerian species of rocks, such as horn-flone, trapp, &c.; on the other hand it has been jumbled together with various mineral substances, under the vague and mislytematic appellations of roche cornéene, petrofilex, and particularly (by German mineralogists) under that of "hornschiefer," or creosmal flate. This latter was applied by some mineralogists to the subject of this article; but by others it was indiscriminately given to hornblende-flate, to varieties of clay-flate, to mice, and to porphyry-flate; whence professor Werner, to prevent the fame confusion that has been introduced into mineralogy, by the term "flate," expunged that of hornschiefer, (though he had made use of it himself,) applying to the fossil in question the name of kieselschiefer, now generally adopted in Germany, and of which "flint-flate" is a literal translation. The just mentioned author has divided this species into two sub-species, viz. into common flint-flate, and Lydian flone. The latter has been confidered by some as a mere variety of the former; but there are good reasons for keeping it different. See LYDIAN STONE.

Common flint-flate occurs generally of a dark grey colour, which has frequently an admixture of blue, of red, and of yellow; and these tints often pass over into each other, or are seen separately in the same fragments, as spots or stripes. The blood-red and brownish-red varieties are the fairest. It is found massive and in rounded pieces, which latter have a smooth surface. Internally it is dull; now and then rather glimmering. In small fragments its fracture varies; it is sometimes splintery, and imperfectly conchoidal, and sometimes paffes into even; the blackish-grey variety with the latter fracture approaches the Lydian flone. In large masses it manifests its flaty nature. Its fragments are angular and sharp, and but little transparent at the edges. It is brittle, and its hardness nearly the same as that of quartz. Another pretty comitant character of flint-flate is its being traversed by veins of quartz, that are often of a greyish or reddish colour. Specific gravity, according to Gerhard, 2.869; according to Kirwan from 2.596 to 2.631. Those varieties of flint-flate that have been chemically examined are not fusible per se; nor do they much change their colour in the fire; the grey becomes rather lighter colored, the black does not appear to be at all affected by the heat of the blow-pipe. Wieglew's analysis of flint-flate from Fulda (in vol. i. of Chem. Annalen, where, however, it is called hornschiefer, and considered as of volcanic origin) has given the following result:

Flint-flate appears to pass over into Lydian flone, into horn-flone, quartz, and particularly into clay-flate; so that when seen in small fragments, it is often difficult to seize its distinguishing characters. It is found in various parts of Germany, Bohemia, Silecia, in Bareuth, the kingdom of Saxony, the Hartz, Palatinate, Salzburg, &c.; and, according to Mr. Jameson, in various parts of the great tract of transition rocks in the south of Scotland. The geo- nomic relations of flint-flate are not well ascertained, and indeed it is difficult to assign it a proper place among the rocks. It is generally found in huge, cliffy, and clagggy masses, particularly on granite and clay-flate, and more frequently as beds in transition, clay-flate, grauwacke, and grauwacke-flate. From the observations of some geologists it would appear that flint flate is, in many cases, to be referred to the transition rocks of Werner; and, according to Freidleben, the specimen in Laffin's collection of rocks, which by this author are described as varieties of trapp, belong to the transition flint-flate; whence its occurring as angular fragments in grey-wacke, and as rounded pieces in the old red sand-flone can be no matter of surprise. Most frequently, however, it occurs in the shape of boulders, on plains, and in the beds of rivers.

FLINT is used, in our military service, for the purpose of affixing into a vice made at the top of the cock of a musket, or piflot lock; so that when impelled against a piece of steel, called the hammer, it may strike fire, and ignite the gun-powder contained in a pan, concealed by the hammer, until the latter is forced backwards on a pivot, by the great force with which the cock strikes against it; when it not only produces fire, but, by its peculiar form, directs the sparks towards the priming in the pan.

Flints are easily adapted to this purpose; those great masses which are found chiefly in chalky soils, being broken by hammers, yield a number of wedge-like pieces.
FLINT.

of which the sides are trimmed to the proper width, and the backs brought into a proper form, which should be rather concave. This concavity is, however, very little attended to, but is of great service, since it escapes the screw of the vice, and causes the flint to retain a much firmer hold than when its back is made either straight, or convex; the latter is a great fault, but is commonly overlooked.

The proper sizes for flints are as follows; for a musket, one inch and five-eighths, for the length, with a width of an inch and a quarter; the thickness is the back one-third of an inch, and the tapering to be rather fudden than gradual, something like the end of a knife. Such flints fit well in the vice, being previously laid in a bed of thin flint-lead, or for want of it, in flint leather. The edge of a flint, thus formed, is far less subject to splinter, than when the angle is more acute. It may perhaps be objected, that a thin edge strikes fire better than a thick one; but that will be for only a few rounds; whereas the thicker edge refines better, and prefers an equable facility of fortis.

All military men must know that nothing is more adverse to the operations of a regiment, than the necessity (which too often occurs in consequence of the proper form not being sufficiently attended to) for men to quit their ranks for the purpose of either hammering, or changing their flints. To the brave man such a necessity is painful, as well as dangerous, while to the less resolute it serves at least for a pretext to pass the rear, or eventually to relinquish his post altogether.

A carbine flint should be one inch and a quarter in length, by one inch in width; that for a pistol, such as is used among our military, ought to be rather more than an inch in length, by three quarters in width. In fixing them into the vice, great care should be taken that their left sides pass down clear of the barrel, which they would otherwise have very much, and be themselves subject to splinter, while the cock itself might, by being unduly checked, be snapt at its neck.

When flints have a curve, they should always be so fixed in the vice, as to give the curve a downward direction; since, in that way, they act more forcibly, and offer the greatest resistance. Straight flints, after being so far rounded as to yield no sparks, when their chambered flints have been uppermost, may be again rendered serviceable by being reversed, so as to bring their flat sides uppermost. Soaking flints in water refines them partially, probably by exposing them with hydrogen, but in a very small degree, and that not permanently.

The best flints are such as, when acted upon by fire, produce strong lasting corruptions, which emit a fulphenous smell, and are sufficiently large to leave some little flint on tinfoil paper, or on fine linen. Such will not only be found to yield a certain fire, but to break up admirably under the hammer employed to reduce them to splinters, and to fit them for the folder's use. On the contrary, however, clear, black, and firm a flint may appear, if its flarks are not vivid, and highly fulphenous, it ought to be at once thrown aside.

The hardest flints being generally the best, experiments were made with agates, cornelions, &c. all of which produce beautiful flarks, but, being extremely brittle, could not be brought into general use; however, in situations where they are obtainable, and where flints are not to be had, they become valuable sublimates. Various attempts have been made to produce flints by means of composition; but such have always proved vitreous, and consequently weak both in substance, and in the production of flarks. We cannot conclude this article without strongly recommending, that more attention be paid at our arsenals to the rejection of flints of defective form and quality.

Flints are generally packed in small casks, called half-barrels, each of which contains Number qr.s. lbs.

Musquet flints 2000 weighing 2 14.
Carabine do. 3000 2 10.
Pistol do. 4000 15.

The tonnage of this article is computed at 28 lbs. of musquet-flints to occupy 18 cwt. and 10 lbs. of pistol-flints to occupy 3 cwt. 2 qr.s. which our readers cannot fail to observe by no means corresponds with the foregoing table of contents.

Flints, in the Glafs-trade. The way of preparing flints for the nicest operations in the glas-trade is this. Choose the hardest flints, such as are black and will refit the file, and will grow white when calcined in the fire. Cleanse the edge of the white crust that adheres to them, then calcine them in a strong fire, and throw them, while red-hot, into cold-water; wash off the ashes that may adhere to them, and powder them in an iron mortar, and sift them through a very fine sieve; pour upon this powder some week aqua fortis, or the phlegm of aqua fortis, to dissolve and take up any particles of iron it may have got from the mortar; sift this mixture several times, then let it rest, and in the morning pour off the liquor, and wash the powder several times with hot-water, and afterwards dry it for use. You will thus have a powder for making the purest glass, as perfectly fine and faultless, as if you had used rock crystal itself. Cramer's Art of Allying Metals, p. 438.

The washing off the ferruginous particles with aqua fortis is not necessary when the glass intended to be made is to be tinged with iron afterwards; but when meant to be a pure white, this is the method that will secure success.

Flints, the small, sharp, hard, vitrifiable stones which often abound in foils of the more thin, poor kinds.

Flints, oil or liquor of; a name given by some to a preparation made of four ounces of flints, calcined and powdered, and mixed with twelve ounces of salt of tartar; these being melted together in a large crucible, by a strong fire, run into a glass, which quickly and strongly attracts moisture from the air, and is entirely soluble in water, except a very small portion of earthy matter; this glass, being afterwards powdered and set in a can, runs into an oil per deliquium, with this and the calc of any metal is prepared one of the metallic Vegetations. If any acid be added to the liquor of flints, so as to saturate the alkali, the flint, which was kept dissolved in water by means of this alkali, will be now precipitated in the state of a fine earth, which earth is entirely soluble by acids.

FLINT WAlls. See Wall.

FLINT NODULES, in Geology, are a phenomenon of a curious and important kind, when their regular disposition through the chalk strata are taken into consideration, as well as the angular and somewhat regular shapes which they assume. The great assemblage of chalk strata which form the uppermost but two of the assemblages of strata in Britain, as far as is yet known, (viz. the London-clay and Bagshot-fand,) abound with these nodules in about the upper half thereof, called the upper or flinty chalk, while the under part, called the lower or hard chalk, has few if any flints occurring in it, and these, at its upper part, if such do occur. It is well ascertained, that none of the chalk flints are entirely free of minute grains of siliceous or gritty matter in them, whence the use of chalk or whiting in founding tin, copper, and other wéths arises; and modern observations by Mr. Smith and his pupils have thrown, that these layers of flints...
FLINTS. This county extends in length 33 miles, and in breadth from 8 to 9, containing about 165,000 acres of land, of which, according to the report to the Board of Agriculture, only 20,000 are in an arable state 116,000 under palt urge, and the remainder in a state of waste. The principal rivers are the Dee, which rising in Merionethshire, after running through Denbighshire, falls into this county, and is navigable from Chester to the sea. The Clwyd also has its source in Denbighshire, and, running in a northerly direction, is joined by the Alan below St. Asaph, and falls into the Irish sea. It is also watered by the Sevon, the Wheel er, and a few minor streams. The face of the country is much less diversified than any other Welsh county. A ridge of low hills rises abruptly on the north-eastern part of the county from the Dee, and, running parallel with that river, terminates at the sea. The vale of Mold is a rich level country, and, on the vale, rather valley of Clwyd, has been long celebrated for its picturesque beauty. The northern part is champagne, and abundance with corn; the valleys consist of an argilaceous soil, and are productive in graz. The cattle are small, but considered excellent milchers. Quantities of honey are annually produced, which the inhabitants manufacture into a kind of wine called Methelin. The hills are barren, but are internally rich, containing free-stone, lime-stone, coal, lead, copper, and calamine, the ores of which are worked, and the metals exported via the port of Chester. The county politically is divided into five hundreds, viz. Colegill, Mayler, Mold, Prestlaw, and Rhuddlan, comprising one city, St. Asaph, one borough, Flint, and four other market towns, viz. Caerwy, Caerwyl, Mold, and Holywell; and twenty-eight parishes, 23 of which are in the diocese of St. Asaph, and five in that of Chester. By the returns made under the population act to parliament, in 1801, the number of houses was 37,582, and inhabitants 39,623; in which number it appeared 10,332 were occupied in the labours of agriculture, and 6,89 in employed in trade. Many of the latter find employment in the mines and smelting-bores, and others in the linen trade, a manufacture of which was, by the patriotic exertions of Mr. Fitzwilliams, introduced into the country, and has since spread, and is at present in a flourishing state. The county is represented by one member in the British senate.

FLINTY GRAVELS are such gravelly soils as contain a large proportion of flints in their compositions. They are met with in many situations.

FLINTY SOILS, all such as are constituted with a large proportion of flinty matters. These soils are mostly thin, and of no very great fertility. They prevail in many situations. See Soil.

FLUP, a sort of sailor's drink, made of malt liquor, brandy, and sugar, mixed.

FLUSHNGUE, in Geography, a small island or fortres in the East Indian sea, a little to the west of Amboyna.

FLUTTER-Mouse, in Zoology, the bat. See Vespertilio.

FLUX, in Geography, a small town of Spain, in Catalonia, formerly defended by a castle on an eminence, but now dismantled, penetrated by the Ebro; 8 leagues above Tortosa, near the cataract of that river.

FLUX WOOD, in Botany, a species of water-cresses, which grows in uncultivated places, and by the side of foot ways in many parts of England; it flowers in June, and the seeds, which ripen in August, are greatly recommended by some for the gravel and retention of urine.

FLIZE, in Geography, a town of France, in the department of the Ardennes, and chief place of a canton in the diocess,
FLOAT, or FLEET. See FLOAT, and FLEET.

FLOAT of a fishing-boat, &c. See FISHING-BOAT.

FLOAT, sometimes called catamaran, also denotes a certain quantity of pieces of timber, joined together with rafters athwart, thrown into a river to be conveyed down the stream; and even sometimes to carry burthen's down a river with the stream. The invention of floats is of great use; it is said to have been first put in execution at Paris in the year 1618. (See BOAT.) The term also signifies to turn water upon meadow-land, with the view of dressing and improving it. And it likewise implies the piring off the surface, turf, or level of grassy lands. See RAFT.

FLOAT, in Engineering, signifies a low or shallow boat, often called a dirt-boat, used in the repairs of canals; which see. See FLATTS.

FLOAT-BORDS, those boards fixed to water wheels of underfoot mills, serving to receive the impulsion of the stream, whereby the wheel is carried round. See WATER-WHEEL.

It is a disadvantage to have too great a number of float-bords; because, when they are all struck by the water in the best manner, the force of the water upon each of them, the sum of all these impulses will only be equal to the impulise made against one float board at right angles, by all the water coming out of the penstock, through the opening, so as to take place on the float-board. The best rule in this caue is, to have just so many, that each of them may come out of the water as soon as possible, after it has received and acted with its full impulsion; or, which comes to the same thing, when the succeeding one is in a perpendicular direction to the surface of the water. As to the length of these float-bords, it may be regulated according to the breadth of the stream. See Defaguerius, vol. ii. p. 425.

FLOAT-GRAVE. See FLOATS.

FLOAT-ORE, in Mining, or lead-ore, signifies in some places, the same with dream-ore, or that found alluvial in the bottoms of valleys, as tin often is in the valleys in Cornwall.

FLOAT-BOAT. See QUARTZ.

FLOATAGES. See FLOATS.

FLOATING Bodies. On the Stability and Equilibrium of Floating Bodies.—Although the general principles relating to this subject will be considered in their proper order under the articles FLUIDS and SPECIFIC GRAVITY, yet there are a few interesting theorems more particularly belonging to floating bodies, and which, forming a subject of themselves, seem to merit attention in this place.

Taking for granted the elementary principles of hydrostatics, as previously established, we shall examine the cases in which floating bodies are in equilibrium, when that equilibrium is stable, and when tottering or unstable. In every system of bodies, whether floating in fluids or acted on by the force of gravity, there are two states of equilibrium, entirely distinct. In one, if the equilibrium be ever so little deranged, the bodies which compose the system only oscillate about their primitive position, and the equilibrium is said to be firm or stable. This stability is absolute if it takes place, whatever be the nature of the oscillation; it is relative if it only takes place in oscillations of a certain kind; in the other state of equilibrium, if the system be ever so little deranged, all bodies deviate more and more, and the system, instead of having any tendency to recover itself in its primitive position, is overtaken, and assumes a new position, entirely different from the former.

We may form a just conception of these two states, by supposing an ellipse placed vertically on an horizontal plane; if the ellipse is in equilibrium on its smaller axis, it is evident that, upon a slight derangement, it will tend to regain its original position, after several small oscillations, which will soon be terminated by the friction and resistance of the air; but if the ellipse be placed in equilibrium on its greater axis, if once it deviates from this position, it will continue to deviate more and more, till it finally turns itself on its lesser axis. In the above example there is this remarkable circumstance; the four positions of equilibrium of the ellipse on the extremities of its two axes are alternately stable and unstable, and this takes place in every case. For suppose two positions of stable equilibrium to take place in any body, and such that there does not exist between them any position of the same kind, if the body is placed in one of these positions, and is made to deviate from it, and to approach the other, according as this deviation is greater or less, the body will either return to its original state, or will arrive at the other position. There will evidently, therefore, be some intermediate position in which the body will neither tend towards one or the other of the former, but will remain at rest: but this state of equilibrium will be unstable, since, if the body be made to deviate from this position so little towards one of the other positions, it will necessarily arrive at it. Hence it appears, that if a body turning round a fixed axis passes through several positions of equilibrium, they will be alternately stable and unstable.

The flablility of a floating body is the greater as its centre of gravity is lower than that of the displaced fluid, or as the distance between these centres is increased; it is for this reason that ballast is put in the lower part of vessels to prevent them from being overrilt.

The nature of the equilibrium, as to stability, depends on the position of a certain point, called the meta-centre, or centre of pressure. The term was first adopted, we believe, by Bouger, in his Traite du Navire.

When the meta-centre is above the centre of gravity, the equilibrium is stable; on the contrary, when the meta-centre is lower than the centre of gravity, the equilibrium is tottering; when the meta-centre coincides with the centre of gravity, the body will remain at rest on it, if it is placed without any tendency to oscillation.

The determination of the meta-centre, and of the nature of the small oscillations of a floating body about its primitive position, is a problem of considerable importance.

Laplace gives the following rule for determining whether the force whichsubjects the fluid to restore it to the same state again, when deranged from its primitive position.

"If, through the centre of gravity of the section of the surface of the water on which a body floats, we draw a horizontal axis to pass, such that the sum of the products of every element of the section, multiplied by the square of its distance from this axis, be less than relatively to any other horizontal axis drawn through the same centre, the equilibrium will be stable in every direction, when this sum forms the product of the volume of the displaced fluid, by the height of the centre of gravity of the body above the centre of gravity of this volume."
it is also necessary that its centre of gravity be in the same vertical line with the centre of gravity of the displaced fluid, otherwise the weight of the solid will not be completely counteracted by the pressure of the displaced fluid.

When the lower surface of a floating body is spherical or cylindrical, the meta-centre must coincide with the centre of the figure, since the height of this point, as well as the form of the portion of the fluid displaced, must remain invariable in all circumstances. The place of the meta-centre is determined by the doctrine of Forces combined with the elementary principles of hydrostatics, by considering the form and extent of the surface of the displaced portion of the fluid compared with its bulk and with the situation of its centre of gravity. According to Dr. Young, if a rectangular beam be floating on its flat surface, the height of the meta-centre above the centre of gravity will be to the breadth of the beam as the breadth to twelve times the depth of the part immersed. Hence, if the beam be square, it will float squarely when either the part immersed, or the part above the surface is less than \( \frac{1}{2} \) of the whole, but when it is less unequally divided by the surface of the fluid it will overfall. If however, the breadth be so increased as to be nearly one-fourth greater than the depth, it will possess a certain degree of stability, whatever its depth may be. Plate VIII. Hydraulics, fig. 1, taken from Dr. Young, is intended to illustrate this.

Two square beams floating at the depths shown at A and B, will have a certain degree of stability, but if they sink, as at C, they will overfall; but a beam of the breadth shown at D will always float squarely.

Theory of the Stability and oscillations of floating Bodies.—When a floating body is in equilibrium, if it be deranged from this state by any cause whatever, it is the object of this investigation to determine the circumstances in which it will return to this state, or continue to deviate more and more from it.

In the state of equilibrium (fig. 2), the straight line GO, which joins the centre of gravity G, of the body DEF, to the centre of gravity O, of the displaced fluid AFB, is vertical. Let this line be taken as the axis of \( \pi \); (see Forces, where this method of analysis is explained). If the body be deranged, this line GO becomes inclined, and O is no longer the centre of gravity of the displaced fluid \( AFb \); the derangement is here supposed infinitely small; the plane of \( x \) and \( y \) is taken as horizontal, and passing through G, the axis is projected as a point in G. \( G \times \) is the axis of \( x \). A B represents the floating surface in a state of equilibrium, \( a B \) in its new position; the co-ordinates \( y \) are supposed parallel to the axes of these surfaces, which separate the immersed part of the body from that which is above the fluid; this axis may be called the axis of the floating surface; it is projected on the point C. The point O may be placed lower than G, without changing any of these considerations. The figure supposes a body not homogeneous, but having the inferior part artificially rendered specifically heavier than the fluid, as in the case of ships. The angle \( aCA = \beta = GOV \) is supposed infinitely small; so that we may imagine the elementary solid \( ACa \) as formed by the revolution of the surface AC, round the axis C of the floating surface. The same may be said of \( BCB \); \( \varphi \varphi \), and \( pp \), are the projections of the arcs described by the centres of gravity of BCC, A from the vertical motion of the body, we may consider \( ABb \) as equal to \( AFb \); so that the portion \( ACa \) out of the fluid is equal to the part \( BCB \), which is immersed in it. If it were otherwise the weight of the body would no longer be equal to the pressure of the fluid; and these two forces acting on \( C \) would produce a vertical motion in the body; besides which it would turn round C as a fixed centre; and as this last motion is independent of the first, and the only one which we are to investigate, this hypothesis simplifies the question by confining it to the latter motion only. The expressions, therefore, for the volumes \( ACC, BCB \), are to be made equal, that is, \( AC \times p'p' = CB \times q'q' \); and since the momenta of the areas \( ACC \) and \( BCB \) are equal with respect to the axis \( C \), the centre of gravity of the surface \( AFB \), or \( aB \), is situated on this axis. The equilibrium being disturbed, we are to consider the motion which the body will take. Let \( GO = a \), the volume \( AFB = afB = S \); also \( \sin \beta = b \), \( \cos \beta = 1 \).

The pressure of the fluid on the merged portion \( aB \) is equal to the weight of the displaced fluid; this force acts on the centre of gravity of \( aB \), and since it is the position of this centre which is to determine the motion of the body about the point \( G \), its position must be determined by taking the moments relatively to the planes \( \pi \), \( \varphi \).

\[ \varphi \times (ABG + BCB) \]

is the momentum of \( aB \), supposing \( CG \) in \( \alpha \).

\[ BCb \times q' \]

will be that of \( CBb \), because \( q' \) differs but an infinitely small quantity from the extremity of the vertical passing through the centre of gravity of \( BCB \).

Likewise, \( aCA \times \varphi \) will be that of \( aCA \).

Let \( g \) be the projection of the vertical passing through the centre of gravity of \( aB \), then \( aB \times CG = S \alpha \) will be the momentum of \( aB \), supposing \( G \alpha = x \). The momentum of \( aCA \) should be taken with a contrary sign from that of \( aB \), since the weight and the pressure tend to make them revolve in contrary directions round the axis \( y \).

Hence

\[ Sx = ACa \times \varphi = S \alpha \beta + CBb \times q' \]

and \( Sx = S \alpha \beta + CBb \times \varphi q \).

To determine the centres of gravity of the elementary portions \( A C a, BCB \), we must divide the sum of the momenta of their portions by their volumes; let any element, \( \gamma \), be taken of the surface \( ACa \), whose distance from the axis of the floating body \( C \) is \( \beta \); then \( \beta \) is the arc of rotation of \( ACa \) round this axis, or the height of the little elementary parallelepiped which it describes; \( \beta \) will equal its sum, \( \gamma \beta \) its momentum relatively to a vertical plane passing through \( C \); \( \beta \gamma \) is the sum of the momentum of the fluid in the nature of inertia of the area \( AB \) relative to its axis, which momentum is positive and known, since this axis is parallel to that of \( \varphi \), and passing through the centre of gravity of \( AB \); hence, the abscissa \( G \alpha = \) of the pressure of the fluid is

\[ x = \left( a + \varphi \beta \right) \beta \]

The momentum of the volume \( AFB \) is positive, only because the centre of gravity \( O \) of the displaced fluid is more elevated than that of the body. If, on the contrary, the point \( O \) had been lowered, the perpendicular \( GV \) would have fallen on the opposite side, then the momentum of \( AFB \)
A F B would have tended to turn in a contrary direction, and we should have had

\[ x = \left( -a + \frac{b^t}{S} \right) \theta. \]

The general formula is therefore \( x = \left( \frac{b^t}{S} + a \right) \theta \); the sign + for the case of the centre of gravity of the body being lower than that of the fluid, the sign - for the contrary.

The co-ordinate \( x \) being thus determined, it now remains to determine \( y \).

We have already \( A F B + A C A = A F B + C B b \), and the moments relatively to the plane of \( xz \), that of \( A F B \) is \( S_y \), that of \( A C A \) is \( S_x \), since the centre of gravity \( O \) is in the plane \( xz \); we have therefore only to eliminate \( b \) of the two elementary sections.

Let us suppose that the ordinates of their respective centres of gravity in the direction of the axes of \( x \) are positive, the element \( t \) taking upon \( C B \) gives the elementary parallelohedron \( S_z t \), denoting its distance from the plane \( xz \); \( b t \) denotes its momentum; the sum of these moments is therefore \( \int f(t; r) \), observing that their signs must vary with the sign of \( r \), that is, as these elements are situated on one or the other part of the plane of \( xz \), the momentum of \( B C b \) is therefore \( \int f(t; r) \); a similar expression will be obtained for \( A C A \), but with a contrary sign, since the pressure relative to \( C b \) and \( A F B \) acts evidently in a contrary direction to the weight of \( A C A \): this negative expression, transposed on the contrary side of the equation, becomes positive, hence \( S_y = \int f(t; r) \); and \( y = \frac{\int f}{S} \phi (i, r) \). The symbol \( \phi \) denotes the integration relatively to the whole floating surface, and of a right line which is the intersection of this surface with the plane of \( xz \), it may therefore be considered as known, but it is not necessarily positive, like \( \int f(t) \) since the elements vary with their signs; therefore the co-ordinate \( y \) of the meta-centre may become either positive, negative, or zero with \( \int f(t; r) \). If the body is cut symmetrically in two equal parts by the plane of \( xz \), \( \int f(t; r) = 0 \) and \( y = 0 \), and the co-ordinate \( x \) of the centre of gravity is given by the formula found above, \( x = \left( \frac{b^t}{S} + a \right) \theta \).

When \( a = 0 \), the centres of gravity, and the displaced fluid, are in the same vertical \( G \), therefore the equilibrium subsists in the new position of the body: this happens when \( a \) being negative, \( a = -a \), but when this is not the case, as the pressure of the fluid acts upwards, it is evident that when \( x \) is positive, the body tends to regain its former position, and the equilibrium is then stable: this happens when \( a \) is positive, or when \( a \) is negative, and at the same time \( b^t > \frac{S}{S} \). Finally, if \( a \) is negative, and \( b^t < \frac{S}{S} \), \( x \) is negative, which denotes that the centre of gravity of a \( F \) is on the other side of the vertical \( G \); the pressure of the fluid then causes the body to deviate more and more from its original position, and the equilibrium is tottering or unstable. This point in the axis of \( z \), which is met by the pressure of the fluid, is called the meta-centre, and hence is derived the theorem mentioned above. That a floating body is in a stable equilibrium when the meta-centre is above the centre of gravity of the body, that the equilibrium is unstable when the meta-centre is below, and that when the two centres coincide the body has no tendency to oscillate. It is evident that the point \( G \) is more or less elevated than the point \( G \), or coincides with it according as the value of \( G \) is positive, negative, or zero.

We shall conclude this article with the following theorem from Dr. Young, which will serve to illustrate the preceding theory.

If a floating body have its section made by the surface of the fluid a parallel-gram, its equilibrium will be flable or tottering, accordingly as the height of its centre of gravity above that of the fluid displaced is smaller or greater than one-twelfth of the cube of the breadth, divided by the area of the transverse vertical section of the immersed part.

Let the body be inclined in a small degree from the position of equilibrium \( A B C \) into the position \( D E F \); then the triangles \( G H I \) and \( J K L \) will be equal, since the area of the section immersed must remain constant, and \( G K \) and \( J L \) will ultimately bisect each other in \( H \). Now the centre of gravity of the section \( I E \) is the common centre of gravity of its parts \( I H M \) and \( I L M \), making \( K M = G I \); but \( N \), the centre of gravity of \( I H M \), is in the line \( H F \), bisecting \( I \), and the common centre of gravity may be found by making \( N O \) parallel to \( H K \) or \( H L \), in the same ratio to the distance of the centre of gravity of \( I H M \) from \( H \), that \( H \) bears to \( I F \). Now the distance of the centre of gravity of any triangle from the vertex is two-thirds of the line which bisects the base, that is, in this case, \( \frac{2}{3} H \), and the area of the triangle \( I H M \) is \( H K \cdot K P \); therefore \( NO = \frac{2}{3} H K \cdot K P \); but drawing \( O Q \) vertically through \( O \), \( N O : N Q = K P : H K \), and \( N Q = NO = \frac{2}{3} H K \cdot K P \); \( H K \cdot K P = \frac{1}{3} I F \cdot F K \). If therefore the centre of gravity \( G \) is in the body, it will remain in its position in any small inclination; since the result of the pressure of the fluid acts in the direction of \( O Q \), if the centre of gravity be below \( G \), it will descend towards the line \( O Q \), and the body will recover its situation; if above \( G \), the body will overtake; hence the point \( Q \) is sometimes called the centre of pressure, or the meta-centre. The theorem may be easily accommodated to bodies of other forms.

**Floating Bridges.** A bridge consisting of several boats covered with planks, which ought to be so solidly framed as to bear both horses and cannon. See Bridge.

**Floating Islands.** See Islands.

**Floating Meadows.** In Rural Economy, the practice of overflowing them with water in order to the improvement of their crops. See Meadow, and Watering Land.

**Floating Vessels.** See Boat, Vessel, &c.

**Floating Upwards.** An old turnus in watering lands, where large dams for keeping up the water were had recourse to.

**Floby,** in Geography, a town of Sweden, in the province of Gotland; 51 miles N. E. of Gothenburg.

**Floc**, a town of Norway, in the diocese of Bromsn; 48 miles E. N. E. of Ramfjord.

**Flock,** a number of sheep kept together under a shepherd. Flocks are sometimes diffused into the pasture, and mountain kinds.

**Flock.** Setting of, the practice of calling and sorting the different kinds of sheep flock. It is usually had recourse to annually for lambs, where sheep husbandry is extensive.

**Flock Paper.** See Paper.
FLODAY, in Geography, one of the smaller Western islands of Scotland. N. lat. 57° 42'. W. long. 7° 13'.

FLODOARD, or FRODOARD, in Biography, an ecclesiastic and historian, was born at Epernay, in Champagne, in 894. He was educated at Rheims, and was appointed keeper of the archives in the cathedral, and afterwards canon. He had other preferments, and in 936 was deputed pope Leo VII. by whom he was kindly received. At length he became an abbot of a monastery in the diocese of Rheims. An attempt was made, in 951, to place him in the see of Noyon, but without success. In 963 he resigned his abbacy, and devoted himself to pious exercises. He is known as an author by "A Collection of Histories in Verse," containing the triumphs of Jesus Christ and his disciples, and the abridged history of all the popes down to Leo VII. and of the most illustrious fathers, &c. He wrote also "A History of the church of Rheims," and "A Chronicle composing the History of the Times from 910 to 966." Moret.

FLOETZ. See FLEETZ.

FLOGEL, CHARLES FREDERIC, in Biography, a learned Silesian author, was born at Jauer, in December 1729. In the year 1774 he was appointed professor of philosophy in the academy of Leignitz, and died in March 1788, at the age of 59. He left behind him many able works, among which was "A History of the Human Understanding," and "A History of the present state of Belles Lettres in Germany." He had read a great deal, and possessed an extensive knowledge of the history of literature, as well as of philosophy and other sciences. He was highly esteemed on account of his integrity and agreeable disposition, and his memory has been immortalized by his excellent works. Gen. Diog.

FLOGNY, in Geography, a town of France, in the department of the Yonne, and chief place of a canton, in the district of Tomerre; six miles S.S.W. of St. Florentin. The place contains 333, and the canton 8376 inhabitants, on a territory of 15.5 kilometres, in 15 communes.

FLOHA, a town of Germany, in the circle of Erzgebirg; six miles E.N.E. of Chemnitz.

FLOHAU, a town of Bohemia, in the circle of Saatz; eight miles S. of Saatz.

FLON, a river of France, which runs into the Arly, about a mile S.W. of Flumet.

FLONE, or FLOEN, a town of France, in the department of the Orthe; eight miles S.S.W. of Liege.

FLONHEIM, a town of France, in the department of the Rhine and Moselle; 12 miles E.S.E. of Cranznach.

FLOOD, a deluge or inundation of waters. See DILUGE.

Flood is also used in speaking of the tide. See TIDE.

When the water is at low, it is called flood; when rising, young, or old flood, when at highest, high flood; when beginning to fall, ebh-water.

Flood-mark, the mark which the sea makes on the shore, at flowing water, and the highest tide: it is also called high-water mark.

Flood Sand. See Sand.

Flood-gate, among Engineers, signified a gate or sluice which can be opened or shut at pleasure to retain or give passage to the water of a river liable to be swelled by floods. Flood-gates are necessary in many situations upon rivers where the water is retained for the service of mills, canals, navigations, docks, &c.; in those only a certain quantity of the stream can be employed, and the surplus in time of a flood must be suffered to escape by another passage. For instance, in the case of mills upon a large and rapid river, the stream of water is intercepted by a weir erected across it, and penned up the proper height to obtain a sufficient fall for the mill, which is situated by the side of the river, with a channel leading from above the weir, to convey the water to the mill, whilst another conducts it into the river below the weir. In ordinary times this arrangement is sufficient, for whenever the mill is not in action, the water which would otherwise pass through it, flows over the weir, and escapes into the river below. Now if the sudden falling of rain, or melting of snow, causes a flood in the river, it often happens that the length of the weir is insufficient to vent the torrent of water coming down; and without some contrivance answering the purpose of a flood gate, to give passage to the water, it becomes penned up many feet above the crown, or highest level of the weir, inundating the lands adjacent to the channel, above the weir. If the river is provided with a proper flood-gate, it acts, when open, in the same manner as removing a part of the weir, and allows the water to pass down quietly without rising much above the level which is common in ordinary times. From this, the use of a flood-gate will be comprehended; navigable rivers, which are penned up to form locks, require flood-gates, which are applied in the same manner as before-mentioned.

Flood-gates may be constructed in various forms; but it is indispensable that they should be capable of being opened or shut during the time when a pressure of water is acting against them. Small gates are always made to slide up and down in a groove in the manner of a sluice; some very considerable rivers are furnished with a number of such small draw-gates, which open a great extent of water, when drawn up. In the most extensive works it is necessary to make use of a different kind of gate, which can be opened or shut with greater ease than a number of shuttles, and which will lay open a more extensive passage; for in violent floods it is not uncommon for large trees, bushes, hay ricks, thatched roofs of low buildings, &c. to be brought away by the torrent; and if the flood-gates have any obstruction, these matters accumulate before the passage, and, when the flood lasts long, frequently choke up the gate, and the water overflows its banks. To avoid such accidents is the study of the engineer in constructing works of this kind; the late Mr. Smeaton designed several flood-gates, in which the pressure of the water was balanced, so that the gate at any time could be opened or shut with ease, even while the pressure of the water was acting against it on one side only. Figures 5 and 6 of Plate XV. Miscellanies, is a plan, and fig. 2, an elevation of this contrivance; A A B represents a channel made through the weir, or, if more convenient to suit the local circumstances, it is made by the side of the river, leading from above the weir to below it; this channel must be substantially built in masonry to resist the violent action of the water rushing through it when the gate is opened; in some convenient part of this passage a float beam C is placed across the bottom, and another, D, across the top, both firmly bedded in masonry; these support the gudgeons of the vertical axis E of the gate F F. When this gate is turned so as to present its edge to the current, the water has free passage by it, and on the other hand, when it is placed perpendicularly across the channel, the whole of the water is detained: the axis of the gate is placed so as to pass very nearly through the centre of pressure of the superfoies exposed to the action of the water; and as the pressure of the surfaces on each side of the
FLOOD-GATE.

axis so as to turn the gate in contrary directions, they balance each other, and the gate may be turned with scarcely any other friction than the friction of its gudgeons. The gate must necessarily be framed exceedingly strong to bear the great weight of the water acting against it, without yielding. G, H, are two ground-cills firmly bolted down upon the floor of the conduit and the piles which are beneath it; one of the arms of each of these cills support the gate when shut, and the other arms fill it when open, as is clearly shown by the figure; these must be very firmly fixed to avoid any danger of the gate removing them; one of the upright sides of the gate is supported by bolting into a recess made in the masonry of the conduit, and to keep the other side of the gate up to its sill, a lever, called a vallet, which is in the form of a triangle K, and moves upon a vertical axis placed in a recess in the masonry so as to be out of the way of the gate's motion, when placed in the position at fig. 5, leaving the gate at liberty to open; in the other position it acts as a lever to close the gate, being drawn tight by tackle, and afterwards hauled by a small line to the beam D. The gate is retained shut, but can be opened instantaneously by cutting the line; and as the gate is made rather larger on the side of the axis where the vallet is placed, that it may have a tendency to open when released by the preponderating preffure on one side. The gate in question is 15 feet in height, and the seam in breadth; when open, it allows two passages of 15 feet by 6 feet, 3 inches in width; the gate is to be shut by the application of a capstan and blocks, for which purpose eye-bolts are provided upon the proper points of the gates and beam D.

This gate, though very proper for large rivers where a watchman must be in constant attendance to open and shut it when necessary, is not so applicable as a common sluice to a small mill-dam, where, if a sudden flood occurs in the night, the miller must rise to open the gate; and, unless he constantly attends to shut it when the flood subsides, the mill-dam may be emptied and the water lost, which he would wish to reserve for the ensuing day. Great complaints are frequently made in the country of lands being overflowed in the night when the miller is not in the way to open his flood-gate; to remedy this a self-acting flood-gate would be desirable, and we beg leave to suggest the following. Let A A, fig. 7, be a gate similar to the one before mentioned, but of smaller dimensions, and placed upon a horizontal axis passing rather above the centre of preffure of the gate, so as to give it a tendency to shut close: a a is a lever fixed perpendicular to the gate, and connected by an iron rod with a cask b floating upon the surface of the water, when it rests to the line h, which is assumed as a level of the weir or mill-dam E E, in which the flood-gate is placed; by this arrangement it will be seen, that when the water rises above the dam, it floats the cask, opens the gate, and allowing the water to escape until its surface subsides at the proper level B D; the cask now acts by its weight, when unsupported by the water, to close the gate and prevent eakage; the gate should be fitted into a frame of timber H K, which is set in the masonry of the dam, the upper beam H of the frame being just level with the crown of the dam, so that the water runs over the top of the gate, at the same time that it passes through it; to prevent the current disturbing the cask it is connected by a small rod c at each end to the upper beam H of the frame, and joined in such a manner as to admit of motion in a vertical direction.

This flood-gate would be very useful in mill-dams of small dimension, which are therefore liable to be suddenly overflowed, for being self-acting, it requires no attendance, and from its simplicity is not very liable to be deranged, as before mentioned; for large rivers the principal object is, to open a great extent of water-way, which will admit the passage of large bodies brought down by the stream; Mr. Smeaton's gate above mentioned, as the axis is always in the channel, would be liable to be choked by trees, &c.; for this reason large sluices or shutters are very generally adopted, though the great power and expensive machinery required to raise such gates are an objection.

A flood-gate lately erected by Mr. Barlow is the most perfect in this respect of any that we have met with; it is raised (on the hydrostatic principle which he has so successfully applied to many other useful purposes) with such facility, that a passage 19 feet wide, and 10 feet high, can be opened by one man in 15 minutes, and this when the pressure of 10 feet of water is acting on one side only. Fig. 8, is an elevation of this gate, and fig. 9, an horizontal section; A, A, represent two large beams which are partly received into the masonry of the conduit; the lower ends are framed into a strong ground-cill B, and the upper ends connected by a framing; this forms a frame in which the gate rides and falls: it is guided in its motion by two iron plates a, a, bolted to the sides of the gate, forming a groove, as shown in the plan. Two square pieces of cast iron, denoted by b, b, and the dark shading in the plan, are bolted against the inner surfaces of the beams A, A, and received into the grooves of the gate, to confine it to move in a vertical direction; these pieces of iron have cylindrical chambers through them, as shown by the small white circles in the plan, to admit two polished iron cylinders d, d, attached to the end of the upper rail D D of the ornamental framing on the top of the gate; a close fitting is made round the cylinders d, d, by leathers confined with screws to prevent them from the top of the iron barrels, so that no fluid can pass out of the chambers in the barrels b, b, &c., in the plan, are two small pipes communicating with the chambers at the bottom of each barrel, and these pipes are united at f, proceeding to a pump, by which water is injected into the two chambers together; and as this fluid is incomprehensible, it follows that the cylinders d, d, must be forced out of their respective chambers raising up the gate. As the area of the pump is much less than that of the cylinders, and as it supplies two of them, it follows that the motion of the piston of the pump will inject such a quantity of water as, when distributed into the two chambers, produces a very small protrusion of the cylinders; it is on this principle of the differences of the two motions that the power is gained: the area of the pump in the present instance is 7.854 of a square inch, and the cylinders about 7.27 square inches, or nine times as much; by this means a power is gained in the two cylinders equal to 18 times the force exerted upon the piston of the pump, which being moved by a lever multiplying the power ten times, the power of a man applied to the pump is increased 80 times; so that a weight of 100 lbs. applied to the lever, will raise 18,000 lbs. on the piston rods.

The pump may be placed at any convenient distance from the gate, a small copper tube only half an inch diameter conducting the water into the cylinders in many situations this will be extremely convenient, as it obviates the necessity of an expensive scaffold or framing over the gate, which is indispensible in other situations to support the labourers and the machinery for drawing up the gate; the pump is explained by figs. 10, and 11, on a much larger scale than the other parts; b is a sifter containing water, and the pump-barrel fixed perpendicular in it; the plunger of polished iron is solid, a and leather packed round it is a winder handle.;
similar to the cylinder; it is confined to a rectilinear motion by sliding through a fixed socket at the upper end, and in the middle it has an opening to admit of a lever $m$, by which the pump is moved; it is connected with the rod by a coupling rod within the opening, which allows its deviations from the rectilinear motion; the pump has two valves, the one is situated in the bottom of the barrel at $n$, and the other in the pipe beneath $p$; its action is similar to the ordinary force pump, inhaling the water into the barrel when the piston is lifted up, and expelling it through the pipe $f$ when forced down; at $p$ is a head-yard and weight acting upon a small valve, which permits the escape of the water if the preasure should be so great as to endanger the rupture of the pipes when the gate is lifted up to the top of its frame; hence it is termed the safety-valve: it should never be loaded with a greater weight than will keep the valve shut against a sufficient preasure to elevate the gate. At $r$ is a cock which discharges the water from the pipe into the cistern, and permits the descent of the gate. To refit the great preasure of the water against the gate, it is strengthened by three trussed frames, represented by $l, k, l$, in the elevation, fig. 8, and in the plan; each truss is an iron rod attached to the gate at each end, and supported in the middle by a block, which answers the purpose of a king-post: the rods can be drawn tight by iron wedges passing through the gate; therefore it is evident that in this state the gate cannot yield to the preasure of the water, unless one rod is shortened and the other stretched; these frames render the gate so stiff that it does not show any signs of weakness when the preasure acts against it; the trusses are placed nearer together at the lower part of the gate, where the greatest strength is wanted.

The limits of our plate do not allow us to do justice to the precise and more minute parts of this admirable invention, but as these will again come under our notice in the article Press, Hydrostatic, we refer the more complete elucidation of the pump, mode of packing the cylinders, &c. to the plates belonging to that article. It should be noticed, that the gate represented in our figure is intended to admit the passage of loaded barges beneath it, and is therefore much higher in the frame $AA$ than would be necessary for flood-gates in all situations; it would form a most excellent sluice for clearing out harbours from mud, as the torrent of water it lets out would be much more effective than three or four of the small sluices at present in use.

Flood-bridge signifies a low bridge constructed for the towing-path of a canal, over a weir or overflow for discharging superfluous water. See Canal.

Flood-bolt signifies a tide lock, or that opening into the sea, or a tidal river.

FLOODING, Proflumций Sanguinis, in Surgery, may be applied to any unnatural or profuse discharge of blood from the uterus. The most common of these is profuse menstruation, or an increased discharge of the menstrual flux, (see Menstrues), or those discharges of blood from the uterus, which precede, and not unfrequently occasion abortion. (See Abortion.) The hemorrhage also, which follows a partial or total separation of the placenta from the uterus, if profuse, whether it takes place before or after the birth of the child, is called a flooding. Flooding is sometimes, though rarely, occasioned by falls or blows, and sometimes by ulcers, polypi, or other diseases of the uterus. In all cases of flooding the patient should be confined, as much as conveniently may be, to a recumbent posture, the body should be kept cool and open, and a few spoonfuls of the infusion of red roses should be given two or three times in the day, adding to the portion given at night from five to ten drops of the tincture of opium.

Flooding Land, in Agriculture, is the practice of flooding, or covering grass lands with the water of rivers, &c. at particular seasons. In this mode the water is suffered to remain upon the ground for a considerable length of time, which is quite different to that of irrigation, in which it constantly runs off as fast as it is brought upon the land. This method has probably been introduced in conformance of observing the fertilizing effects that take place after pasture lands have been overflowed with water for some time in the winter season. This plan of watering is of vast importance in mossy meadows, even where the water is perfectly clear and free from any material that is capable of being deposited.

In preparing lands for being flooded, there are two circumstances that must be particularly regarded, namely, first, to lay them as level as possible, either by dividing them into different levels, or any other means; and secondly, to convey the water upon them in the most safe and convenient manner for the cultivation of the surrounding grounds. In sandy or mossy lands, this is often not accomplished without considerable difficulty. See Watering Land.

FLOOD, in Building, the under-side of a room, or that part on which we walk, or perform different operations, such as threshing, dressing, and measuring grain, &c.

Floors are of divers sorts; some of earth, some of brick, others of stone, others of boards, &c.

Carpenters, by the word floor, understand as well the frame-work of timber, as the boarding over it. The supporting timbers are called naked flooring, which fife. The boarding is also of different kinds, as batten floors, common boarded floors, dowelled floors, and straight-jointed floors.

For brick and stone-floor, see Pavement.

For boarded floors, it is observable, that the carpenters never floor their rooms with boards, till the ceiling is set up, and also inclining with walls, lest the weather should injure the flooring. Yet they generally rough-plane their boards for the flooring, before they begin any thing else about the building, that they may set them to dry and season, which is done in the most careful manner. This operation should be performed for at least one year, so that the natural sap may be thoroughly expelled. The best wood for flooring is the fine yellow deal well seasoned, which, when well laid, will keep its colour for a long while; whereas the white fort becomes black by often washing, and looks very bad. The battens used for flooring are of three kinds: the bell is that free of knots, shakes, tap, and crofs grained fibres, well matched. The second kind is that in which only small, but found knots are permitted, and free of shakes and tap. The third and common kind is that which remains after taking away the bell and second bell.

With respect to the joints of flooring boards, they are either quite square, or plowed and tongued, or rebated, or dowelled. In fixing them, they are either nailed upon one or both edges. They are always necessarily nailed upon both edges, when square jointed, without dowels.

When
When they are dowelled, they may be nailed on one or both edges, though one edge only is necessary; and in the best dowelled work there are no brads or nails seen whatever, the outer edge being fastened by driving the nail obliquely through the wood, without piercing the upper surface; so that the floor, when planed off, appears without blemish.

In laying boarded floors, the boards are sometimes laid one after the other; or otherwise one is laid flat down, then the fourth, leaving an interval somewhat less than the breadth of the second and third together. The intermediate boards are next laid in their places, with an edge of the one upon the edge of the first board, and an edge of the third upon the inner edge of the fourth, and the two middle edges together, which will form a ridge; to which level, two or more workmen jump upon it, till they have made the under surface coincident with the joists, then they are nailed down in their places. The operation is called folding floors, and the boards are laid to be folded. This mode is only taken when the boards are not sufficiently seasoned, or suspected to be so. In order to make close work, it is obvious that the two edges forming the joint of the second and third boards must make angles, with the faces, together less than two right angles, or each one of each board less than a right angle. The seventh board is fixed as the fourth, and the fifth and sixth inserted as the second and third, and so on till completed. In this kind of flooring the headings are generally square or splayed.

When floors are dowelled, the regulating line for the centre of the dowels should be drawn from the lower side, which as has been observed, ought to be straightened on purpose. The distances to which the dowels are set are from six to eight inches, generally one over each joint, and one over each inter-joint.

When it is necessary to have a heading joint in the length of the floor, it should always be upon a joint; one heading joint should never meet another. In dowelled floors the heading points are always plowed and tongued.

In common floors the boards are added on the lower side, in order to bring them to a thickness between rebated edges. In doing this, great care should be taken so as not to make them too thin, which is frequently the case; they must then be raised with chips, which is a very unsuitable residence to a pressure upon the floor. The nature of measuring floors is by squares of ten feet each side, so that taking the length and breadth, and multiplying them together, and cutting off two decimals, the content of a floor in squares will be given. Thus 18 by 16 gives 288 of 2 squares and 38 decimal parts.

Floors, Earthen, are commonly made of loam, and sometimes, especially to make mellow on, of lime, and brock- fand, and gun-duff, or awl-duff from the forge; the whole being well wrought up and blended together with blood. The fillings of lime-duff have also been found highly useful when formed into floors in this way.

On blood and fine clay, tempered together, Sir Hugh Plat says, make the finest floor in the world. The principal object in constructing floors of this nature is that of blending and incorporating the different substances in a full and perfect manner for some time before they are laid; and when that is done they should be repeatedly beaten down and rendered perfectly smooth and even.

The manner of making earthen floors for plain country habitations is as follows. Take two-thirds of lime, and one of coal ashes well fitted, with a small quantity of loam clay; mix the whole together, and temper it well with water, making it up into a heap; let it lie a week or ten days, and then temper it over again. After this, heap it up for three or four days, and repeat the tempering very high, till it become smooth, yielding, tough, and gliny. The ground being then levelled, lay the floor therewith about 2½ or 3 inches thick, making it smooth with a trowel: the hotter the season is the better; and when it is thoroughly dried, it will make the best floor for houses, especially malt-houses.

If any one would have their floors look better, let them take lime made of rag-flones, well tempered with whites of eggs, covering the floor about half an inch thick with it, before the under flooring is too dry. If this be well done, and thoroughly dried, it will look, when rubbed with a little oil, as transparent as metal or glass. In elegant houses, floors of this nature are made of stucco or of plaster of Paris beaten and sifted, and mixed with other ingredients. Well wrought coarse plaster likewise makes excellent fine upper-floors, for cottages, out-houses, &c. when nately spread out upon good strong laths or reed.

See Plaster-floor.

Floor of a ship, strictly taken, is only so much of her bottom which lies on, when aground.

Such ships as have long, and withal broad floors, lie on the ground with most security, and are not apt to feel, or tilt on one side; whereas others, which are narrow in the floor, or, in the phrase, 'cranked by the ground,' cannot be grounded without danger of being over-turned.

Floor-timbers, in a Ship, are those parts of a ship's timbers which are placed immediately across the keel, and upon which the bottom of the ship is framed; to these the upper parts of the timbers are united, being only a continuation of floor-timbers upwards.

Floor, in Mining, or sole, till, or pound stone, signifies the bottom of the work in a mine, or in coal-mining, the stratum immediately under the coal-heap; which, if soft, the upper part of it for six or eight inches in height generally is “holed in,” as the colliers call it, that is, the same is picked out in order to undermine or loosen the coal, but if the floor be hard, as clunch is, the holding or picking is then made in the bottom or some inferior bed of the coal itself, in order to under-go or give room for wedging down the blocks or webs of coal. In examining and comparing the fillings of the numerous coal-pits in Derbyshire and Nottinghamshire, Mr. Fairley lately discovered, what seems likely to prove a general and important geological fact, viz. that the floor of every coal is a freemake, more or less thick, more or less perfect in its innumerable property, and more or less indurated; sometimes being in a soft or ductile state, when it is called floor, spar, fire-clay, pipe-clay, (if white,) potter's-clay, brick-clay, &c. at others, in an indurated or almost flinty state, but which it quickly loses and falls to clay, on exposure to the atmosphere, in which case it is called clunch, which is the same that the floor of coal most generally bears. This new fact appears to throw a great degree of light on the new theory of the formation of coal, near the end of our article Colliery, by rendering it probable that the growth of the subaqueous beds of vegetables there spoken of were produced by this peculiar subsidence as their fall or pelabum.

Floor, a superficial measure of 400 square feet or docking, is a square whose side is 20 feet, and occurs in the facing of the sewer-hanks, and in other works on the sides of Cambridgehire and Norfolk, &c.

Floor, a solid measure of 400 cubic feet, or a superficial floor, one foot thick, used in measuring the pitch dug to obtain earth for forming the banks against the tide or rivers in the lines of the eastern coal. (Smeaton's Reports, vol. i. p. 330.)
Floquet was born at Aix in Provence, 1750; and was the first musical author that was called for by the audience to be crowned, and to receive on the stage their approbation in person. A mass of his composition was performed in the cathedral at Aix before he was eleven years old. In 1774 he set another opera, which not having the fame success as the first, he determined to travel into Italy to receive instructions from the most able masters of that country, and obtained them for some time at Naples, under the celebrated Saba, the worthy successor of Durante, and master of the Conservatorio de la Piet&#232;, which had furnished the musical art, and all Europe, with so many great masters. On quitting Naples he went to Bologna, and had the further advantage of receiving instructions from the profound father Martini, the greatest theorist that Italy has ever produced. A Te Deum, a de Cori, of his composition, was performed at Naples with great success; and he was admitted of the Philharmonic Society at Bologna; it is however known, that to be received into that academy, it is necessary for a candidate to give proofs of his abilities three several nights; but M. Floquet performed all the several exercises the same evening, and composed in two hours and a half, on canto fermo, a f gue in five parts, and the verfe cruxiex of the credo; so that he was immediately received unanimously. On his return to France, he composed the opera of Helle, performed in 1778, but which had no success; but not that the music manifested the progress which the young Floquet had made in his art; but from the badness of the works enfla a total want of interest in the subject. This composer was ill advised by friends to attempt giving meaning to a drama so detestably dull. We advise him to be more cautious in future in the choice of his works, and will venture to answer for his successes. Laborde, 1780.

Flora, in Mythology. See Florales Ludii.

Flora, in Botany, is very generally applied as a title to books whose professed object is to enumerate, define, or fully describe the wild plants of any particular country or district. Publications of this kind, with which the botanical library at the present day abounds, are not less various in their scope than in their merits. Some are mere catalogues, disposed either in alphabetical or systematic order, while others are compendious histories of the plants they enumerate, respecting not only their botanical characters and distinctions, but also their scientific history, and even that of animals connected with them, as well as their actual or probable uses and qualities. Of this last kind, the Flora Lap-
The materials, which illustrate the may be praiseful, them is unequal, some from perpetual its lead is p.

tions is rare

Synopis, out a nononymy in knowledge. generic every propensity love very few

Willdenow's T Flora accurate answer has Dillenius, from Hudfob in our Flora, in the former our plants, or carcan, and under Catalogues of plants, or Catalogues of Gardens, have generally implicitly adopted his definitions, at least his generic ones, fearfully presuming they could he incorrect. Some mistakes having thence arisen, which the introduction of the Linnean herbarium into this country first led us to correct, the author of the Flora Britannica judged it necessary to bring every definition to the letter of examination, such being one of the few means left him, after the labours of so many able preceding botanists, to render his work importantly useful. With regard to species indeed, Mr. Hudson, when he found the Linnean specific characters not accord with his own plants, very properly, and often advantageously, reform them, but he by no means detected every error of this kind. On the other hand, too great a propensity to correct and reform should not lead us, in cases where one idea or expression is as good as another, and certainly preferable, from being already adopted, to make alterations in the face of shewing our zeal; for it is very probable we may alter for the worse, though our self-love will make us the last to perceive it.

T is leads me to consider the subject of systems, or methodical arrangement, which the writer of a Flora should well confider before he aims at distinction by any reformation in that department. He would be wise, in the first place, to adopt the most popular and easy system, and hence molt persons have followed that of Linneus. Some excellent and original writers in this line have chosen methods of their own, which, from some of their transgressions or imperfections, can not be considered much better than those they deceived; as Villars in his Flora of Dauphiny, Allioni in his Flora Pedemontana, Gerard in his Flora Galloprovincialis, and Seppel in the first edition of his Flora Carnitica, though in the second he widely adopted the Linnean arrangement. Whether the systems of these writers possess any merit or not, nobody thinks it worth while to examine. The reader results at them as a perpetual inconvenience. A Flora is too limited a theatre for the display of a new botanic system, and we expect a different kind of information from it, which it is the writer's duty to give us in the safest, most intelligible form, without troubling us to learn a new language on purpose. In early times indeed, before any system was regularly established, it became leading botanists, like Ray, to attempt to teach the world some scientific principles; but not the great man concurred, in his first catalogue of British plants, to give an alphabetical arrangement, as did a scarcely less excellent writer in this department. Magnesium in his Botanicon Manufacrenis. An alphabetical arrangement is, at any rate, unexceptionable, not proving a hindrance, if it affords no scientific aid.

Some Floras, besides scientific definitions, descriptions, or synonyms, are illustrated with figures, a very useful though sometimes expensive addition; as the Flora Lindencitrn above-mentioned, the English Botany, Jacquin's splendid Flora Austriaca, to which the Plante Rariores Hungarice by Waldstein and Kitabeh are a sort of sequel, as is also the still more splendid Flora Greaca, published according to the will of the late professor, John Sibthorpe of Oxford. The Flora Danica consists of little else than plates, which may be had either coloured or plain. The Flora Rustica of Pallas, intended, by its original patrons, to crown every work of the kind, and to be belted gratuitously on every person worthy to possess it throughout Europe, very soon proved abortive, and became a job in the hands of those entrusted with its publication; nor is the execution of the plates to be commended, they having often been coloured from dried specimens. Of extra-European Floras illustrated with plates, though uncoloured, the Hortus Malabaricus of Rheede, Herbarium Amblyopus of Rumphius, and the recent Flora Peruiciana by Ruiz and Pavon, are the most magnificent. The performances of the Burmanns in this line are but indifferent, though much quoted by Linnaeus. The Flora Japonica of the celebrated Thunberg is valuable for the novelty of its materials, but nothing can be more rude than his figures subsequently published to illustrate it. In point of novelty nothing can exceed the Nota Holandica Plantarum Specim. by Lobbardus, full of useful, though not elegant plates, nor is it likely a most inferior to any. The elegant Flora Atlantica of his countryman Desfontaines, with more beautiful plates, though less singularity of materials, deserves no less commendation.

We cannot attempt in the compus of this article to mention, still less to do justice to the merits of, every Flora that has appeared. We refer the reader to the article Figures of Plants for some remarks connected with the subject. More particular notice of several of the publications alluded to, as well as an account of many similar ones.
from another passage in Varro it appears, that there were
priests of Flora with sacrifices, &c. as early as the times of
Romulus and Numa. To which we may add that Pliny
(1. xxxiv. c. 4.) speaks of a statue of this goddess by the
hand of Praxiteles, which proves that her worship was
famous in Greece, whence it was propagated to Italy,
long before Romulus, who adopted it, when he entered into
an allocution with Tatius and the Sabines. Moreover, we
learn from Julius, that the Phoceans, who built Marselles,
worshipped the same goddess.

FLORAL GAMES. There is also a kind of floral
games observed at this day in France; first instituted in
1324.

The design and establishment were owing to seven persons
of condition, lovers of poetry, who, about All-saints-day,
in 1323, sent a circular letter to all the Provençal poets,
called Troubadours, to meet at Thouolute on May-day
following, there to rehearse their poems; promising a prize
of a violet of gold to the person whose piece should be
judged the best.

The capitouls found the design so good, that it was after-
wards resolved at a council of the city, to continue it at
the city-charges; and this was done in a manner that did honour
to the place.

In 1325, a chancellor and secretary of the new academy
were chosen; and the seven initiators took the quality of
maintainers thereof. Two other prizes were afterwards
added to the violet; viz. an eglantine for the second prize,
and a panzy for the third. It was also decreed, that the
person who bore away the first prize, might demand to be
made bachelor; and that whoever bore away all three,
should be created doctor in the gay science, that is, in
poetry.

There is a registre of these games kept at Thouolute,
which gives this account of their origin; though others
represent the matter differently. It was an ancient custom
they say, for the poets of Provence to meet yearly at Thou-
loule, to confer together, rehearse their verses, and receive
a prize allotted to the best performance. This held till
about the year 1540, when a lady of quality left the best
part of her fortune to endow the custom, and bear the
expenze of prizes; the number of which she increased,
ordering an eglantine, a panzy, a violet, and a pink: the
three first, a cubit high; and worth fifteen piliotes a piece.

The ceremony began on May-day, with a solemn mass,
music, &c. The corporation attended; and poems were
rehearsed every day: the third day a magnificent treat was
given by the magistracy, &c. and that day the prizes were
adjudged. The three prizes were the reward of three dif-
ferent kinds of compositions; viz. a poem, an elegy, and
an ode.

FLORALIA, in Antiquity, a general name for the
feals, games, and other ceremonies, held in honour of the
goddes Flora.

FLORENCE, in Geography, the capital city of Etrus-
cia, (which see), and regarded as the Athens of modern
Italy, is situated on the river Arno, at the foot of the Apen-
nines. The Arno divides it into two unequal parts, over
which there are no fewer than four bridges in sight of each
other. That called the Ponta della Trinita, is uncommonly
elegant, being built entirely of white marble, and orna-
mented with four beautiful statues, representing the four
seasons. The quays, the buildings on each side, and the
bridges, render that part of Florence, through which the
river runs, by far the finest. Florence was first founded
by the soldiers of Sylla, embellished and enlarged by the
triunvirs
triumvir, destroyed by Tullia, and rebuilt by Charle-
magne. The environs of this city are beautiful, rich, and
populous; containing, as it has been said, 65,000 villas or
country-houses. The habitations of the peasants likewise
seem to be peculiarly neat and commodious; the country
all round is divided into small farms, with a neat farm
house on each. The circumference of the city is about
two leagues; the fortifications consist only of a wall and
ditch, with two or three forts which defend it, and
command a part of the town. This city vies, as to beauty,
with Rome itself. The buildings are magnificent, most of
the streets clean, paved with square stones, so as to have
the appearance of a rock made level; they are generally
winding, and many of them too narrow for carriages to pass
each other. They reckon 17 public places, or squares;
seven fountains constantly playing, six pillars or columns,
two pyramids, 160 beautiful statues, placed either in the
public squares, or in the streets, or in the front of some
palaces; one metropolitan church, 12 collegiate, and 44
parochial; 35 convents for men, 60 for women, 37 hos-
pitals, and about 9,000 hospices. The number of inhabi-
tants is estimated at eighty thousand. Florence has been
equally distinguished by a spirit of commerce, and for
the fine arts; some of the Florentine merchants were
formerly men of great wealth, and lived in a most
magnificent manner. One of them, about the middle of
the 15th century, built that noble fabric, which, from
the name of its founder, is still called the Palazzo Pitti. The
building was raised by the expense; but the palace con-
tinued to be the residence of the sovereigns. The gardens
belonging to this palace are on the declivity of an eminence.
On the summits there is a kind of fort, called Belvedere,
from which, as well as from some of the higher walks, you
have a complete view of the city, and the beautiful vale of
Arno, in the middle of which it stands. The prospect is
bouded on every side by an amphitheatre of fertile hills,
adorned with country-houses and gardens. In this palace
is a library containing about 35,000 volumes, with a great
number of pictures by Raphael, Rubens, Titian, Andrea-
del-Sarto, Titoreto, Guercino, &c. The Palazzo Vecchio,
or old palace, contains a room 172 feet long, and 72 wide,
for public entertainments, in which the most celebrated
actions of the republic are painted by Vafarini in fresco; and
in the corners are four capital historical pictures by Cigoli,
Ligazzi and Passignani. These two palaces are connected
by a gallery, which presents an inexhaustible fund of im-
proving amusement in sculpture and painting, to which the
public have daily access. In this place was instituted a ce-
nobled society for the improvement of the Italian language,
called "Academia della Crusca," (see Academy;) and
yet the Florentines are noted for bad pronunciation of their
language, accompanied with a guttural accent, though they
write it with great elegance; whence has arisen the proverb,
"Lingua Toscania, in bocca Romana." In Florence there
are several theatres, all open during the carnival, which be-
gins on the day after Christmas day, and lasts till Ash-
Wednesday. At other times one of them only is open, except
in Lent and Advent. The two principal are the Pergola,
finished in 1755, and the new Opera-houses, first opened in
the year 1779. The manufactures of Florence are chiefly
silks and satins of excellent fabric. The woollen manu-
facture, to which it was indebted for its splendour and
opulence, has so much declined as scarcely to suffice for the
supply of the common people. At Doccia, three leagues
from the city, is a manufacture of porcelain. The Floren-
tines have been long famous for their Mosaic work, which
is formed of the inner marbles, agates, jaspers, and other
hard stones, some thin, and inlaid in form of birds, flowers,
&c. The wine of the adjacent country is excellent, and
furnishes a considerable trade in Italy and other countries.
Society is maintained with ease and freedom in this city,
besides their conversation, many of the nobility meet every
day at a house called the "Cafino," and these meetings bear
some resemblance to the clubs of London. They also pay and
receive visits at the opera, where the dancing engages a much
greater degree of attention than the music. The country sur-
rounding Florence, or the Florentin, is one of the most
fertile countries in Italy. Florence is situated 125 miles
N.N.W. of Rome. N. lat. 43° 50'. E. long. 11° 14'.

Florence-Court, a small port-town of Ireland, in the
county of Fermanagh, adjoining which is the Earl of Enniff-
kinen has a beautiful seat, with very extensive plantations.
It is in the western part of the country, about 74 miles
N.W. from Dunkirk, and 6 from Enniskillen.

Florence, a town of France, in the department of the
Somme and Meuse, and chief place of a canton, in the
district of Dinant; 16 miles S.W. of Namur. The place
contains 14,101, and the canton 6,711 inhabitants, in 22
communes, on a territory of 240 kilometres.

Florence, a town of France, in the department of the
Hérault, and chief place of a canton, in the district
of Béziers; 10 miles S. of Béziers. The place contains
1740, and the canton 4,990 inhabitants, in 4 communes,
on a territory of 1751 kilometres.

Florence, a town of France, in the department of
Golo, in the island of Corfu, and in the district of
Corfica; containing in its cantons 1,487 inhabitants.—Also,
a town of France, in the department of the Maine and
Loire, and chief place of a canton, in the district of Beauré;
19 miles W.S.W. of Angers. The place contains 1,125;
and the canton 10,101 inhabitants, on a territorial extent
of 190 kilometres, in 10 communes.—Also, a town of France,
in the department of the Cher, seated on the Cher; 7 miles
S.W. of Bourges.

Florentin, a town of France, in the department of the
Yonne, and principal place of a canton, in the district
of Auxerre; 13 miles N.N.E. of Auxerre. The place contains
3,210, and the canton 9,740 inhabitants, on a territory
of 1624 kilometres, in 12 communes.

Florentine. See Florence and Mosaic Work.

Florentine, in the Manufactory of Cloth, is the term
used for a species of satin or tweedilk, which has evi-
dently been either originally or extensively practiced at
Florence. As from its very nature it must always prove an
expensive article of dress, accessible only to the rich parts
of any country or community, it must be deemed of small,
or at least secondary importance in one, where the extension
and success of every article of manufacture depend almost
exclusively on the lowness of the price at which it can be
furnished to the consumer, after frequently paying the pro-
fits of many intermediate agents. It may, however, be
proper to preserve and record the manner of executing it;
although it is by no means probable that it is likely to be
introduced as a matter of traffic in Britain. This descrip-
tion of satin or tweedilk is generally very fine and close
in the fabric. It is woven with sixteen leaves of heddles,
and two or three reeds placed parallel to, and at a small
distance from, each other. It is the most comprehensive
kind of what is called Broken or alternate tweeding. Its
only variety from other tweeds consists in the superior rich-
ness of appearance, which this extensive apparatus gives it.
Below is a plan of the draught and coiling, by which it is
effected.
From the cloisons of the fabric, it would prove very inconvenient, if not absolutely impracticable, to weave goods of this kind in a single reed: for so many threads must be crowded together in every interval, that, in rigging and sinking, they must impede each other so much, that the shuttle could seldom, if ever, find a clear passage between the raised and sunk warp. To obviate this inconvenience, the additional reeds are used; the threads which pass through the same interval in the last reed being divided in the second, and again in the third, by which means both the friction and tendency to obstruction are so much lessened as to render the operation comparatively easy; although in fabrics of cloths, it will require the most close and unremitting attention in the weaver to keep his warp in proper order, and his shed or passage for the shuttle thoroughly open. The mode of placing the reeds seems very similar in plan and effect to the mode adopted by practical geometerians, of dividing small distances with accuracy by means of the diagonal scale.

FLORENTINE, in Geography, a town of France, in the department of Fercé, and chief place of a canton, in the district of Neufchâtel. The place contains 1,268, and the canton 6,072 inhabitants, in 15 communes, on a territory of 287.25 square kilometres.

FLORENCE, in Botany, a town of European Turkey, in Moldavia; 60 miles E. of Stephanowze.

FLOREAT, in Botany, a flower, is applied to the individuals which all together compose either a compound or aggregate flower, but more especially the former. Flowers of compound flowers are invariably monopetalous and superior. They are of two kinds, ligulate or strap-shaped, as in the radial margin of a daisy, sunflower or marigold; or tubular, as in the disk, or central part, of the same flowers. Ligulate florets are toothed at their extremity, more or less equally, the number of their teeth being usually five, more rarely but three. Tubular florets have a regular border, cut into equal spreading segments, almost universally five in number; in Eclipta, however, they are but four, and in one species of Scutellaria, the fenestralis, no more than three. The filaments, whose filaments are inserted into the tube, always agree in number with the segments of the flower. The generality of florets, whether ligulate or tubular, have a perfect or fertile pistil as well as stamens. In the diminutive marginal florets of the Gnaphalium and Artemisia, whose corolla is ligulate indeed, but so rolled up, or coiled by its edges, as to form a capillary tube, the pistil is very perfect, though the stamens are wanting.

Some compound flowers consist entirely of ligulate florets, which in that case are all perfect, furnished with stamens and
and pilli, and fertile. These are the *semisterculis* of Tournefort, and make the first section in Linnaeus’s *Syngenesia Polygamiarum aquilina*, as the Dandechon, Souththiile, Hawkweed, &c. Such flowers are generally yellow, sometimes blue, very rarely reddish. They expand in a morning, and close towards noon, or in cloudy weather. Other flowers, when young, are found of tubular florists only, as the Thistle, and *Bidens*. The greater number consist partly of tubular, and partly of ligulate ones, and the latter are always marginal, or external with respect to the former. Very frequently the marginal ligulate florists, though furnished with an apparent pillar, are abortive, and sometimes they have merely so much of the rudiment of a germin, as is necessary to form a basis for the petal. It appears that some of the tubular florists, from circumstances are capable of becoming ligulate, which is analogous to the doubling, or change of the organs of impregnation into petals, in simple flowers. Witness the Chamomile. Another change happens in the *Chrysanthenum*, and *Tagetes* or African Marigold, whose ligulate florists become tubular, or, as the gardeners term it, quilled. Such quilled florists are abortive of course, being owing to preternatural luxuriance. Compound flowers entirely consisted of tubular florists, all prolife, occasionally assume matter or abortive ones in their margin, which are likewise tubular, but greatly dilated. This happens in some species of *Cardius* and *Serratula*, and according to the Linnaean system they thus become *Centesura*, for no system can provide against such anomalies. In like manner some species of *Bidens* acquire a ligulate radius, and constitute the genus *Cereoffs*. Hence have arisen many spurious genera of botanical authors. In the Order *Polygamiarum necessaria* of Linnaeus, the florists of the dish have flaments only, or at least a mere rudiment of a germin; those of the radius being furnished with perfect pillars without flaments. They thus are both necessary to the perfection of the seeds. Linnaeus, considering umbelliferous flowers as aggregate ones, uses the term *fleroderus* for what we prefix to *callflo*, or a simple flower. S.

**FLORID STYLE.** is that enriched and heightened with figures and flowers of rhetoric, in an exegetic degree; or, when the ornaments, applied to flyle, are too rich and gaudy in proportion to the subject; when they return upon us too fast, and strike us either with a dazzling light, or a false brilliancy. In a young composer this is very pardonable; perhaps, indeed, it is a promising symptom in young people, that their style should incline to the florid and luxuriant. *Volubile effetus in adolescentes frequentandus, etca.* says Quincentian; *i.e.* In youth, I wish to see luxuriance of fancy appear. Much of it will be diminished by years; much will be corrected by ripening judgment; some of it, by the mere practice of composition, will be worn away. Let there be only sufficient matter at first, that can bear some pruning and lopping off. At this time of life, let genius be bold and inventive, and pride itself in its efforts, though these should not, as yet, be correct. Luxuriance can be easily cured; but for barrenness there is no remedy.” But a similar apology cannot be pleaded for perfons of mature years, which is admitted for young composers in their first essays. Judgment, as it ripens, should chasten imagination, and reject, as juvenile, all such ornaments as are redundant, unfit for the subject, or not conducive to illustrate it. Nothing can be more contemptible than that tinsel splendour of language, which some writers perpetually affect. This cannot always be ascribed to the real overloading of a rich imagination. If this were the case, it might be in some measure excused; and we might accept amusement where we sought instruction.

But with these facile writers, it is a luxuriancy of words, not of fancy. We see a laboured attempt to rise to a splendour of composition, of which they have formed to themselves some loose idea: but having no strength of genius for attaining it, they endeavour to supply the defect by poetical words, by cold exclamation, by commonplace figures, and every thing that has the appearance of pomp and magnificence. It has eluded these writers, that artificery in ornament is one great secret for rendering it pleasing; and that, without a foundation of good sense and solid thought, the most florid style is but a childish imposition upon the public. The public, however, are too apt to be imposed on; at last, the mob of readers, who are very ready to be caught at first with whatever is dazzling and gaudy. Dr. Blair, after paying a deferred tribute of respect to the good qualities of Mr. Hervey, cloths to observing that the perpetual glitter of expression, the sickly imagery, and strained description, which abound in his writings, are ornaments of a base kind. “I would, therefore, advise fudents of oratory to imitate Mr. Hervey’s poesy rather than his style; and in all compositions of a serious kind to turn their attention, as Mr. Pope says, from flimsy to solid, from fancy to the heart.” Blair’s Lectures, left. 18.

Longinus uses the terms florid and affected style indifferently, and lays them down as quite contrary to the true sublime.

**FLORIDA**, in Geography, a country of North America, bounded on the North by Georgia, on the E. by the Atlantic, on the S. by the gulf of Mexico, and on the W. by the Mississippi. This country is said to have been discovered by Sebastian Cabot in the year 1496, 18 years before it was known to the Spaniards; but received its name from John Ponce, who, failing from Porto Rico in 1513, landed here in April, when the country appeared in full verdure and bloom. Florida has frequently changed its masters; in 1564 the French took possession of some part of it, but they were driven from their settlements in the following year by the Spaniards, who then began to form establishments for themselves. In the year 1763 Florida was ceded to Great Britain in exchange for the Havana, which had been taken from the Spaniards. Whilst the English were in possession of it they divided it into two governments, viz. East and West Florida, separated by the Appalachicola. During the American war, both the Floridas were reduced by the Spaniards, and guaranteed to the crown of Spain by the definitive treaty of 1783.

Although this country was of little utility to Great Britain, the possession of it would be valuable to the United States, more especially since they have obtained the province of Louisiana. On the part of Spain, the cession of it would be politic, as it might force to divert the attention of the States from the riches of the west, and as a means of unity. Well Florida in particular, is chiefly useful as presenting avenues of commerce. East Florida extends much farther south than West Florida; the gulf of Mexico washing the western coast from N. lat. 5 to 30°, whereas the most southern part of West Florida is in N. lat. 29° 30′. The form of East Florida is triangular, the base towards the N. being 162 miles in breadth from E. to W. near the southern extremity about 40, and about 350 from N. to S. Along the coasts the bays of small islands are numerous. The soil near the sea-coast is sandy and barren; but further inland it improves. The productions are chiefly rice and indigo. West Florida is about 320 miles from E. to W., and from 40 to 80 in width from N. to S.; on the W. it is bounded by the river Mississippi.
The country is pleasant, and the soil is exceedingly fertile, so that the inhabitants have sometimes two or three harvests of maize in the same year. Towards the coast it is flat, but rises gradually into hills, which are covered with verdure and large trees, such as white and red oak, crab oak, mulberry, magnolia, pine, hickory, cypress, red and white cedar, &c. Orange and lemon trees grow here without cultivation, and produce better fruit than in Spain and Portugal. They have also vines, which yield grapes equal in size and flavour to the best muscadine; and they have abundance of other fruits of excellent flavour. The cabbage tree furnishes a food that is pleasant and wholesome. Cotton is produced in great plenty; as well as flax and hemp. Among the richer productions of the country we may reckon conchineal and indigo. The coasts furnish oysters and amber. The rivers abound in fish, but are meekled by alligators. In the western parts are numerous herds of cattle and flocks of sheep: hogs also, whose flesh acquires an excellent flavour from the acorns and chestnuts on which they feed, are numerous. In the forests and deserts are found several species of wild beasts, and also a variety of birds. In summer the air is very hot, but in several places it is pure and wholesome; the winter is commonly temperate, though the cold sometimes destroys the orange trees. The rivers are covered with ice. The principal town in W. Florida is Pensacola, and in E. Florida St. Augustine. The population of W. Florida is very considerable; Mobile and Pensacola together not containing above 1500 souls. The interior of E. Florida is little known, and only inhabited by a few Creeks or Seminoles. The town of St. Augustine in E. Florida is less healthy than some have supposed it to be; but the climate, and also the general appearance of the country, would be much improved, if industry and labour were bellowed upon it, and the inland marshes were properly drained.

Florida, a port-town of America, in Orange county, New York; 50 miles N.W. of New York city. Alto, a town of Montgomery county, New York, on the S. side of Mohawk river, at the mouth of Schoharie creek. It has 1218 inhabitants.

Florida, Læ, one of the Solomon islands, in the Pacific ocean, discovered by Mendana, in 1557. S. lat. 9° 30'.

Florida, Cape, the most southerly point of land of Joel Florida. X. lat. 25° 24'. W. long. 81° 50'.

Florida, Gulf of, or Bahama straits, the narrow channel that separates the peninsula of Florida from the Bahama islands.

Florida Stream, or Gulf stream, a channel which separates the island of Cuba from the coast of Florida, between the gulf of Florida and the gulf of Mexico.

Florilegium, Florilegis, a name the Latins have given to what the Greeks called anthologia, anthology; viz. a collection of choice pieces, containing the most and brightest thoughts in their kind.

Florilegis, is also particularly used as a kind of breviary, in the Eastern church, compiled by Arcadius, for the convenience of the Greek priests and monks, who cannot carry with them, in their travels and pilgrimages, all the volumes wherein their office is dispersed.

The Florilegium contains the general rubries, psalter, can- tileus, the horologium, and the office of the ferie, &c.

Florin, sometimes used for a coin, or real money; and sometimes for any imaginary money, or money of account.

Florin, as a coin, is of different values, according to the different metals, and different countries where it is struck. Pieces under this denomination were anciently very frequent in commerce; at present they are less common, though there were abundance of them struck in Holland, of English silver, during the war, which was terminated by the treaty of Rywick. In all appearance they took their name from the place where they were first struck, viz. the city of Florence. The era is about the year 1251; though others ascribe the name to a flower de lisle, which was struck on one side.

Villani observes, that there were gold florins in the year 1067, from which time the names frank or florin became applicable to the gold coins, which till that time had been called solidi, siliings. See Coin and Exchange.

Florin, as a money of account, is used by the Italian, Dutch, and German merchants and bankers, in keeping their books, and making up their accounts. But this florin is very various, and admits of different divisions. See Coin and Exchange.

Florin, or Florentine, was also a gold coin, struck in England in the eighteenth year of Edward III. of the value of six shillings. Camden says, it was so called, because made by Florence. Fabian observes, the florins were not of so fine gold as the nobles and half-nobles of that prince.

But what is most observable is, that Fabian calls the florin a penny, value 6s. 8d. the half-florin, a halfpenny, value 3s. ad. the quarter-florin, a farthing, value 1s. 4d. These words were often met with in old histories and accounts, applied to several coins, as roials, angels, &c. Where we are therefore only to understand by penny or denarius the whole, by ob. tus the half, and by quadrans the fourth part, or farthing.

By indulgence of the mint, in 18 Edw. III. every pound weight of old standard gold was to be coined into fifty florins or florins, to be current at six shillings a-piece; all which made in tale fifteen pounds; or into a proportionable number of half and quarter florins.

Florin, in Geography, a town of the island of Sardinia, eight miles S. E. of Saffani.

Floriniani, or Florianini, in Ecclesiastical History, a sect of heretics, of the second century, denominated from its author Florinius, or Florinianus, a priest of the Roman church, deposed along with Blasius, for his errors.

Florinians had been a disciple of St. Polycarp, along with Irenæus. The made God the author of evil; or rather affected, that things forbidden by God are not evil, but of his own appointing. In which he followed the errors of Irenæus, and joined himself with the Carpoctarians. He seems to have maintained the doctrine of two principles, with other Gnostic errors.

They had also other names given them. Philastrius says, they were the same with the Carpoctarians. He adds, that they were also called soldiers, militiae, quia de multibus iacens. St. Irenæus calls them Gnostics; St. Epiphanius, Phibionites; and Theodoret, Barborites, on account of the impurities of their lives. Others call them Zaccæans; others Caddians, &c. though for what particular reason it is not easy to say, nor perhaps would it be worth while to enquire.

Floris, Francis, in Biography, a painter of history, born at Antwerp in 1520. Having practised the art of sculpture till he was 20 years of age, he then indulged his partiality for painting, and changing his profession, studied the latter under the tuition of Lambert Lombard. He
afterwards went to Rome, there copying the works of the ancients; but he appears to have felt with more fervour the works of Michael Angelo Buonaroti; which he imitated with great zeal, particularly his Last Judgment; unhappily, however, attending more to the parts than the whole.

The tale which he imbibed by these studies not a little surprised his countrymen on his return to his native city; and it acquired for him the honourable appellation of the "Raphael of Flanders," though not very justly, for his style of design is more in imitation of M. Angelo than of Raphael.

He painted for the Confraternity Hall of St. Michael at Antwerp a large picture, which now graces the walls of the Louvre at Paris. The subject is "The Fall of Lucifer and his Angels." It is highly celebrated for the grandeur and symmetry of the composition and handling, for the variety of attitudes in the fallen angels, and for the strong expression of the muscles in the naked figures. In fact it is a very curious picture, painted with great capacity, and exhibits a powerful, though eccentric, imagination. The scenes in M. Angelo's Last Judgment are not more horrible, or nearly so grotesque. The power of colour also is admirable, and in some parts has been rarely surpassed.

He had a strong and bold manner, and, like his great model Buonaroti, marked the muscular parts too fully for a just imitation of nature. He invented and composed with ease, but in a dry and gothic manner; and though sometimes his figures have an agreeable air, yet in general they possess a reprehensible degree of the flabby and formality peculiar to the age and country he lived in. He died in 1575, aged 50.

FLOREONIST, in Gardening, a name applied to such persons as are curious in, or have much skill in the knowledge and nature of flowers. A good florist should be perfectly acquainted with the names, characters, and kinds, or sorts of flowers; and at the same time have a thorough knowledge of their nature, habits, and methods of cultivation and management.

FLOREUS, J. ANNAUS, in Biography, a Latin historian, who wrote about 250 years after the reign of Augustus. This is his own country, from which he was else-where, viz. that he lived under Trajan; it has been conjectured that his history was written about 150 years after Augustus. His work is "A Compendium of the Roman History," from the foundation of the city to the reign of the emperor Augustus, in four books. It is to be regarded rather as a Panegyric on many of the great actions of the Romans, than a faithful and correct recital of their history. Throughout the narrative there are, unquestionably, pleasing reflections which display great animation, and strong powers of sensibility. It has obtained a sufficient share of popularity to be recommended very generally as a proper book for the learners of the Latin language; and it has employed the attention of several critical authors. Flores was a writer of poetry as well as an historian, and has been thought to have entered the lists against the emperor Adrian. The best editions are, that by Duker, in 2 vols. 8vo. Lug. Bat. 1722; 1714; the Dolphin edition; and that of Gravelot, Rome, Heli. Lempresdr.

FLORES, DEEPANUK, who was famined "the Master," a deacon of the church of Lyons, born in the ninth century. He obtained so high a reputation for learning and asceticism, that he was chosen by the church of Lyons to answer the treatise of John Scotus Erigena, on the subject of predetermination. This was published in the year 852, and entitled "Libri de predeterminatione, contra Johannis Scoti errores definitiones." It is to be found in the

8th vol. of the "Bibliotheca Patrum." It is not ascertained how long the author lived after the production of this work. Flores was the author of "Commentarius in omnes S. Pauli Epistles," which has been lately assigned to the venerable Bede, and admitted into the collection of his works, and several other theological pieces. Moretti.

FLOREUS, in Ornithology, a name by which Aldroand and some other authors have called the bird commonly known with us by the name of whinchat, a kind of the Passerine or今后 such. See Muscicapa Rubra. See also LOXIA Chloris.

FLOREY, FLOWERY, FLOWERS, FLORETTI, Fleur-de-lis, &c. terms in Heraldry, used when the outlines of any ordinary are drawn as if trimmed with, or in the form of flowers, lilies, fleur-de-lis, &c. Thus, he bears a cross flory, &c.

FLOS, in Botany. See Flower.

FLOS AERIS. See Fert.*

FLOS AMBREUALT, in Botany, a name given by some to the polygala or milkwort. See POLYGALA.

FLOS ARGENTI. See FLORES ARGENTI.

FLOS AFRIC. in Natural History, a name given by Swenfeld and some other writers, to that falt which is found on the surface of the earth in some part of Africa, in form of an efflorescence, and is called the Smyrna soap earth.

This falt is evidently the same with the nitre of the ancients. It will ferment with any acid in the manner of our potash, or other fixed farts, made by fire: and with oil or any fatty substance, boils into a soap. Endius gives us a great many different places for its production, from which it is distinguished it is several kinds; all these lie in the eastern parts of the world; but to these Wormius adds, that it is found in New Spain. It is always easy to be known, however, in whatsoever place it is found, being a native alkali falt, perforated like a sponge, and of a lixivial taste. Its principles seem to be a marine and a urinous falt.

That it contains a marine falt seems manifest from this, that it has the same taste in solution, or nearly so, with marine falt; that the particles of it, when coagulating in the evaporated water in which they were dissolved, first rise to the top of the surface, as those of common falt do, and that it is always of a foamy texture, or full of holes, which is always the case with those things in which the common falt makes a part, its natural concretions being hollow pyramids. Its containing an urinous falt is plain, from its producing with salt of tartrate the same sort of spirit that is soluble when mixed with that fixed falt.

FLOS CALL, the flower of th. horizon, a name given by the alchemists to the holoth, which often appearing after rain, was supposed to fall from heaven. See FLOS TERRA.

FLOS MARTINII. See FLORES MARTINII, AND IRON.

FLOS SALL. The flower of salt, flows down with the Nile, and is also found on the surface of some lakes. It is to be chosen of the colour of saffron, somewhat of a rank, small like garlic, of a biting taste, and of a fettish substance. What is coloured with mustard, or is grumus, is to be rejected. Before, what is pure and genuine is not to be dissolved but in oil; whereas what is adulterated is partly dissoluble in water.

It is efficacq against malignant and phlegmatic ulcers, nausea in the pudenca, and purulencies in the ears; it also cures dimness of sight, and removes specks and albugo from the eyes. It is mixed with plasters and ointments, as also with oil of roses, for the sake of the colour it communicates to them. Taken inwardly, in wine or water, it provokes sweat, disturbs the belly, and incommodates the flomash. It is also an ingredient in acopa and fermenta, for extenuating the hair. In general, it is of an astringent nature.
FLO

rious and pyritic quality, as are all falks themselves. Dioscor. lib. v. cap. 170.

Floetl Terre, flower of the earth, a name given by some of the chemical authors to the nothof, a remarkable plant, which resembles the common green easter-weed, but that it is thicker and more like a jelly. It suddenly appears on gravel walks and gardens after rain; and the alchemists, who knew not what to think of its origin, supposed it to contain an universal spirit, capable of turning metals into gold. See Northco.

Flotis Timopus. In Botany, a name given by Thoreto, and many others, to the gentianula victrix, or dryer's-weed, called also lutes herba, and latum by the Latins, and al-semenium, cymene, and thalpoc, by the Greeks. See Genista.

Gen. Ch. Cal. Perianth inferior, funnel-shaped, hairy, coloured, permanent; its border in three ovate, curved, spreading segments. Petals three, ovate, crec, as long as the segments of the calyx. Stam. Filaments five, sub-cylindrical, longer than the corolla; anthers roundish, with two lobes. Fil. Germen superior, ovate, compressed, two-lobed; style awl-shaped, flexsed, longer than the stamens; stigma rather thick. Peric. Capsule nearly ovate, two-lobed, two-celled. Seeds solitary, ovate, compressed, borne, with many concrescent radiating furrows.

1. F. flabellata. Deci hoa choi of the Cochii-chinese. Native of hills in Cochii-china. Stem flosely, climbing, without tendrils or spines, unbranched, long, round. Leaves alternate, lanceolate, entire, heath-like, many-sundered; fringed at the base; rough on the upper side; smooth beneath. Flowers small, pale violet, on very short partial flasks, in cleacter, rigid, clustered, level topped spikes resembling a bower. Lourieoa.

By the above description of Lourieoa, this plant is evidently very nearly akin to Tradescantia and Commulata, but its simple filaments, and two-celled capsule, seem to authorize its being kept distinct. We have from Sierr Leon a plant which, in the character last-mentioned and the influence, how far else we cannot say, agrees with it, and is surely of the same genus, if not the very identical species.

It seems to us that Tradescantia paniculata. Roxb. Corom. v. 3. 6. t. 109, must be the same genus, if not the very same species, as the above. The simple filaments evidently show it not to be a Tradescantia, which the influence confirms. Perhaps Flosca is not generally different from the Calystiga of Jacquin and Linnæus. See Calystiga.

Flosculus, a term used by Mr. Tonnerton, and others, to express such flowers of plants, as are composed each of a great number of other small flowers placed close to one another, and inclosed in the same common cup; each of these smaller flowers consists of one petal, which is slender and hollow, and wider than the bottom, and usually divided into many segments, which sometimes are disposed in the form of a star. Each of these flowers stand upon an embryo, or young fruit, from which there grows a capillament, which reaches beyond the flowers. These embryos are lodged in the bottom of the cup, which is called by authors the thalamus of the flower, and finally become seeds winged with down, or sometimes without that, and sometimes are armed with prickles. Of this sort are the flowers of thistles, knapweed, &c.

Flosculus. See Floret.

Floess, in Geography, a town of Bavaria; five miles N. E. of Weiden. — Alt, a river of Sicilia, which runs into the Oder, six miles N.W. of Breslau. See Flois. Horn, a cape on the N. coast of Iceland. Nat. lat. 66 6.

Floila, a small western island of Scotland, near the N. coast of Lewis. — Alt, one of the small Orkney islands, between South Ronalds and Hoy. Nat. lat. 53° 25' W. long. 21° 59'. — Alt, one of the smaller Hebrides, on the S. E. coast of North Uist. Nat. lat. 57° 28'. W. long. 7° 8.

Flocta, or Flotta, Floto; a name the Spaniards give particularly to the ships which they send annually from Cadiz, to the port of Vera Cruz, to fetch thence the merchandizes gathered in Mexico for Spain. It consists of the captains, admiral, and patach, or pinnahe, which go on the king's account; and about sixteen ships, from four hundred to a thousand tons, belonging to particular persons. They set out from Cadiz, about the month of August, and are eighteen or twenty months before they return.

These few to fetch the commodities prepared in Peru, are called galesons. See Galeon.

The name flotta is given to a number of ships, which get before the rest in their return, and give information of the departure and cargo of the flota and galeons. See Flota.

Flotanges, all such things as are floating on the top of the sea, or great rivers, a word chiefly used in the commissions of water-bailiffs.

Flote-Fascie Grai, a kind of natural grass which is found in watery situations, and said to be an excellent cattle grass, affording much fodder. See Festa.

Flosson, Flotsam, or Flotus, a term signifying any goods lost by shipwreck, and swimming on the top of the water; which, with jelsam or jelsam, and lagun or ligon, and share, belong to the king, if no owner appears to claim them; but if any owner appears, he is entitled to recover the possession. For even if they be cast overboard, without any mark or buoy, in order to lighten the ship, the owner is not by this act of necessity construed to have renounced his property (Lind. 2. 1. § 48); much less can things ligon be supposed to be abandoned, since the owner has done all in his power to avert and regain his property. Things jelsam, folaum, and lagun, are accounted as far distinguished from wreck (which fees) by the king's grant to a man of wrecks, the others will not pass. Over those the admiralcy courts have jurisdiction, as they are in and upon the sea. (5 Rep. 138.)

Jelsam is what is called out of a ship, being in danger of a wreck, into the sea, and there sink and remain under water. Lagun or ligon, is that which lies in the bottom of the sea; but tied to a cork or buoy, in order to be found again (5 Rep. 136.) Share, are goods due to several persons by proportion. See Floisse. L. E., in Geography, a town of France, on the N. coast of the island of Re.

Flotz, a town of Germany, in the principality of Anhalt Zerbit; six miles N.W. of Zerbit.

Flander, in Ichthyology, the English name of the fish called by the generality of authors (a) pemur, and (c) fust. It is a species of the Pleuronectes, which fees. The flounder inhabits every part of the British sea, and even frequents our rivers at a great distance from the salt-waters. It never grows large in our rivers, but is reckoned sweeter than those that live in the sea. FLOIS

2
FLOUR, the meal of any grain, but more particularly of wheat, ground and sifted for the purpose of food.

The grain itself is not only subject to be eaten by insects in that state, but when ground into flour, it gives birth to another race of destroyers, who eat it unmercifully and increase so fast in it, that it is not long before they wholly destroy the substance. The finest flour is most liable to breed them, especially when stale or ill prepared; in this case, if it be examined in a good light, it will be perceived to be in a continual motion; and on a nearer inspection, there will be found in it a great number of little animals of the colour of the flour, and very nimble. If a little of this flour be laid on the plate of the double microscope, the insects are very distinctly seen in great numbers, very brisk and lively, continually crawling over one another's backs, and playing a thousand antics tricks together; whether for diversion or search of food, it is not easy to be determined. These animals are of an oblong slender form, their heads are furnished with a kind of trunk, or oblong hollow tube, by means of which they take in their food, and their body is composed of several rings. They do visit mitchell among the magazines of flour, laid up for armies and other public uses; when they have once taken possession of a parcel of this valuable commodity, it is impossible to drive them out, and they increase so fast, that the only method of preventing the total loss of the parcel, is to make it up into bread as soon as can be. The way to prevent their breeding in the flour is to preserve it from damp; nothing gets more injury by being put up damp than flour, and yet nothing is so often put up so. It should be always carefully and thoroughly dried before it is put up, and the barrels also dried into which it is to be put; then if they are kept in a room tolerably warm and dry, they will prefer it well. Too dry a place never does any hurt, though one too moist always spoils it. See Meal.

FLOUR, St. in Geography, a town of France, in the department of the Cantal; before the revolution, the capital of Upper Auvergne and the see of a bishop; containing in its north and south divisions 5000 inhabitants; in the canton of the former 10,538, and in that of the latter 15,121, on a territory of 585 kilometres, in 27 communes. The inhabitants carry on a considerable trade in corn, with manufactures of cloth, carpets, and cutlery. N. lat. 45° 2'. E. long. 3° 10'.

FLOWER, in Physiological and Systematical Botany, comprehends all those organs of a plant which are preparatory and necessary to the impregnation and perfection of the fruit or seed. (See Fecundation and Fructification.) Of the seven parts of fructification distinguished by Linnaeus, five constitute the flower. These are, first, the calyx or flower-cup; second, the corolla or petals; neither of these is indifferenciable, one, and sometimes both of them being occasionally wanting; (see Calyx and Corolla) third, the stamen or stamens, generally filamentous bodies, ranged internally with respect to the two former; these are essential, being the male organs; fourth, the pistil or pistils, in the centre of the flower, which consist of the rudiments of the fruit, and the female organs of impregnation, being therefore essential, though not always situated in the same individual flower, nor even on the same plant, with the stamens; fifth, the receptacle, or common point of connection, which must be present in some shape or other, and in compound flowers is very important; see Compound.

Flowers are usually the most ornamental part of vegetables, but the most fleeting and transitory. After their production, the vegetation of the plant, however rapid and luxuriant before, is checked, at least for a time, even in perennial plants and trees; and annual ones survive flowering only till they can ripen their seed. The same flower, which will endure for several winters without blossoming after this event loses its vigour, and yields to the first attacks of frost. Pliny observes that "blooms are the joy of trees, in bearing which they assume a new aspect, veiling with each other in the luxuriance and variety of their colours." Linnaeus has adopted and exemplified this idea, to concur with his own theory of vegetable propagation, and with the importance which he gives the flower in his principles of classification, as the sure guide to a true differentiation of the kinds of vegetables. The various modes in which flowers are situate upon, or connected with, the plant that bears them, will be explained under the article of Inflorescence, an important subject in systematic botany. In position they greatly differ in different genera or species. Most generally they expand, and present themselves to the light, in a remarkable manner, either drooping when its stimulus is withdrawn; but some flowers always droop, hiding their internal organs, and protecting them from rain, as long as their own delicate filament endures. Flowers are eminently distinguished from the other parts of a plant by their general beauty and vivacity of colour, chiefly seated in the corolla, and likewise, in many instances, by their peculiar fragrance, the theme of poets and the admiration of all whose nerves, which is not always the case, can endure it. This fragrance is proved by experiment to depend on a volatile, essential oil, in many cafes obtainable by distillation, in others by infusion in spirits, or in expelling oil, either of which imbibe or diffuse it. Flowers do not give it out alike at all times; some have no scent during the day, but become highly fragrant in the evening. These enhance the luxury of the bright moonlight nights of India, nor is our own country deficient of many such flowers. They are elegantly termed by Linnaeus fœces trites, sad or melancholy flowers. Their colour is very frequently pale and sickly, inclining to greenish or brownish yellow, agreeing remarkably in plants of very different classes and characters, which moreover have usually the same fame luminous evening scent. Among these are Hydrilia tælæ, Pelargonium tritile, M.femoranthemum noviflorum, Nyctanthes Arbor-tritile, and others. Many oriental flowers have a fine lemon-like odour in an evening, which are, for that reason, affably cultivated by the Chinese; as the Chloranthus incopiscus, whose merit in this respect was not discovered in England till it had long been cultivated, nor was the sweet and powerful scent, obserable on first opening the hot-house in a morning, suspected to proceed from so minute and inconsiderable a blossom, till the late Mr. Aiton of Kew, whom no natural phenomenon could escape, first made the discovery. There seems to be an analogy between the smell and colour of flowers in other instances. The yellow variety of Chrysanthemum indicum differs altogether in scent from the dark-purple one, agreeing rather with the yellow wall-flower, which it also resembles in colour. The deep crimson Carnation, called the Clove Carnation, and the Clove Pink now nearly extinct, have a clove-like fragrance, richer than the paler or whiter kinds.

Ever since Botany has been cultivated on scientific principles, the flower and fruit have unceasingly been referred to for the leading distinctive characters of plants. (See Classification.) On these conjointly all natural characters of Genera, Orders and Classes are founded. The heritage of the plant is, according to the Linnean idea, a sort of mark, which conceals its true characters till they become manifest in the flower. Artificial systems of arrangement
ment have been contrived by some authors on the fruit, by others on the flower. The former are usually considered as most according with natural affinities, the latter as the most convenient. The principal of these last are those of Rivinus and Tournefort, in which the corolla takes the lead; and the sexual sytem of Linnæus, founded chiefly on the lames and pellils.

The medical properties and sensible qualities of flowers, their peculiar odours excepted, agree much more with the herbage, than with the fruit to which they are intimately attached. Thus in the class *Icaflandria*, as far as least as that class is a natural one, the flowers, as in the peach and cherry for instance, partake of the acrid, noxious, effiential, oil of the leaves and bark, not at all of the sweet, acid, or aromatic qualities of the pulpy fruits. S.

**Flowers, Colours of.** It has been affected by some chemists, that all colours arise from sulphurs, and that they differ according to the different admixtures of salts with these sulphurs. Perhaps on these principles, it may be possible to form some rational conjectures in regard to the origin of colours in the flowers of plants. We know very well that the flowers of all plants abound in an effiential oil or sulphur, to which, according to this doctrine, their colours may be rationally ascribed to be owing; and though this oil should be proved to be of the same or similar substances in all, yet their variety of colours may be accounted for in part, since we find that one and the same oil, the effiential oil of thyme, according to Mr. Geoffroy’s experiments, may be turned to all the colours that we find in the different flowers of plants, from white to deep black, with all the shades of red, yellow, purple, blue, and green, by mixing it with different fluids; and by the same laws, the effiential oil of plants, when mixed in their flowers, may by the different mixtures they meet with, give them all their beautiful variety of colours. See *Effiential Oils*.

We know that the infusions of flowers, and of other parts of plants, become red on being mixed with acids, and green on being mixed with alkalies; and there is no reason to doubt, that it is the sulphureous part of the vegetable in these infusions which thus changes colours on these mixtures. This, however, ought to be proved possible, before it is allowed in argument.

*This proof is given in the change of colours before mentioned, which are produced in oils merely by the admixture of different fluids; and as all the colours in these are the regular result of certain combinations, there is great reason to believe, that in those plants whose flowers give the same colours, there may be the same combinations.*

The principal colours of plants, and their several parts, are green, yellow, red, purple, blue, white, black, and transparent whiteness; all the others are produced by different combinations of these. The green, which is the common colour of the leaves of plants, is probably the effect of an oil rarefied in that part of the plant, and there mixed with the fixed and volatile fluids of the sap, which remain entangled by the earthy particles after most of the aqueous humidity is evaporated, and by that means become in a state to act upon the oil. A clear proof of this is, that if the leaves are covered up in such a manner that the aqueous humidity of the sap cannot evaporate itself, the oil and fluids cannot act upon one another as they naturally would, but becoming diffused among to be of great a quantity of water, lose the colour they would otherwise have obtained together, and become whitish or transparent. This is seen in the obvious influence of succory and celery, the leaves of both which plants, though naturally green, become white by being covered up with earth by the gardeners.

The leaves of both plants and trees usually turn red in autumn, or on the attack of the first frost; the reason of which is, that the several canals of the sap being constricted by the cold, the juices are detained in the vessels of the leaves, or at least its circulation is greatly interrupted; and being detained there, it naturally grows four, the acidity of this altered juice destroying the green colour, produced by the alkaline fluids. The sap brings on a red colour, in the very same manner that the effiential oil made green by a mixture of oil of tartar is again changed to red, by adding to it a proper quantity of distilled vinegar. Where we find in our common experiments the acids of the mineral kingdom turning the infusions of flowers red, it seems by the analogy of these experiments to be only owing to their destroying the blue, brown, or other colour, which the alkaline fluids of the plant had made with its effiential oil.

All the shades and degrees of yellow and saffron colour in the flowers of plants, seem wholly owing to a mixture of an acid in their juis, with their effiential oil; as the oil of the apricot, which itself has very little colour, is made to pass through all these shades of colours, only by digesting it with distilled vinegar. From the digesting the volatile alkalies, such as spirit of sal ammoniac and urine, with the same oil, it appears that all the shades of red, from the pale flesh-colour, to purple, and even to the violet blue, are only owing to the different admixtures of an alkaline volatile fluid of the urinous kind, mixed in different manners with their effiential oil.

Black, which is a very uncommon colour in flowers, and which in them ought to be regarded only as a very deep violet, seems the effect of an addition of an acid juice to their oil, already turning purple to violet colour by a volatile alkali.

All the shades of blue and purple seem also, by the analogy of the same experiments, to be only the effects of mixtures of alkalies of the fixed and volatile kind, with the oils of plants; since these colours are all produced in these experiments, by mixing the spirit of sal ammoniac, and the oil of tartar with oil of flowers.

This bright green of some flowers seems also to be produced by the same fats, only acting on oils more rarefied. For the oil of thyme of a purple violet-colour diluted with rectified spirit of wine, being diluted with oil of tartar, becomes green. Mem. Acad. Par. 1707.

Bocccone is of opinion, that in many plants the colour of the flowers is wholly owing to the colour of the juices of the root. This he infers in the greater celandine, whose roots and flowers are of the same yellow colour. The barberry in like manner, he observes, has both its roots and flowers yellow. The gentian has its roots and flowers both of a pale red, and the acacia indica Aldini, and many other plants, he says, are infusions of this. The reason that he assigns for this is, that the more fixed parts, wherein this colour confines, preserve the same tincture, without being altered by so long a circulation as that from the root to the flower; and he adds another very remarkable observation, which is, that in these plants and trees, whose roots and flowers are of the same colour, the juices are more fixed; and therefore, that these are more fit for dyeing than any other coloured wood of plants. Vide Bocccone, Muf. de Plant.

Dr. Lewis, in his notes on Neumann’s Chemistly, has many curious observations on the colours of flowers.

There
There are few of them which are durable in themselves, or that can be made durable by art. The only permanent colour is yellow. The red, the blue, and the intermediate shades of purple, crimson, violet, &c. are very perishable. Many flowers lose their colours on being dried, and especially if they are dried in a shady and not warm place. The colours of all of them perish by keeping even in the closest vessels; the more badly they are dried, and the more perfectly they are secured from air, the more the longer do they retain their beauty. The colouring matter of flowers extracted and applied to other bodies is still more perishable.

The colour of many blue flowers is extracted by infusion in water; but from others, water acquires only a purplish blue. Of those which have been tried, not one gives a blue colour to spirit of wine; some give no colour, and some give a reddish colour. The expressed juice of these flowers is generally blue. The blue juices and infusions are rendered red by acids; and the most florid red is given to them by marine acids. The flowers also, by maceration, impart a red colour to acid liquors. Alkalies fixed and volatile, and lime-water, change these blue colours to green. And those infusions or juices which have nothing of the colour of the flower, suffer the same changes from the addition of acid and alkaline liquors. Even when the flowers have been kept till their colours are lost, their infusions acquire a red colour from acids, and a green colour from alkalies, but in a less degree than when the flowers were fresh. The red colour produced by acids is scarcely more durable than the original blue; applied upon other bodies, and exposed to air, it gradually degenerates into a faint purple, and at last disappears, without leaving a stain behind. The green produced by alkalies changes to a yellow, which does not fade so fast. The green made by lime-water is more permanent and beautiful. Green lakes, prepared from blue flowers by means of lime-water, have been used by painters. The flowers of cypress have been much commended for affording elegant and blue pigments. But Dr. Lewis has not been able to extract from them any blue colour. They retain their colour, when badly dried, longer than other blue flowers, but do not communicate their original colour to any menstruum.

Red flowers readily communicate their colour to water; and those of a full red colour give to a rectified spirit also a deep red tincture, brighter, though somewhat paler, than the watery infusion. But the light red flowers, and those which are purplish, impart little colour to pure spirit. The colours of infusions of these flowers are lifted to be heightened by acids, and to be rendered green by alkalies. But this is not universal. For amongst those examined by Dr. Lewis, the red colours and purplish red were changed by acids nearly as blue flowers are; but the full deep reds were not. The deep infusion of red poppies was turned by alkalies not to a green, but to a dusky purple.

Yellow flowers communicate to water and to spirit of wine durable yellow colours, not alterable but in degree by acids or by alkalies; the former only rendering them paler; and the latter, as also alum, rendering them deeper. 'Wool, or silk,' impregnated with a solution of alum or tartar, receives, on being boiled with the watery infusion or decoction, a durable yellow dye. A durable yellow lake is prepared by precipitating with alum an infusion of yellow flowers made in an alkaline ley. In some of the orange-coloured flowers the yellow matter seems to be of the same kind as that of the pure yellow flowers; but the red matter seems to be different from that of the pure red flowers. The yellow matter is extracted from these flowers by water; and the remaining red matter is extracted by spirit of wine, or by a weak solution of fixed alkali in water. Such are the saffron coloured flowers of carthamus. These flowers, after the yellow matter has been extracted by water, are laid to give a red tincture to ley, from which a deep red, or scarlet, called safflower, Spanish red, and Chinslike. This pigment gives a beautiful red colour to spirit of wine, but none to water. The yellow farrina or fine dust, resting on the tips of the stamens of flowers, gives a fine bright yellow colour to spirit of wine, and a darker yellow colour to water. The colours of both the watery and spirituous tinctures were heightened by alkalies, rendered red by acids, and again restored to a yellow by adding an alkali. This is the only known instance of the yellow colour of a vegetable being rendered red by acids. White flowers, or their expressed juices, impart a green colour to alkaline leys, but have not been observed by Dr. Lewis to give a red colour to acids. The white flowers of the common wild convolvulus give a deep yellow or orange colour to water, which is affected by acids, by alkalies, and by alum, as the infusions of yellow flowers are. The white flowers of xeranthemum give a beautiful yellow colour to water acidulated with spirit of nitre. See Neumann's Chem. by Dr. Lewis, p. 430, 432.

Flowers, in Gardening, are distinguished into early, or spring-flowers, which flourish in the months of March, April, and May. Of this class are the anemones, daffodils, hyacinths, tulips, jonquils, cowslips, primroses, &c. Summer-flowers, which open in June, July, and August, as pink, gilly-flowers, lilacs, daisies, campanulas, poppies, sun-flowers, &c. Autumnal, or late flowers, denote those of September and October; as the chrysanthemum, Indian pink and roses, pansy, flower-gentle, &c. Of these flowers, those which subside all the year, we mean in the stem, or root at least, are called perennials. And those which are to be planted or sown afresh every year, according to the season, are called annual.

Flowers, Preservation of: The method of preserving flowers in their beauty through the whole year has been diligently sought after by many people; some have attempted it, by gathering them when dry, and not too much opened, and burying them in dry sand; but this, though it preserves their figure well, yet takes off from the liveliness of their colour.

The primrose and cowslip kind are very eminent instances of the change of colours in the flowers of dried specimens; for those of this class of plants easily dry in their natural shape, but they not only lose their yellow, which might be expected naturally enough, but they acquire a fine deep green, much superior to that of the leaves in their most perfect state. The flowers of all the violet kind lose their noble blue, and become of a dead white, so that in dried specimens there is no difference between the blue-flowered violet and the white-flowered kinds.

Muntingius gives a method, which he says is preferable to all others; this is as follows: gather roses or other flowers when they are not yet thoroughly open, in the middle of a dry day; put them into a good earthen vessel, glazed within; till the vessel up to the top with them; and when full, sprinkle them over with some good French wine, with a little salt in it; then set them by in a cellar, tying the mouth of the pot carefully down. After this, they may be taken out at pleasure, and on setting them in the sun, or within the reach of the fire, they will open as
FLOWER.

if on the tree, and not only the colour, but the smell, will be preferred.

Sir Robert Southwell has communicated to the world a method of drying plants, by which all flowers are preferred in their natural shape, and many in their proper colours. To this purpose two plates of iron are to be prepared to the size of a large half sheet of paper, or larger for particular occasions; there plates must be made so thick as not to have any power of bending, and there must be a hole made near every corner for the receiving a screw to fasten them close together.

When these plates are prepared, lay in readiness several sheets of paper, and then gather the plants with their flowers, when they are quite perfect; let this always be done in the middle of a dry day, and then lay the plant and its flower on one of the sheets of paper doubled in half, spreading out all the leaves and petals as nicely as can be. If the flalk be thick, it must be pared or cut in half so that it may lie flat; and if it be woody, it may be peeled, and only the bark left; when the plant is thus expanded, lay round about it some loose leaves and petals of the flowers, which may serve to complete any part that may prove deficient; when all is thus prepared, lay several sheets of paper over the plant, and as many under it; then put the whole into the iron plates, laying the papers smoothly on one, and laying the others over them; then sew them close, and put them into an oven after the bread is drawn, and let them lie there two hours; after this make a mixture of equal parts of aquafortis and common brandy; make these well together, and when the flowers are taken out of the pressure of the plates, rub them lightly over with a camel's hair pencil dipped in this liquor; then lay them upon fresh brown paper, and covering them with some other sheets, press them between this and other papers with a handkerchief, till the wet of these liquors is dried wholly away. When the plant is thus far prepared, take the quantity of a num-ber of gum dragon, put this into a pint of fair water cold, and let it stand four and twenty hours; it will in this time be wholly dissolved; then dip a fine hair pencil in this liquor, and with it rub over the backside of the leaves, and lay them carefully down on a half sheet of white paper fairly expanded, and press them with some more papers over these. When the gum-water is fixed, let the press and papers be removed, and the whole work be finished. The leaves retain their verdure in this cafe, and the flowers usually keep their natural colours. Some care must be taken, that the heat of the oven be not too great. When the flowers are thick and bulky, some art may be used to pare off the backs, and dip-pose the petals in a due order; and after this, if any of them are wanting, their places may be tamped with some of the supernumerary ones dried on purpose; and if any one of them be only faded, it will be prudent to take them away, and lay down others in their stead: the leaves may be also dipposed and mended in the same man-ner. Another way of keeping both flowers and fruit the whole year without spoiling, is delivered by the fame au-thor in the following manner: take salt-petre, one pound; balsam, a pound; clean common sand, three pounds; mix all well together, then gather fruit of any kind, that is not fully ripe, with the stalk to each; put them in one by one into a wide-mouthed glafs, laying them in good order; tie over the top with an oil-cloth, and carry the glafs into a dry cellar, and let the whole upon a bed of this prepared matter of four inches thick in a box; fill up the remainder of the box with the fame preparation, and let it be four inches thick over the top of the glafs, and round all its sides. Flowers are to be preserved in the fame fort of glaffes in the fame manner, and they may be taken up, after a whole year, as plump and as fair as when buried.

FLOWER Garden, the place where flowers are chiefly grown, cultivated and preferred. It should have a sheltered southern aspect, but which is not by any means close.

FLOWERS, in Antiquity. We find flowers in great request at the entertainments of the ancients, being provided by the master of the feast, and brought in before the second course; or, as some are of opinion, at the beginning of the entertainment. They not only adorned their heads, necks, and breasts, with flowers, but often bestowed the beds whereon they lay, and all parts of the room with them. But the head was chiefly regarded. Potter Archæol. Græc. tom. ii. p. 383. See Garland.

Flowers were likewise used in the bedecing of tombs. Potter Archæol. Græc. lib. iv. cap. 7. tom. ii. p. 232, seq. See Burial.

FLOWER, in Architecture, according to Vitruvius, is a representation of some imaginary flower, by way of crowning, or finishing, on the top of a dome, &c.

In bu of this the moderns commonly use a vase, ball, or the like.

FLOWER-de-lu-cé, Fleur-de-lis, in Heraldry, is a bearing anciently of great dignity; being reputed the noblet of all flowers, and as such having been in all ages the charge of the royal escutcheon of the kings of France, though time has made the bearing thereof more vulgar.

In some coats it is borne single; in others triple; in others it is, some, fedem all over the escutcheon. During the existence of monarchy in France the arms consisted of three flowers-de-lis or, in a field azure. These arms, however, were superseded in 1789 by the cap of liberty, and the three-coloured flag, when the battle was taken and destroyed by the inhabitants of Paris.

FLOWER of the Capital is an ornament of sculpture, in form of a rose, in the middle of the sweep of the Corinthian abacus.

In that of the Composite, it is not a rose, nor any real, but an imaginary kind of flower.

FLOWERS, in Chemistry, are the finest and most subtle parts of dry bodies, raised by fire, into the vessel's head, and added; and adhering to them in form of a fine powder, or dust. Such are the flowers of sulphur, benjamin, &c.

FLOWERS of Antimony. See Antimony.

FLOWERS Argentine, of regula of antimony, are made by putting the regula into an unvarnished earthen pot, placed in a furnace, so that its bottom may be red-hot, while its upper part shall be much colder. The pot is to be covered with a lid, without luting it, and heat is to be applied for an hour or more. When the pot is cold, its internal surface, and the remaining part of the regula are found covered with white flowers, in form of beautiful, transparent, and shining needles, which are to be gathered with a feather. After this, a second sublimation may be commended, and managed in the same manner; and the whole regula may be changed into flowers. These flowers appear to be nothing else than the earth of regula of antimony deprived of almost all its phlogiston. They are neither emetic nor purgative; they are soluble in aqua regia.

FLOWERS of Arsenic, white, are made, as all other flowers are, by subliming arsenic; from which they do not differ in their nature and properties.

FLOWERS of Benjamin, or Benzoin, are made by putting a quantity
quantity of this refined into a varnished earthen pan, and covering it with another inverted pan of flone-ware: and let the edges of these pans be made to fit well to each other, and to be well luted together with paper dipped in paste. Put the earthen pan containing the benzoin on a gentle fire, and with that the sublimation is performed; when the vesicles are cool and unluted, the flowers are to be swept off with a feather. For the properties and medical uses of these flowers, see Benzoin.

**FLOWERS OF BISMUTH. See BISMUTH.**

**FLOWERS OF COBALT. See COBALT.**

**FLOWERS OF COPPER** have been prepared by subliming falso-ammoniacum with the caput mortuum of blue vitriol. See COPPER.

**FLOWERS, Martial. See FLORES MARTIALIS.**

**FLOWERS OF SAL AMMONIAC** are nothing more than false ammoniac sublimed; and the sublimation is facilitated by generally mixing with it an equal part of decrystallized common salt. See SAL AMMONIAC.

**FLOWERS OF SULPHUR, or Bismuth.** are the vapours of melted bismuth conveyed from an iron pot (in which it is kept boiling) through a proper tube, into a close room or oven, where this vapour condenses into flowers. See SULPHUR.

**FLOWERS OF ZINC.** See CADMIUM and ZINC.

**FLOWERS, in the Animal Economy,** denote women’s monthly purgations, or menstrue.

Nicot derives the word in this sense from flower, q. d. flowers. Others will have the name occasioned, that women do not conceive till they have had their flowers; so that these are a sort of forerunners of their fruit.

**FLOWERS, in Rhetoric, are figures and ornaments of discourse,** by the Latins called florilegium.

**FLOWER-SCISSES, Barbados.** See POINCIANA.

**FLOWER-SCISSES, Bahama.** See Adenanthera.

**FLOWER OF BREEF.** See Lychnis.

**FLOWER OF CONJUNCTIVITIS.** See Lychnis.

**FLOWER DE-LUARD, in Botany.** See Iris.

**FLOWERS OF AN HOUR.** See Hibiscus.

**FLOWERS, Eternal, or Everlasting.** See GNAPHALIUM, GOMPHRENA, and XERANTHUM.

**FLOWERS, Four o’clock.** See Mirabilis.

**FLOWER, Gentle.** See AMARANTHUS.

**FLOWER, Side Saddle.** See Sarracenia.

**FLOWER, Sky.** See Cineraria.

**FLOWER, Sultan.** See Centaurea.

**FLOWER, Sun.** See Helianthus.

**FLOWER, Trumpet.** See Bignonia.

**FLOWER, Wind.** See Anemone.

**FLOWER OF OLEOCOCCA,** a name given by the people employed in finding the oleocolla to a fort of white marley matter, which they usually find on the surface of the ground in the places where the oleocolla lies underneath. It seems very nearly allied to the nature of the oleocolla itself, and usually has under it some of that blackish matter resembling rotten wood, which the oleocolla itself is formed upon, and which fills up those hollows we find in most of the pieces, while the whole is in the ground. This rotten vegetable matter has much the resemblance of the roots or branches of trees, and is called by the common people the root of the oleocolla or hammersel radix. Phil. Trans. N° 39. See OLEOCOCCA.

**FLOWER-root-worm, in Natural History,** a peculiar species of fly-worm, which makes its habitation only in the bulbous roots of flowers. The roots of the narcissus, at the time they are taken up out of the earth toward the end of autumn, very frequently are found to contain each a single worm which eats and destroys them. Sometimes, one root is found to contain two of them; but this is but rarely the case. The roots which have them may easily be known, by having each a round hole in some part, at which the destroyer has entered while it was small, and which probably serves it now in its large state for respiration of the free air. The interior part of these bulbs is always found rotted and destroyed, and the worm is found in them, lying in a brown frit of dirt made by its own liquid excrements, mixed among the fragments of the coats of the root which it has destroyed. Réaumur’s Hist. Insect. vol. iv. p. 499.

These worms undergo all their changes in a shell made of their own skin, which is of the same egg-shaped shape with that of the blue sickly-fly, but considerably larger, and of a greyish colour. But this is not all its difference from these shells; for on its anterior and superior part it has two horns of the same kind with the four of the shells of the rat-tailed worm; and seeming to force to the fame purposes, and to convey the air necessary for the life of the creature, into its coecula: the old firmament, which served the creature in its worm-state, being now obliterared, and something necessarily wanted in their place. After having undergone all the necessary changes, the shells are built open, in the month of April, and let out the fly they contained.

This has so much the appearance of a humble-bee, that at first sight it is scarce to be distinguished from it. It is covered with black, yellow, and reddish hairs, as the smaller kinds of the common humble-bees are; but its antennae, which are of the boredale fashion, prove plainly enough, that it is really no bee, even before one can determine with certainty that it has only two wings.

FLOWERAGE, a collection of flowers of several kinds set together in hanks, and hung up with strings.

FLOWERED, in the Manufacture. A stuff, or cloth, is said to be flowered, furred, fringed, or figured, when there are representations of flowers, either natural, or imaginary, wrought thereon.

There are fluffs flowered of almost all kinds of matter: flowers of gold, silver, silk, wool, thread, cotton, &c. Stuffings and cloths are usually designated from the ground wherein the flowers are raised.

Thus, there are flowered velvets, taffeties, damasks, fattins, moahs, dimities, &c.

Theodore flowered with gold and silver are more usually called brocades.

The flowers are usually wrought at the same time with the cloth, or ground. The threads of the warp are raised and lowered by means of packthreads passed through them in mounting the loom; and the manufacturer shooting his warp, or matter of the flowers, whether gold, silver, silk, or the like, between the threads thus raised, forms the flowers.

It is very curious to see them mount a loom; or, as they call it, read a design, to be represented on a stuff; but it is next impossible to describe it; yet we have endeavoured to give some idea thereof under Design.

FLOWERING, Bulbous-rooted Plants, in Gardening, the art of blowing these sorts of flower-plants in the house. This can be easily done by proper care, as they are capable of both growing and flowering in water without any sort of earth. When well managed in this way, flowers of this kind have a beautiful and elegant appearance, at a season when they cannot be found in other situations.

It is the usual practice to blow single roots in pots or glasses made for the purpose, nothing more being requisite than...
than that of supplying them properly with water, so as not to rise much upon the bulbs of the roots, as they are very liable to rot when they are too much immersed in water.

Other contrivances have likewise been had recourse to in order to blow several roots of the same, or other kinds together, in which situations they have very pretty effects. Where glass or earthen-ware flands for this purpose are not at hand, the bullfins may be easily and conveniently accomplished by means of a common garden pot, which should have the hole in the bottom perfectly closed, and two pieces of pretty strong sheet lead cut so as to exactly fit the bottom and top of the pot; proper holes should then be made in the upper piece for the reception of the root-bulbs, and small perforations formed in it, and the lower or bottom piece, for receiving suitable sticks for supporting the flowering items of the different roots. Water must then be poured in so as to fill the pot quite up to the upper plate of lead, when the roots should be placed in the large holes made for them, so as just to touch the surface of the water. Where different kinds are used, by Narcissus, Narcissus, jonquils, tulips, &c., they may be put in, in a varied manner, and placed in a rather warm situation in the house.

In this way the whole will be brought into flower at an early period, and continue for some time to afford a fine display of beautiful flowers. In this manner, by a careful regulation of the heat of the room, and an occasional proper supply of fresh water, they may be kept flowering from December till the beginning of the spring.

When they have done flowering, the roots should be removed and laid by in a dry, but not warm situation, until they may be wanted in the following season.

It is found by much experience that those bulbs which are kept in a dry flat flower by much the best, as they gradually take in that quantity of moisture which is necessary in the process, and are not liable to rot or full faint injury in that way.

The proper way of managing them is to let them at first only just come in contact with the surface of the water, that they may strike forth their root-fibres in a full manner, after which it may be raised a little higher to promote the full flowering of the plants. During the whole time of flowering, they should be kept quite steady by the support of proper sticks.

There is an advantage in flowering bulbous roots in glass flands, as they succeed equally well in them, by the progress of their roots being capable of being more perfectly judged of, and at the same time the supplies of water more conveniently afforded.

Such roots as have been in the ground are always improper for being employed in this way, as they never flower in any perfect manner. Before the roots are made use of, it is constantly necessary to lightly rub off all the loose old coaty matters that may hang about them. And it is a good practice to change the roots every two or three years, in order to prevent their becoming weak, and of course flowering imperfectly.

It has been observed that the early flowering of roots of this sort may be greatly promoted by the use of weak solutions of nitre, and ammonia in its crude state. Where either of them is tried, a small portion should only be poured into the pots or glazes containing the water at a time, and not too frequently repeated. See Root.

FLOWING, or Flow-sheets, in Sea Language, denote the positions of the sheets, or lower corners of the principal sails when they are loosed to the wind, so as to receive it into their cavities in a direction more usually perpendicular than when they are clove hawled, but more obliquely than when the vessel is failing before the wind. This position of the sheets takes place when the wind crosses the line of her course nearly at right angles.

FLOOD, in the Colour Trade, a very well cleaned wool, used to absorb the colours of cochineal, &c. It is prepared in this manner: infuse a pound of the finest shavings of woolen cloth in cold water for one day; then take them up, and press them well together, to wash off the uncertainty the wool naturally has. This is the simple flood, which, when impregnated with a solution of alum, is called alomed flood. This is done in the following manner: Take four ounces of roach-alum, and two ounces of crude tartar, both in fine powder; put them into an earthen vessel with three quarts of water, let it over the fire, and when it begins to boil, then put in the flood; let the liquor now boil half an hour over a gentle fire, then take it off, and when all is perfectly cooled, wash the vessel with fair water, letting them stand in it two hours, then press them in the hand, and let them dry.

FLOYD, in Geography, a new township of America, and chief place of a district in Ossaca Herkimer county, New York, containing 367 inhabitants.—Also, a county of Kentucky, containing 427 inhabitants, of whom 29 are slaves.

Floyd's Fork, a river of Kentucky, which runs into the river Salt. N. lat. 37° 48'. W. long. 85° 57'.

FLOYER, Sir John, in Biography, an eminent physician, was born at Hints, in Staffordshire, about the year 1649, and received his education at the university of Oxford, where the degree of doctor of physic was conferred upon him, on the 8th of July, 1680. He settled himself in the practice of his profession at Litchfield, in his native county; where his indefatigable attention to the sick, and the consequent practical skill which he attained, not only procured for him the confidence of the inhabitants, but gained him a reputation extensive, that his sovereign honours him with knighthood, as a reward for his talents. He was a great friend to the use of cold bathing, and left no means untried, by which he might diffuse the knowledge of its utility and safety, and bring the practice into general vogue; he particularly recommended it in chronic rheumatism, and in nervous disorders, and he maintained that consumptions had prevailed extensively in England only since the practice of baptizing children by immersion had been relinquished. There are the titles of his different publications. 1. "The Touchstone of Medicines," London, 1687, 8vo. 2. "The Preparative State of the Animal Humours described by their sensible qualities," London, 1696, 8vo., in which he maintained the doctrine of fermentation. 3. "An Enquiry into the right use of Baths," London, 1697, 8vo. This work afterwards appeared under different titles, such as "Ancient Psychrolathy revived," London, 1702; and the subject was more amply treated in another edition; 4. "History of hot and cold Bathing, ancient and modern, with an Appendix by Dr. Baynard," London, 1709, and again in 1715, and 1722. His next work was "A Treatise on the Althma," first published in 1668, and re-published in 1717 and 1726. He was himself the subject of althma from the age of puberty, yet lived to be an old man. 5. "The Physicians' Pulse-watch," 1707 and 1710, in two volumes, 8vo. Sir John Floyer was one of the first to count the pulsations of the arteries; for although the pulse had been the subject of observation from ancient times, the number of beats in a given time had not been attended to. 6. "Medicina Geromonica; of preferring old men's health; with an appendix concerning the use of oil and ointment, and a letter on the regimen of younger years," London, 1695.
London, 1724. Several of these treatises were translated into the continental languages.

FLUENTIA, in Chemistry, a genus of salts formed by the union of fluoric acid with any alkaline or faubulous base. Little is known of these salts, but the properties of the principal of them are enumerated in the article FLUID, to which the reader is referred.

FLUCTUATION denotes, in Surgery, the motion communicated to any collection of pulpy matter, or other kinds of fluid, by applying some of the fingers of each hand, at a certain distance from each other, to the surface of the tumour, and pressing with them alternately in such a manner, that the finger of one hand are to make a little pressure, while those of the other hand remain lightly placed on another part of the swelling. When the ends of one set of fingers are thus delicately applied, and the surgeon taps, or makes gentle pressure with the fingers of the other hand, the impulse given to the fluid is immediately perceptible to those fingers which are lightly laid on the tumour, and the sensation thus received is one of the principal symptoms by which practitioners are enabled to discover the presence of fluid in a great variety of cases.

When the collection of fluid is very deeply situated, the fluctuation is frequently exceedingly obscure, and sometimes not at all distinguishable. In this circumstance, the existence of the fluid is to be ascertained by the consideration of other symptoms. For example, in cases of hydrops pectoris, and empyema, surgeons do not expect to feel the undulation of the fluid in the thorax with their fingers; they consider the patient's difficulty of breathing, the uneasiness attending his lying on one particular side, the edema of the pates of the chief, the dyspepsia of other parts, the more raised and arched position of the ribs on the affected side of the body, the preceding rigors, fever, and several other circumstances from which a judgment is formed, both with regard to the presence and the peculiar nature of the fluid.

FLUDD, Robert, or as he styled himself in Latin, De Fluibus, in Biography, the second son of Sir Thomas Fludd, treasurer of war to queen Elizabeth, was born at Milgate, in Kent, in 1574. He was educated at St. John's college, Oxford; and after taking his degree in arts, attached himself to the study of physics, and spent almost ten years in his travels through the principal countries in Europe. It was probably during these peregrinations that he imbied a taste for the Rosy-Serican Philosophy, of which he was ever after a most strenuous supporter; and indeed almost the only one who became eminent in it in this kingdom. He proceeded as doctor of physic in 1605, and about that time settled in London, and was made a fellow of the college of physicians. He was a very voluminous author in his feet, diving into the farthest profundities and most mysterious obscurities of the Rosicrucians, and blending, in a most extraordinary manner, divinity, chemistry, natural philosophy, and metaphysics. Eloc allows him some credit on the score of mathematical and mechanical knowledge, but characterizes his physics as a tissue of impertinent nonsense. Yet such a vein of wrauth enthusiasm runs through his works, that we may readily suppose him to have been a believer in the mystical jargon of his system. He had the faculty, at all events, of impressing his patients with an idea of his importance, and of inspiring them with great faith in his skill, by the ufe, it is said, of a kind of sublime unintelligible cant, whether successful or not; he was therefore at least very eminent in his medical capacity. He died at his house in Coleman-street, London, on the 5th of September, 1637, and was buried in the parish church of his native place.

It is said that Dr. Fludd was in possession of the manuscripts of Simon Forman, the astrologer. Although the sect of Rosy-crusians is now entirely extinct, a list of the works of Fludd, which were chiefly written in Latin, may be given to the curiosity of the learned. The list, entitled, "Utriusque Caelestis, majoris et minoris, Technica Historia," opens, 1617, is two volumes folio, contains some extremely singular prints, which are intelligible only to an adept. 2. "Tractatus Apologeticus integritatem societatis de Rosca cecum defendendi," Leyden, 1617. 3. "Monochordon mundi nymphaeum, rei Preripiti ad Apologian Joannis Kepler," Francfort, 1624. 4. "Anatomie Theatra trium tripli cfficie dignitatum," ibid, 1625. 5. "Philosophia Sacra et vera Christiana, seu Meteorologia Comfica," ibid, 1626. 6. "Medicina Catholica, seu, Mythicum artis Medicandi Sacrarum," ibid, 1626. 7. "Integrum Morboyn Mysterium," ibid, 1631. 8. "De Morborum Signis," ibid, 1631. These two treatises are a part of the Medicina Catholica. 9. "Clavis Philosophiae et Alchemyi Fluddanae," ibid, 1632. 10. "Philosophia Mathea," Gouda, 1633. 11. "Pathologia Daemoniaca," ibid, 1632. Aikin, Biograph. Memoirs of Med. Ely, Dict. Hist.

It is true, that as the great Kepler, his contemporary, from the high respect which he bore even to the prejudices and philosophic dreams of antiquity, in his work, entitled "Harmonia Mundii," endeavors to illustrate and demonstrate the Pythagorean harmony of the spheres, and to reconcile it to geometrical laws, and the Copernican system; but as it was in this vain attempt that he made the great discovery of the elliptic orbits of the planets, his visionary analogies between the distance of the planets, and the harmonic intervals in music, have been excused. Now Fludd, anxious for the honour which he thought Kepler had gained by the very attempt which most disgraced him with posterity, in his fanciful demonstration of the music of the spheres, opposes him and his analogy with abuse and furyt, and sets up a sytem of his own still more wild and absurd; for in the third book of the first tract, entitled "De Musica Mundana," he supposes the world to be a musical instrument, resembling a monochord, extending from the summit of the empyrean heaven to the baits of the earth itself, dividing it into parts constituting consonances; so that if the half part were touched or struck, it would produce the consonant diapason, or octave, in the same manner as in the instrumental monochord. Malter doctor Fludd has given us a diagram of his sytem, representing his mundane monochord, the finger-board of which he has graduated by flats into a scale of disdiapason, to G sol re ut in the treble, and placed opposite to each note of this gamut, ascending from the earth, the elements of water, air, and fire; then the celestial bodies from the moon to Saturn, affixing a place to each orb opposite to some found of his musical scale.

After adjusting his mundane monochord, and dividing it into syllables of diatessaron, diapente, and diapason, our author, chap. iv., undertakes to demonstrate his whimsical hypotheses by the figure of a pipe or flute. But if our readers have had perseverance to follow us thus far, we can hardly suppose that their patience will last one inch farther; we shall therefore only observe, that this bewildered author, in order to enable himself to put together his system of metaphorical music, must previously have studied real practical music, concerning which, in his second tract, he speaks like other Christian fusts.

FLUDDER, or FLO-FLUFFER, in Ornithology, the name of a water-fowl of the columbus or diver-kind, described by Gellner, and some other authors, under the name of the

FLUDDER, or FLUDDE.
columbus maximus, or largest diver. See Columnus Glacialis.

FLUE, St. Nicholas de, in Biography, a very distinguished patriot of Switzerland, was born at Saxelen in 1417. Descended from an ancient family, he signalized himself in defence of his country, and particularly during the war which the Swifs supported against Sigimond, archduke of Austria. He was no less remarkable for humanity than valour. To his countrymen, when they were preparing to pillage and burn the convent of St. Margaret, near Dieffenboden, he exclaimed, "If God grants you the victory over your enemies, use it with moderation, and spare those cities which are consecrated to him." This remonstrance was effectual, and preferred the convent from destruction. To the most excellent qualities of the heart and understanding, to great political sagacity, he added the exterior graces of figure, dignity of character, and the most winning affability. Raised by his countrymen to high employments in the state, he repeatedly declined the office of landaman from motives of delicacy, because he disapproved the principles of the governing party. At length, hurried away by his detestation of evil, and a zeal for monkish devotion, he quitted his family in the 52th year of his age, and retiring from the world in a fit of gloomy superlusion, turned hermit. The place of his retreat was Ranft, a few miles from Saxelen, where he built an hermitage and a small chapel, and practised all the severities required by that austere mode of life with the strictest observance. But though he withdrew from the world, the flame of patriotism was not extinct; but he was the happy instrument in rescuing Switzerland from the impending horrors of civil discord. When a quarrel took place among the cantons, and the deputies assembled, in 1481, at Stantz, in order to compromise the difference, De Flue quitted his hermitage, and in the 64th year of his age travelled during the night, and arrived at Stantz on the morning when the deputies, having failed to terminate their dispute amicably, were preparing for their departure. He conjured them to remain; and, having by his mediation succeeded in composing the public dissensions, returned to his hermitage, where he died, in 1487, in the 64th year of his age, regretted and grieved by all Switzerland. Such a general opinion of his extreme piety prevailed among his contemporaries, that the bigotry of those times ascrib'd to him an exception from the common walk of human nature. The following epitaph was inscrib'd on his tomb: "Nicholas de Flue quitted his wife and children to go into the desert; he served God 19 years without taking any influence. He died 1487." — Coxe's Travels in Switzerland, vol. 1.

FLUR, the long tube of a chimney, from the fire-place to the top, for giving passage to the smoke. For a more particular account, see Chimneys.

FLUELLIN, in Botany. See Antirrhumin.

FLUENT, in Analysis. It is not easy to give such a definition of the term fluent as shall be intelligible to those not previously acquainted with the use of the word. And indeed mathematicians themselves differ in their conceptions of it according to the different points of view in which they have been accustomed to consider the principles of the fluxionary or differential calculus.

As the converse of a fluxion, a fluent is the flowing quantity, the rate of which increase is expressed by the fluxion. According to other writers the fluent or integral is the sum of an infinite number of small factors increasing or decreasing according to some given law, each of which may be considered as the fluxion or differential of the whole integral or fluent. See Fluxion.

According to the more accurate ideas of modern analysts, a fluent or integral is nothing more than an algebraic expression, consisting of variable quantities with or without others that are constant, which expression being expanded into a series according to certain rules, gives for the first term the fluxion or differential of which it is the fluent. In this view of the subject a fluent and its fluxion, or an integral and its differential, are merely certain analytical or symbolical relations, not depending on any theory relating to velocity, or indeed on any disputable hypotheses whatever, since it is founded on arbitrary definition alone: and it is presumed that this will be sufficient for all the purposes to which the application of the differential or integral calculus can possibly be applied. But the discussion of this subject will be again resumed under Analytic Function.

The most luminous and correct explanation of the real meaning of the term fluent is given by Mr. Woodhouse in the Transactions for 1772, in a paper on the independence of the analytical and geometrical methods of investigation. His object is to shew that analytical expressions, involved in geometrical language, are foreign to the subject, and tend to produce confused and erroneous notions. Such, for example, are the following: sin x; cos x; hypo. log. x; sin. n x = 2 cos x. sin. (n - 1) x - sin. (n - 2) x; f x (1 - x) = circular arc; f x \sqrt{1 - x^2} = elliptical arc, &c.

The value of f x (1 - x) is said to be a portion of the area of a hyperbola intercepted between two ordinates to its asymptotes; but as Mr. W. observes, this is a circunscriptory mode of expression, since to find the value of the area, (1 - x) must be expanded, and the integrals of the several terms taken, which same operation must have taken place in order to approximate to the value of f x (1 - x), if no such curve as the hyperbola had ever been invented.

Mr. W. then proceeds to explain what he himself understands by an integral or fluent of an expression. We shall use his own words.

Let x denote a function of x; if x be increased by θ then x becomes x + θ and x + θ, developed, according to the powers of θ, becomes x + P + Q x + Q x + &c., where P is derived from x, Q from P, R, Q, &c., by the same law, so that the manner of deriving P being known, Q, R, &c., are known. The entire difference or increment of x is x + θ - x; but the differential or fluxion of x + θ, is only a part of this difference, or P θ. If instead of θ, d x or θ be put, it is P d x or P + P d x; the integral or fluent of P + P d x is that function from which P + P d x is derived; and in order to remount to it, we must observe the manner or the operation by which it was deduced, and by reversing such operation the integral or fluent is obtained. Now in taking the fluxion of certain functions of x, it appears that there are conditions to which the indices of x without and under the vinculum are subject. Hence, whether not a proposed fluxion can have its fluent affined, we must see if the fluxion has the necessary conditions.

Expressions such as x, x + bx, x + bx, &c. have not these conditions; and consequently there is no function x of
FLUENT.

of \( x \), such that the second term of the development of \( \varphi \) \((x + \dot{x})\) is equal either to \( \frac{x}{x} \), or \( \frac{x}{1 + x} \), or \( \frac{x}{\sqrt{1-x^2}} \), &c. There are, however, integral equations from which such expressions may be derived. Thus, let \( x = \dot{x} \),
then \( \frac{x}{n} = \dot{x} \); let \( t + x = \dot{x} \), \( \frac{x}{1 + x} = \dot{x} \); let \( x = \frac{t}{\sqrt{1-x^2}} - \frac{1}{\sqrt{1-x^2}} \).

Now from these equations, the differential equations \( \frac{x}{n} = \dot{x}, \frac{x}{1 + x} = \dot{x} \), &c. may, by expunging the exponential quantities, be derived; consequently, if the symbol \( f \) is to designate a reverse operation, I can only know what that reverse operation is by attending to the manner in which the expressions affected with the symbol \( f \) were derived. Hence

\[
\int f(x) = z, \text{ when } x = e^t, \\
\int f(t) = z, \text{ when } t + x = e^t, \\
\int \frac{f(t)}{x} = z, \text{ when } x = (2 \sqrt{1-t})^{-1} \left\{ t - t^{-1} \right\}. \\
\int \frac{f(t)}{1 + x} = z, \text{ when } x = \left\{ e^t - 1 \right\}^{-1}.
\]

In like manner,

\[
\int f(x) = x^2 + \sqrt{1 + x^2} = e^t, \text{ or } x = \frac{\sqrt{1 + x^2} - 1}{\sqrt{1 + x^2} + 1}, \\
\int f(t) = x^2 + \sqrt{1 + x^2} = e^t, \text{ or } x = \frac{\sqrt{1 + x^2} - 1}{\sqrt{1 + x^2} + 1}, \\
\int \frac{f(t)}{x} = x^2 + \sqrt{1 + x^2} = e^t, \text{ or } x = \frac{\sqrt{1 + x^2} - 1}{\sqrt{1 + x^2} + 1}.
\]

Again, suppose \( x = \left\{ e^t - 1 \right\}^{-1} \left\{ t - t^{-1} \right\} \).

\[
\int f(x) = x^2 + \sqrt{1 + x^2} = e^t, \text{ or } x = \frac{\sqrt{1 + x^2} - 1}{\sqrt{1 + x^2} + 1}, \\
\int f(t) = x^2 + \sqrt{1 + x^2} = e^t, \text{ or } x = \frac{\sqrt{1 + x^2} - 1}{\sqrt{1 + x^2} + 1}, \\
\int \frac{f(t)}{x} = x^2 + \sqrt{1 + x^2} = e^t, \text{ or } x = \frac{\sqrt{1 + x^2} - 1}{\sqrt{1 + x^2} + 1}.
\]

And a variety of forms may be obtained by substituting

for \( x \) different functions of \( x \), in the expression \( \frac{z}{\sqrt{1-x^2}} \).

Hence if the symbol \( f \) is made to denote a reverse operation, the integral equations of the preceding differential equations have been rightly assigned. All other methods of assigning the integrals by the properties of logarithms, by circular arcs, by logarithmic and hyperbolic curves, are indirect, foreign, and ambiguous. Mr. Woodhouse next proceeds, by the above method, to integrate certain differential equations which Euler and Lagrange have before treated of, and which are said to admit for the complete integration an algebraic form, although the integration of each particular term depends on the quadrature of the circle and hyperbola.

Let \( f(x), f(y) \), denote functions of \( x \) and \( y \). Suppose the differential equation to be \( \frac{x}{n} + \frac{y}{y} = 0 \); then \( f(x) + f(y) = a \) when \( x = f(x), y = f(y) \). Hence \( x = f(x) + f(y) = a \), a constant quantity.

2dly. Let \( \frac{x}{\sqrt{1-x^2}} + \frac{y}{\sqrt{1-y^2}} = c \).

\[
\int f(x) + f(y) = a, \text{ being } \left\{ 2 \sqrt{1-t} \right\}^{-1}, \\
\int f(x) = \left\{ 2 \sqrt{1-t} \right\}^{-1} \left\{ t - t^{-1} \right\}. \\
\int f(y) = t - t^{-1}, \text{ or } x = \frac{\sqrt{1 + x^2} - 1}{\sqrt{1 + x^2} + 1}, \\
\int \frac{f(x)}{x} = \left\{ e^t - 1 \right\}^{-1} \left\{ t - t^{-1} \right\}.
\]

Again, \( f(x) = \left\{ e^t - 1 \right\}^{-1} \left\{ t - t^{-1} \right\} \).

\[
\int f(x) = x^2 + \sqrt{1 + x^2} = e^t, \text{ or } x = \frac{\sqrt{1 + x^2} - 1}{\sqrt{1 + x^2} + 1}, \text{ or } x = \frac{\sqrt{1 + x^2} - 1}{\sqrt{1 + x^2} + 1}.
\]

In like manner

\[
\int \frac{f(x)}{x} = x^2 + \sqrt{1 + x^2} = e^t, \text{ or } x = \frac{\sqrt{1 + x^2} - 1}{\sqrt{1 + x^2} + 1}, \\
\int \frac{f(x)}{1 + x} = x^2 + \sqrt{1 + x^2} = e^t, \text{ or } x = \frac{\sqrt{1 + x^2} - 1}{\sqrt{1 + x^2} + 1}, \\
\int \frac{f(x)}{\sqrt{1-x^2}} = x, \text{ or } x = \frac{\sqrt{1 + x^2} - 1}{\sqrt{1 + x^2} + 1}, \\
\int f(x) = x^2 + \sqrt{1 + x^2} = e^t, \text{ or } x = \frac{\sqrt{1 + x^2} - 1}{\sqrt{1 + x^2} + 1}.
\]

And a variety of forms may be obtained by substituting

for \( x \) different functions of \( x \), in the expression \( \frac{z}{\sqrt{1-x^2}} \).

FLÄUGGE, in Botany, so named by M. Louis Claude Richard, in honour of Mr. John Flügge, a very able German botanist of the present day, whose affilience is particularly acknowledged by professor Schradt in the first volume of his own truly excellent Flora Germanica, just imported into this country. Richard in Schradt's New Journal, v. 2. fac. r. 8. (Ophiopogon ; Gawler in Curt. Mag. v. 27. 163.) Clas and order, Alexandria Monogynia. Nat. Ord. Sartrractae, Linn. Aparatagi, Jaff.

Gen. Ch. Cal. none, except, with Richard, we take the corolla for fuch. Cor. inferior, of one petal, bell-shaped, in fix deep, equal, oval, spreading, permanent segments. Stam. Filaments fix, very short, inserted into the bafe of the corolla ; anthers oblong, vertical, erect, shorter than the corolla, somewhat arrow-shaped at the bafe. Pub. Germin superiour, in the bottom of the corolla, roundish, of three cells, with rudiments of a double row of seeds in each; style solitary, rather longer than the flamen, erect, columnar, furrowed, tapering at the fummi; stigma minutely bearded, acute. Peric. Berry superiour, globofe, when ripe generally of one cell only. Seed foliary, large, obicular, carilhous.

A. (Ophiopogon japonicus; Gawl. in Curt. Mag. r. 163,) Convallaria japonica; Thunb. Jap. 140. &c. Linn. Syst. 224. Ait. H. K. v. 1. 457. Willid. Sp. Pl. v. 2. 160. Redout. Lil. v. 2. t. 850. Mondon; Kämpf. Amer. 823. t. 824. Adamson. v. 2. 496.) Grafs-leaved Flüggea, or Japan Suckle, Native of flindy places among shrubs, near Nagasaki in Japan. Thunberg. Kept with us in greenhoufes, where it flowers in June. Thunberg made it known to the Dutch, from whose gardens we obtained roots in 1784, and who treat it as a hardy plant. The root is perennial, creeping by means of fliny horizontal flroots, which are mucilaginous and nutritive. Stem none. Leaves radical, numerous, naked, grantly, linear, recurved, blufh, flat, rough-edged, winged at the bafe with a broad thin membrane. Stalk central, solitary, much shorter than the leaves, compressed, racemous. Flowers drooping, small, white, or blue, with yellow anthers. Berry the size of a pea, of a rich deep blue. The leaves in our plants are from three inches to a foot long. Thunberg speaks of a variety in which they exceed two feet, but of this we know nothing.

This plant appears to be properly enough separated from Convallaria, on account of its habit, and perhaps the effential characters given above may serve to define the genus, which was published by the two writers to whom we have referred, in the same year, unknown to each other. We conceive the gemen is proved by analogy to be truly superior, and the ripe fruit is altogether so; nor can we account for that part of M. Richard's description which represents it as "fearred at the top by the veftige of the flower;" this, if true, would decide the fruit and gemen to be inferior. Redoute's beautiful figure faithfully represents the plants in quidion. Richard's plate is more minute as to the ftructure of the flower, and flows the gemen to be in an early flate attached to, and as it were imbedded in, the bafe of the corolla, but the more advanced flate of the fruit proves that it cannot be deemed even halff inferior, nor is it, by that mark, to be discriminated from Convallaria.

FLUIDITY, in Physis, that flate or affection of bodies which denominates or renders them fluid.

Fluidity fluids in direct opposition to ffirmnes, or fo- lidity, which see.

Fluidity is distinguished from liquidity or humidity, in that the idea of the first is absolute, and the property contained in the thing itself; whereas that of the latter is relative, and implies wetting, or adhering, i.e., somewhat that gives us the sensation of wetness, or moifure, and which would have no existence but for our fentes.

Thus melted metals, air, or ether, and even smoke, and flame itself, are fluid bodies, but not liquid ones; their parts not leaving any fene of moifure; whereas water, milk, wine, &c. are at the fame time both fluids and liquids.

The nature and caufes of fluidity have been variously affigned.

The Gaffendifts, and ancient Corpusceleans, require only three conditions as neceffary to it, viz. a smallness and smoothness of the particles of the body; vacuities interpreffed between them; and a spherical figure. Thus the Epicurean poet Lucretius:

"Illa antem debent ex levibus atque rotundis. Elle magis, fluindo quae correps liquida contraet."

The Carteifans, and after them Dr. Hook, Mr. Boyle, &c. before the circumstances above mentioned, require a various, perpetual, intertine motion of the particles of the bodies, as that which principally contributes to fluidity.

Fluidity
FLUIDITY.

Fluidity then, according to these philosophers, consists in this, that the parts of the body, being very fine, and small, are so disposed by motion, or figure, as that they can easily slide over one another's surfaces all manner of ways; and that they be in constant, various, separate agitation to and fro; and that they only touch one another in some few parts of their surfaces. Mr. Boyle, in his "History of Fluidity," mentions three conditions principally required to fluidity, viz.

1. The minutest of parts; thus, in effect, we find that fire, by dividing metals into fine, small parts, renders them fluid; and that acid meuliirum diffuses and renders then fluid after the like manner; and that fire turns the hard body of common salt almost wholly into a liquor, by distillation; not but that the figure of the particles may have a considerable fluid in fluidity.

Thus mercury, whose parts are doubtless much greater than those of oil and water, is yet more fluid than either of them: and thus oil, by the action of fire, may be converted into a constant substance like butter.

2. A number of vacuities interposed between the corpuscles, to give room for the several particles to move among themselves.

3. A motion and agitation of the corpuscles; either from some principle of mobility within themselves, or from some extraneous agent, penetrating and entering the pores, moving variously among them, and communicating to them a part of its motion.

That this last is the qualification chiefly required in fluidity, he argues from divers observations and experiments. Thus, a little dry powder of alkaline, or platter of Paris, finely sifted, being put in a vessel over the fire, soon begins to boil like water; exhibiting all the motions and phenomena of a boiling liquor. It will tumble variously in great ways like that; it will bear the jostling with a flick or lade like that, without refilling; may if strongly stirred near the side of the vessel, its waves will apparently dash against them; yet it is all the while a dry powdered powder.

The like is observed in sand; a dish of which being set on a drum-head, briskly beaten by the flicks, or on the upper floor of a mill, it in all respects emulates the properties of a fluid body. A heavy body, e. g. a stone, will immediately sink in into the bottom, and a light one emerge to the top. Each grain of sand has a constant vibratory and dancing motion; and if a hole be made in the side of the dish, the sand will spout out like water.

That the parts of fluids are in continual motion, the Cartesians evince from divers considerations: as, 1. The transformation of solids into fluids, e. g. ice into water, and vice versâ; the chief difference between the body in these two states, confining in this, that the parts being mixed and at rest in the one, refil the touch, whereas in the other, being already in motion, they give way to the flattest impulse.

2. The effects of fluids, which commonly proceed from motion: such are the infiltration of solids among the pores of bodies; the softening and dissolving of hard bodies; the actions of corrosive meuliirum, &c. Add, that no solid can be brought to a state of fluidity without the intervention of some moving or moveable body, as fire, air, or water.

Air the same gentlemen hold to be the first spring of these causes of fluidity, it being this that gives motion to fire and water, though itself receives its motion and action from the ether or subtle medium.

Boerhaave, however, pleads strenuously for fire's being the first mover, and the cause of all fluidity in other bodies, as air, water, &c. Without this, he shews that the atmosphere itself would fix into one solid mass. To the same purpose, Dr. Black maintains that fluidity is the effect of heat. The different degrees of heat which are required to reduce different bodies into a state of fluidity, he supposes, may depend on some particulars in the mixture and composition of the bodies themselves; and this is rendered further probable from considering that the natural state of bodies in this respect is changed by certain mixtures: accordingly, when two metals are compounded, the mixture is commonly more fusible than either of them separately. See Fire and Heat.

Sir I. Newton sets aside this theory of the cause of fluidity, and substitutes instead of it the great principle of attraction. The corpuscular system, with all the improvements of Descartes and Mr. Boyle, did not sufficiently account for the primary condition, requisite to constitute a body fluid, viz. the various internal motion and agitation of its parts. But this motion is naturally enough accounted for, by supposing it a primary law of nature, that as all the parts of matter attract each other within a certain distance; so at all greater distances they fly from, and avoid one another. For then, though their common gravity, together with the pressure of other bodies upon them, may keep them together in a mass, yet their continual endeavour to avoid one another singly, and the adventitious impulses of heat and light, or other external causes, may make the particles of fluids continually move round about one another, and so produce this quality.

There is a difficulty, indeed, in accounting why the particles of fluids always keep at such a distance from one another, as not to come within the sphere of one another's attraction. The fabric and constitution of that fluid body, water, are amazing; that a body so very rare, and which has a vast proportion of pores, or interposed vacuity, to solid matter, should yet be incompressible by the greatest force, as philosophers very generally, and for a long time have imagined, (see Compression:) and yet this fluid is easily reducible into that firm, transparent, friable body, which we call ice, by being only exposed to a certain degree of cold.

One would think, that though the particles of water cannot come near enough to attract each other, yet the intervening frigerosic mater doth, by being mingled per minima, strongly attract them, and is itself likewise strongly attracted by them, and so wedges or fixes all the mass into a firm solid body; which solid body takes its fluidity away, when by heat the viscillum is solved, and the frigerosic particles are disjoined from those of the water, and are forced to fly out of it. And thus may the fumes of lead, perhaps, fix quicker.

When a firm solid body, such as metal, is by heat reduced into a fluid, the particles of this new and separable its constituent parts, which their mutual attraction caused before to cohere, and keep them at such a distance from one another, as that they are out of the sphere of each other's attraction, as long as that violent motion lasts; and when by the lightness and activity they are solved off, unless they be renewed by a continual supply, the component particles of the metal will come near enough again to feel one another's attraction.

As, therefore, the cause of cohesion of the parts of solid bodies appears to be their mutual attraction, so the chief cause of fluidity seems to be a contrary motion, impressed on the particles of fluids; by which they avoid and fly one another, as soon as they come at, and as long as they keep at such a distance from each other.
It is observed also in all fluids, that the direction of their
preference against the vessels which contain them is in lines,
perpendicular to the sides of such vessels; which property,
being the necessary result of the particles of any fluid's
being spherical, shows that the parts of all fluids are to, or
of a figure very nearly approaching to it. See Fluids.

**Fluidity of the Earth, in Geology.** It has been a favourite
topic with many of the writers on the theory of the earth,
to enlarge on a supposed fluidity of the materials of which
the solid matters of the globe are now composed, not only
perpetually at the successive periods of their organic forma-
tion, but since, in consequence of the sudden and violent
disintegration or demolition of the ancient mountains and
strata, at the period when the organic remains of animals
and plants were lodged in the present strata; and which
took place, according to most of the followers of this
hypothetical, at the time of the Mosaic deluge: it is said,
however, by some late writers, that the relation of that
event, as given in the sacred writings, (and whence else
can we gain any certain knowledge of such an event?) gives
us no ground for admitting this disintegration or total de-
struction of the antediluvian earth, or the opinion of its
having been at that time reduced to a state of fluidity. In
the article Elipsoid figure of the earth, the writer of that
article has endeavoured to shew, that such fluidity of
the materials of which the globe is at present constituted,
is not any way necessary towards accounting fully for
the present form and dimensions of the earth, as resulting
from its gravitation and rotation on its axis. Those who
have contended for an entire fluid state of the earth, or at least
of so much of its materials as compose the crust thereof,
with which alone we are acquainted, surely never turned
their attention to the vast depth and quantity of water or
other fluid which would be necessary for its solution, or
even suspension, at one time, as seems necessary, or to the
circumstances under which so perfectly heterogeneous a
fluid could be supposed to deposit distinct substances, with
the surpising regularity in which the strata are disposed, in
orders totally different from that of their specific gravities.
See Order of the Strata.

**Fluids** are bodies, whose particles are but weakly
connected, their mutual cohesion being in a great measure
prevented by some interfering cause. In this sense a fluid
stands opposed to a solid.

Sir I. Newton defines a fluid body, to be that whose
parts yield to the smallest force impressed, and by yielding
are easily moved among each other.

That the particles whereof fluids consist are of the same
nature, and have the same properties, with the particles of
solids, is evident, from the conversion of liquids and solids
into each other, e. g. of water into ice, of metals into
fuels, &c. Nor can it be reasonably doubted, that the
component parts of all bodies are the same, viz. hard, solid,
impenetrable, moveable corpuses.

We observe, therefore, with Dr. Clarke, that if the parts
of a body either do not touch each other, or easily slide
over one another; and are of such a magnitude, as that
they may be easily agitated by heat, and the heat be
sufficiently great to agitate them, though it may perhaps
be less than suffices to prevent water from freezing; or,
even, though the parts be not actually moved, yet, if they
be small, smooth, slippery, and of such a figure and
magnitude as dispose them to move, and give way, that
body is fluid.

And yet the particles of such fluid bodies do, in some
measure, cohere; as is evident hence, that mercury, when
well purged of air, will be suffused in the barometer to
the height of 60 or 70 inches; that water will ascend
in capillary tubes even in vacuo; and that the drops of
liquor in vacuo run into a spherical form; as adhering
by some mutual cohesion like that between polished marble
plates. Add, that these fluid bodies, if they confit of
particles that are easily entangled within each other, as
oil, or if they be capable of being flattened by cold, and
joined by the interpolation of little cures or wedges, as
water; they are easily rendered hard; but if their particles
be not so entangled, they are movable by heat; or, if
them be not so entangled, they are movable by heat;
which was supposed to be the case with regard to quicksilver;
then they would never grow hard and
fixed. It is more probable that the primary cause of
fluidity should consist in the imperfect cohesion of the con-
fstituent parts of fluids rather than in their figure. For if
the particles of a body cohere strongly together, they
cannot easily move amongst each other. It is also evident
that the smallness of the particles of fluids will contribute
to their imperfect cohesion, because the surface of a body
composed of small particles must be more smooth and even,
than the surface of a body composed of large particles,
and two flat bodies may be conceived to consist of particles
so small that their surfaces shall differ insensibly from per-
fet planes, so that if these bodies were placed upon
one another, they would slide without the least sensible
friction. Moreover, if the particles of these bodies, thus
placed on each other, be by any means deprived of the
whole, or the greatest part of their cohesion, the bodies
will not only slide on each other in the fore-mentioned plane,
but the parts of them may also slide along each other in
any other direction whatsoever. Consequently they would
readily yield to any impressed force, and in yielding be
easily moved amongst each other, and thus constitute,
agreeably to the definition, a fluid mass. But a perfect
fluid, or that whose parts may be moved from each other
by the least force, exists only in the imagination: for inde-
dependently of its gravity or weight, or tendency towards
the centre of the earth, every non-clastic fluid possest the
attraction of aggregation (viz. of the mutual attraction of
its parts) in a particular degree; of the attraction of co-
hesion, which is likewise, in a particular degree, towards
other bodies; and of the attraction of affinity. Besides,
all fluids manifest more or less a sort of obtrusion, or
resistance to a perfectly free motion. See Affinity,
Aggregation, Attraction, Cohesion, Friction and
Resistance.

Fluids are called either natural, as water and mercury; or
animal, as blood, milk, bile, lymph, urine, &c., or fluidus,
as wines, spirits, oils, &c. See each under its proper article.

Fluids are more commonly distributed by the philo-
osophers into clastic and non-clastic. An elastic fluid is that
of which the dimensions are subject to be altered by augmenting
the pressure, and enlarged by diminishing the pressure upon it:
whereof kind are the different sorts of airs or gases. (See
Gas.) A non-clastic fluid is that, whose dimensions are not,
at least as to length, affected by the increase of pressure,
as mercury, water, &c. These latter are said to be non-
clastic, or incompressible, not because they are absolutely so;
but because their compressibility is so very small, as to
make no sensible difference in our calculations relative to
the pressures, movements, and other properties of these fluids.
See Compression.

The doctrine and laws of fluids are of the greatest extent
in philosophy. The pressure and gravitation of bodies in
fluids, and the action of the fluids in them, make the
subject of Hydrostatics, which see.

**Fluids, Hydrostatics** &c. 1. The upper parts of
all fluids, as water, &c. do pres upon the lower; or, as some philosophers state it, all fluids do gravitate in proprio loco.

The contrary of this was a principle in the school-philosophy; and two iacs have been commonly urged in support of it. A bucket full of water is lighter in the water than out of it, nor does it weigh more when full in the water, than when empty out of it; therefore, it has been concluded, that the water in the bucket, because it is within water, its own el-ment, does not gravitate: and divers, who descend to considerable depths, it has been said, feel no sensible preffure under water; though at the depth of thirty-two feet, the additional preffure they fulfill is not less than twenty thousand avoidpous pounds: for, supposing the surface of the body to contain only ten square feet, and a cubic foot of water to weigh one thousand avoidpous ounces, 32 x 10 feet, or 16 x 20 feet of water will weigh 16 x 20,000 avoidpous ounces, or twenty thousand pounds. However, in this case the uniformity of the pressure, the increased elasticity and refilance of the compreffed internal air, and the firm texture of the membrances, &c. may prevent their complaining of any sensible pain: though there have been many instances to the contrary, in which the difference of the preffure has produced very injurious effects. See Diving.

As to the former fact, it is easily explained by the theory of specific gravity, (which fee). The bucket of water weighs in water, but does not overweigh; because the surrounding parts of water endeavour to descend as well as the bucket, and with equal force, and therefore do not permit it to descend. Thus, according to an observation of Dr. Defaguliers, if two pound weights were hung at the two arms of a balance, no one will say, that neither weighs, because it does not outweigh the other. Defag. Exp. Phil. vol. ii. p.96.

Besides, it is evident, that, in any fluid, the weight of the whole is equal to the weight of all its parts; and if any part be taken from the whole, the weight of the whole will be diminished by the weight of that part; and if any part be added to the whole, the weight of the whole will be increased by the weight of the part which was added; and, therefore, it is reasonible to conclude, that the weight of the whole is composed of the weights of the several parts, and that the parts do, therefore, gravitate in the whole, or in proprio loco. (Cotes's Hyd. and Pneum. Lectures, p. 7.) But the certainty of such preffure is now demonstrated by a thousand experiments; it will be sufficient to instance one or two.

Immerge a tube, open at both ends, and half filled with oil of turpentine, in a vessel of water, the upper end of the tube being stopped with the finger: if now the upper surface of the oil be as low as that of the water, the oil, upon removing the finger, will not run out at the lower end of the tube; but, and if the tube be thril a little lower, the water will rise up in it, and bear the oil above it; but if the upper surface of the oil be considerably higher than that of the water, the oil will drop out of the tube. Whence it follows, that the column of oil in one cafe preffes or gravitates less on the plane imagined to pass under its lower surface than a column of water; and in the other cafe more.

Or thus: a phial, with as much flux in it as will make it sink, clofe flux, being immerged in water, and fupforded by a robe-f'airf to the beam of a balance, with a weight at the other end exactly counterpoofing it: upon unlopping the phial, and filling it with water, it will preponderate, and bear down the end of the balance, without having any communication with the external air. And if the phial had been initially weighed in air, it will be found, that the weights necessary for reftoring its equilibrium in water answer exactly to the additional weight of the phial, when it is again weighed in water with the water in it: so that water weighs in water just as much as in air.

These two experiments abundantly prove the propagation, that the upper parts of fluids do really preff or gravitate on the lower. See Specific Gravity.

From this gravity it follows, that the surfaces of flangent fluids are plain and parallel to the horizon; or rather, that they are segments of a sphere or spheroid concentrical with the earth, because they all gravitate towards the cenfus of the earth.

For, as the particles are suppolled to yield to any force imprefsed, they will be moved by the action of gravity, till such time as none of them can defend any lower. And in this fution, once attained, the fluid must remain at rest, unless put in motion by some foreign caufe; inasmuch as none of the particles can now move without ascending, contrary to their natural tendency.

In this cafe the centre of gravity of the fluid, contained in a vefsel open at top, will lie as low as it possibly can. Thus, let A B D C (Hydraulics. Plate V. fig. 1.) represent one fide of a rectangular vefsel, containing water as high as E F, whole centre of gravity is G; it is easy to prove that when the surface of the water is flat and horizontal, as E F, then the centre of gravity of the water lies lowest; but that if the water be elevated on any part of that furface, and of course lowered on any other part, then the centre of gravity will be removed to some place higher than G. Imagine that the water be difpofed into the fution D K B C, viz. that the portion K E H B is removed to the place B H F; and in this cafe the centre of gravity L of the quantity of water K D H F C remains in its original fution, whilst the centre of gravity of the quantity of water K E H B has been removed higher, viz. from I to S. Now, since the common centre of gravity of two bodies is in a straight line between the repective centres of gravity of those bodies; therefore, the common centre of gravity of both the quantities of water formerly laid at G, is in the line I S; whereas it now flands at O in the line L S, viz. evidently higher than the level of G, which is the line L O. This reafoning, applied to one fide of the vefsel, may be easily adapted to any fection of the water and vefsel, as also to veftils of any shape, and to any irregularity which the surface of the water may be put to acquire; for in any cafe the conclusion is exactly the fame, namely, that the centre of gravity of a given quaitity of some uniform fluid, like water, which is contained in an open veftel of any shape, flands at the loweff possible situation, when the whole surface of the fluid is in the fame horizonal line.

If a body be immersed in a fluid, either wholly, or in part, its loweff face will be preffed upwards by the water and creafht it; and the preffure of fluids upwards is equal to the preffure downwards at the fame place.

The truth of this propofition is evident from the experiment above mentioned, where the oil of turpentine was fupfended and made to mount up in the tube, by the preffure of the water upwards on its lower parts. Thus also, if the upper end of a narrow bored tube be efvved into quick-filver, whilst the other end is fupened with the fingers, and the tube be filled up, a part column of quick-filver will be fupfended in the lower end, whole column, when diipped into water deeper than about twenm times its own length,
will be pressed upwards, after the finger is removed from the orifice.

This upward pressure of fluids may be evinced by causing a piece of lead, &c. to swim in water; which may be done by immersing it to a proper depth, and keeping the water from getting above it. Let C D, Plate V. Hydrodynamics, Fig. 2, be a glass tube opened at both ends, and E F G a flat piece of lead, half an inch thick, exactly fitted to the lower end of the tube, which its upper surface covered with wax, so as to hinder the entrance of the water contained in the outer vessel. Let this leaden plate be held close to the tube, by pulling the string or wire J H L upward at I, with one hand, whilst the tube is held in the other by the upper end C. In this situation, let the tube be immered in water in the glass-veiled A B, to the depth of six inches below the surface of the water at K; and then the leaden plate E F G will be plunged to the depth of somewhat more than eleven times its own thickness: holding the tube at that depth, you may let go the wire or thread at L; and the lead will not fall from the tube, but will be kept to it by the upward pressure of the water below it, occasioned by the height of the water at K above the level of the lead. For, as lead is 11.33 times as heavy as its bulk of water, and in this experiment is immered to a depth somewhat more than 11.33 times its thickness, and no water getting into the tube between it and the lead, the column of water E a b c G, below the lead, is pressed upwards as much by the water K D E G L, all round the tube; which water, being a little more than 11.33 times as high as the lead is thick, is sufficient to balance and support the lead at the depth K E. If a little water be poured into the tube upon the lead, it will increase the weight upon the column of water under the lead, and cause the lead to fall from the tube to the bottom of the glass vessel, where it will lie in the situation b d; or if the tube be raised a little in the water, the lead will fall by its own weight, which will then be too great for the pressure of the water round the tube on the column of water below it. If the plate were brass instead of lead, it ought to be immered under water at least eight times its thickness, in order to be supported by the water; because brass is about eight times specifically heavier than water. A plate of pure gold would require near twenty times its thickness of water; and this led Mr. Boyle to propone one of his hydrodynamical paradoxes in these words, \( \text{\textit{Ter}} \). That a solid body, as ponderous as any yet known, though near the top of the water it will sink by its own weight, yet immered in water at a greater depth than that of twenty times its thickness, will not sink, if its denser be not affected by the weight of the immerced water. (Paradigm 11. Statics. Boyle's Works, abr. by Shaw, vol. ii. p. 311.)

As we have now seen that the heaviest body may be made to swim in water, the lightest wood may be made to lie at the bottom of water or mercury. Thus, let two pieces of wood be planed quite flat, so that no water may get between them when they are put together; let one of them, b d, be cemented to the bottom of the vessel A B, Fig. 2. and the other be laid flat and close upon it, and held down with a flick, whilst water is poured into the vessel, then remove the flick, and the upper piece of wood will not rise from the lower one, for as the upper one is pressed down both by its own weight and the weight of water over it, whilst the contrary pressure of the water is kept off by the wood under it, it will lie as well as the heaviest body: but if it be raised at the edge, so that the water may get under it, it will immediately be pressed upwards; and as it is lighter than its bulk of water, it will rise and float on the surface of the water. See Ferguson's Lectures, 4to. p. 68. and Cotes' Hyd. Lev. 2. See Hydrostatical Experiments, and Art. 11. in the sequel.

The law or quantity of this pressure in this; that a body immered in a fluid loses just so much of the weight it would have in air, as so much of the fluid as is equal to it in bulk, if weighed in the air, would amount to.

This pressure of fluids on the lower parts of an immered body is farther confirmed, by attending to the reason why bodies, specifically lighter than fluids, ascend therein. The effect is owing to this, that there is a greater pressure or weight on every other part of the plane or surface of the fluid imagined to pass under the lower surface of the body, than there is on that wherein the emerging body inflicts. Consequently, to produce an equilibrium in the fluid, the parts immediately under the rising body being pressed by the rent every way, do continually force it upwards.

In effect, the emerging body is continually pressed on by two columns of water, one bearing against its upper and the other against its lower parts: the length of both which columns being to be estimated from the top of the water, that which presses on the lower part will be the longer, by the thickness of the ascending body, and consequently will overbalance it by the weight of as much water as will fill the space that body takes up.

Hence, 1. We are furnished with one reason, why very minute corpuscles, either heavier or lighter than the liquor they are mingled with, will be sustained therein a good while, without either emerging to the top, or precipitating to the bottom; the difference between the two columns of the fluid being here inconceivable.

Hence, 2. If a body A be specifically lighter than B, an equal portion of the fluid in which it is immered, it will rise with a force proportionable to the excess of gravity of B above A; and if A be specifically heavier than B, it gravitates and descends with the excess only of its weight above that of B.

Hence, 3. We have, as some say, a solution of the phenomenon of two polished marbles or other planes adhering so strongly together; because the atmosphere presses or gravitates with its whole weight on the under surface and sides of the lower marble, but cannot do so at all on its upper surface, which is closely contiguous to the upper and fulscended marble. See Coxi's Hydrodynamics.

3. The pressure of the upper parts of a fluid on the lower exerts itself in every way, and every way equally, laterally, horizontally, and obliquely, as well as perpendicularly.

For, as the parts of a fluid yield to any impression, and are easily moved, it is impossible any drop should remain in its place, if, while it is pressed by the superficemont fluid, it be not equally pressed on every side.

The fame is confirmed from experiments: for several tubes of divers forms, straight, curved, angular, &c. being immered in the same fluid, though the apertures through which the fluid enters be differently polised to the surface of the plate, some being perpendicular others parallel, and others variously declined; yet will the fluid rise to an equal height in them all. See STYPON.

Hence, 1. All the particles of fluids being thus equally pressed on all sides, it is argued, that they must be at rest, and not in continual motion, as has been usually supposed.

Hence, 2. Also, a body being immered in a fluid, sustains a lateral pressure from the fluid; which is also increased as the
the body is placed deeper beneath the surface of the fluid.

4. In tubes that have a communication with each other, whatever their magnitude be, whether equal or unequal; and whatever their form, whether straight, angular, or crooked; still fluids rise in them to the same height.

5. If a fluid rise to the same altitude in two tubes that communicate with each other, the fluid in one tube is a balance, or equal in weight to that in the other.

If the tubes be of equal diameters, the columns of the fluid, having the same base and altitude, are equal, and consequently their gravities equal; so that they presst and gravitate against each other with equal force.

This is demonstrated from mechanics. E. gr. Let the base of GI, Plate V. Hydraulica, fig. 3. be supposed quadruple the base of HK; and let the fluid descend in the greater tube the space of an inch, as from L to O; it will then rise in the other the space of four inches, as from M to N. Wherefore the velocity with which the fluid moves in the tube HK is to that with which it moves in GI as the base of the tube GI to the base of the other, HK. But the altitude of the fluid being supposed the same in both tubes, the quantity of the fluid in the tube GI will be to that in the other tube HK, as the base of the tube GI to the base of the other HK.

Consequently, the momentum of the fluid in the tube GI is to that in the tube HK, as the product of the base of the tube GI into the base of the other HK, to the factum of the tube HK into the base of the other GI. Wherefore, the products being equal, the moments must be equal.

The same is easily demonstrated where one of the tubes is inclined, and the other perpendicular, &c.

6. In communicating tubes, fluids of different specific gravities will equiponderate, if their altitudes be in the ratio of their specific gravities.

Hence we have a way of finding the specific gravities of fluids, viz. by pouring one fluid into one of the communicating tubes, as AB (fig. 4.) and another into the other tube CD; and measuring the altitudes GB and HD, at which they stand when balanced.

For the specific gravity of the fluid in A B is to that in DC, as DH to BG. If the fluids employed in this experiment be apt to mix, it may be proper to fill the horizontal tube BD with mercury to prevent the mixture.

Hence, since the densities of fluids are as their specific gravities, the densities will likewise be as the altitudes of the fluids DH and BG; so that we have hence likewise a method of determining the densities of fluids.

7. The bottoms and sides of vessels are pressed in the same manner, and by the same laws, as the liquids contained in them.

And hence, as action and reaction are equal, the fluids themselves sustain an equal pressure from the bottoms and sides. And as the pressure of fluids is equal every way, the bottoms and sides are pressed as much as the neighbouring parts of the fluid; and consequently this action increases in proportion to the height of the fluid, and is equal every way at the same depth; as depending altogether on the height, and not at all on the quantity of the fluid.

8. In perpendicular vessels of equal bases, the pressure of fluids on the bottoms is in the ratio of their altitudes. This is evident, because, the vessels being perpendicular, the bottoms are horizontal; consequently the tendency of fluids by the action of gravity will be in lines perpendicular to the bottoms, so that they will press with all their weight; the bottoms therefore are pressed in the ratio of the gravities. But the gravities are as the bases, and the bulks here are as the altitudes; therefore the pressure on the bottoms are as the altitudes.

9. In perpendicular vessels of unequal bases, the pressure on the bottoms is in a ratio compounded of the bases and altitudes.

From the preceding demonstration it appears, that the bottoms are pressed in the ratio of the gravities; and the gravities of fluids are as their bulks, and their bulks in a ratio compounded of the bases and altitudes. Consequently, &c.

10. If an inclined vessel ABCD, fig. 5. have the same base and altitude with a perpendicular one, B E F G. the bottoms of the one and the other will be equally pressed.

For, in the inclined vessel ABCD, the bottom CD is pressed in the direction BD. But the force of gravity in the direction BD is to the absolute gravity, as BE to BD. Consequently, the bottom CD is pressed in the same manner, as if it had been pressed perpendicularly by the fluid under the altitude BE. Therefore, the bottoms of the perpendicular and inclined vessels are equally pressed.

11. Fluids press upon subjacent bodies, according to their perpendicular altitude, and not according to their latitude, or breadth.

Or, as others state it, thus: If a vessel be taper, or unequally big at top and bottom, yet the bottom will be pressed after the same manner as if the vessel were cylindrical, and the top and bottom equal.

Or thus: The pressure sustained by the bottom of a vessel, whatever the figure of the vessel be, is ever equal to the weight of a column of the fluid, whose base is the bottom itself, and height, the vertical distance of the upper surface of the water from the bottom.

Or, yet more explicitly, thus: If there be two tubes or vessels, having the same heights, and bases, both filled with water; but one of them made to taper upwards that it shall contain but twenty ounces of water; whereas the other, widening upwards, holds two hundred ounces; yet the bottoms of the two tubes shall sustain an equal pressure of water, viz. each of them at the weight of two hundred ounces.

This is a noble paradox in hydrostatics, first discovered by M. Paofchal, and which it well worth the clearing and infilling on. It is found unexceptionably true from actual experiments; and it may even be demonstrated and accounted for on principles of mechanics.

Suppose, e. g. the bottom of a vessel C D (fig. 6.) less than its top A B; since the fluid presses the bottom C D, which we suppose horizontal, in a perpendicular direction E G, but that part of the cylinder B C D F, can press upon its natural buoyancy and pressure of the water being taken off the sides.

Again, supposing the bottom C D (fig. 7.) much bigger than the top F G; or even for the water demonstrates, suppose a tube E F, fixed in a cylinder A B C D; and suppose the bottom C D raised to L, that the fluid may be moved through the interval D L; then will it have risen through the altitude G L, which is to D L, as the base C D to that of G E. The velocity, therefore, of the fluid E F is to its velocity in the vessel A D as the base C D to the base F G.

Hence we have the momentum wherewith the fluid in the tube tends downwards, by multiplying the base of the cylinder C D into its altitude C H.
FLUIDS.

Consequently the bottom C D is pressed with the same force, as it would be pressed by the cylinder H C D L.

To confirm and illustrate this doctrine of the pressure of fluids in the ratio of the base and altitude, provide a metallic vessel A C D B (fig. 7.) so contrived, as that the bottom C D may be moveable, and to that end fitted in the cavity of the vessel with a rim of wet leather, to slide freely without letting any water pass. For this purpose it would be most advisable, that the moveable bottom should have a groove round its edge, and that it be put into a bladder, tied close round it the groove by a strong waxen thread; and the bladder may be made to come up like a purse within the vessel, and put over the top of it at A and B all round, and then the lid of the vessel pressed on it: so that when water is poured through a hole in the lid, it would lie upon the bottom C D, and be contained within the bladder.

Then, through holes in the top A B, apply successively several tubes of equal altitudes, but of different diameters. Lastly, fastening a string or wire to the beam of a balance, and fixing the other end by a little ring K to the moveable bottom, put weights in the other scale, till they be sufficient to raise the bottom C D; then will you not only find, that the height is required, what diameter or magnitude ever the tube be of; but even, that the weight which will raise the bottom when pressed by the faulked tube, will raise it when pressed by the whole cylinder H C D L.

Suppose the vessel A B C D to hold about a pound of water, and that the moveable bottom, wire, and hook, are of equal weight with an empty scale M. When this scale is pulled down, the bottom C D will be drawn up within the box, and that motion will cause the water to rise in the glass tube E F G. If one pound be put into the scale, the bottom will be moved a little, and the water will just appear at the lower end of the tube at a. Another pound will cause it to rise from a to b, just twice as high above the bottom as it was when at a; the pressure of the bottom being equal to two pounds, the counterbalancing weight in the scale M. A third pound will raise it to c, a fourth to d, &c. the distances a b, b c, c d, &c. being taken equal to each other and to the depth of the vessel. If another tube, as /, be put into a hole made in the top of the vessel, and the vessel be filled with water; and, then, if water be poured in at the top of the tube F G E L, it will rise in the tube / to the same height as it does in the other tube: from hence it is evident, that the upward pressure of the water, rising in the tube /, is equal to the downward pressure in the other tube F G E L: the cafe would be the same, whatever be the number of tubes; and the moveable bottom would sustain the weight of the water in all the tubes, besides the weight of all the water in the vessel; and if all the holes to which these tubes (F G E L excepted) were fixed be stopped up, each part, thus stopped, will be pressed upward with a force equal to the weight of water in each tube: and consequently, the whole upward pressure against the top of the vessel, rising from the weight or downward pressure of the water in the tube F G E L, will be equal to the weight of a column of water of the same height with that in the tube, and of the same thickness as the width of the base of the box or of the moveable bottom; and this upward pressure against the top will reach downwards with equal force against the bottom.

If the diameter of the moveable bottom be three inches, the same, and the diameter of the bore of the tube a quarter of an inch, their squares will be nine inches and one sixteenth of an inch; and therefore the whole area of the bottom will be a hundred and forty-four times as great as that of the area of the bottom or top of the tube: so that if the moveable bottom be raised one inch, the water would be raised to the top of a tube a hundred and forty-four inches, or twelve feet in height. The vessel must be open below the moveable bottom, let it to the air; otherwise the pressure of the atmosphere upon it, supposing its diameter three inches, would require a counterbalancing of a hundred and eight pounds in the scale M before the bottom would begin to move. See Hydrostatic Bellows.

12. From the preceding articles, we may easily deduce a method of estimating the quantity of pressure of fluids on any given surface. Let a b c d (fig. 8.) represent a cubical vessel full of water; the side a c will therefore, represent a square; and the measure of the pressure on every physical point of a c will be the altitude of the water above that point; thus, the pressure on l is measured by a l, on m by a m, &c. and the pressure on the whole line will be measured by the sum of as many altitudes a l, a m, &c. as there are points in the line a c. Erect perpendiculars l b, m p, &c. respectively equal to a l, a m, &c. and the sum of these perpendiculars will be the measure of the whole pressure on the line a c: but the sum of these is equal to the area of the triangle a c d; and, when the line a c d is supposed to represent a square, the triangle a c d must represent a prism, having the said triangle for its base, and the side of the square for its altitude: the weight of that prism of water is, therefore, equal to the pressure made against the square, or side of the cube; which, as the prism is half the cube, is equal to half the weight of the whole water contained in the vessel; and as each side bears the same degree of pressure, all the four sides sustain four times half the weight, or twice the whole weight of the water; and because the bottom sustains a pressure equal to the whole weight of the water, the bottom and sides of a cubical vessel taken together sustain a pressure from the water contained in it equal to twice its weight. The fame observation may be easily applied to planes that are oblique to the horizon; and we may conclude universally, that the pressure upon any plane, of whatever figure and situation, is equivalent to the weight of a solid of water, formed by erecting perpendiculars upon every point of the plane proposed, equal to the respective distances of those points from the upper surface of the water; on the pressure on any surface is equal to the sum of all the products which are made by multiplying every indefinitely small part of the surface into its distance from the top of the water. To find the sum of all these products, or a body of water equal to that sum, is, in most cases, a difficult problem: Stevius has attempted the solution of it in few instances, confining himself to regular plain surfaces. Mr. Cotes has laid down the following universal and expedient rule: the pressure on any surface is equal to the weight of a body of water whose magnitude is found by multiplying the surface proposed into the depth of its centre of gravity under water; and the pressure on any number of surfaces of different bodies, however differently situated, is equal to the weight of a body of water whose magnitude is found by multiplying the sum of all those surfaces into the depth of their common centre of gravity under water. The determination of this rule depends on the following theorem, viz. that the force of its produce arising from multiplying every indefinitely small part of any surface, or number of surfaces, respectively, into its perpendicular distance from any proposed plane, will be equal to the product of the whole surface or number of surfaces multiplied into the perpendicular distance of the centre of
of gravity of any single surface, or of the common centre of gravity of the whole number of surfaces from the same plane. Thus, let \( a, b, c, d \) (fig. 9) represent weights, hanging at their centres of gravity \( a, b, c, d \), by the lines \( a, b, c, d, e, f, g, h \) fixed to a horizontal plane \( e, f, g, h \); and let \( z \) be the common centre of gravity of all the weights, and \( z \) its perpendicular distance from the said plane. Let \( x \) be the common centre of gravity of \( a, b, e \), and to \( x \), drawn parallel to the ref, let \( a x \) and \( b x \) be perpendicular. In the similar triangles \( m x a \), \( n x b \) and \( m x n x z : (x a : x b : i \cdot b : a \).

(See Center of Gravity.) Therefore \( ax + bx = b n x \); i.e. \[ \begin{align*}
ax + bx &= b n x \\
ax + bx &= x z + xo, \text{and, consequently, } ax + bx + xo &= n = a + b + x = a + b + x + xo.
\end{align*} \]

In the common centre of gravity of \( a, b \) suspend a weight \( x = a + b \), and a weight \( y = x + c \) in the common centre of gravity of \( x \) and \( c \), and a weight \( z = y + d \), in the common centre of gravity of \( y \) and \( d \). Then \( z \) is the common centre of gravity of \( a, b, c, d \). And we have (as above) \[ \begin{align*}
a x + a x + b x + b x &= b n x, \\
x x o + x c o = x y o, \text{and } x y o + d o = z x o, \text{ consequently, } a x + a x + b x + b x &= x z + xo, \\
and this will be the case, if the suspended lines \( a, c \) are perpendicular to any plane, though not parallel to the horizon. Now taking the upper surface of water for that plane to which we refer the indefinitely small parts of the surface which is exposed to the preffure we are concerned with; since it has been already shown, that the preffure upon the whole is equivalent to the weight of a body of water which is equal in magnitude to the sum of all the products, made by multiplying every little part by its distance from the upper plane of the water; and that this sum of products is exactly equal to the product of the whole surface or number of surfaces multiplied into the distance of the centre of gravity from the upper plane of the water; it will follow, that the same product is the measure of a magnitude of water, whose weight is equivalent to the preffure required. Cotes's Hydrost. Lect. 3. See Center of Preffure.

For the laws of the preffure and gravitation in fluids specifically heavier, or lighter, than the bodies immerged, see Gravity, Specific.

For the laws of the resistance of fluids, or the retardation of solid bodies moving in fluids, see Resistance.

For the ascent of fluids in capillary tubes, or between glafs planes, see Ascent and Capillary Tubes.

The motions of fluids, and particularly water, do also make the subjéct of Hydraulicæ, which see.

Fluids, Hydrostatic Laws of 1. The velocity of a fluid, as water, moved by the preffure of a superincumbent fluid, as air, is equal at equal depths, and unequal at unequal ones.

For the preffure being equal at equal depths, the velocity arising thence must be to one; and vice versa: yet the velocity does not follow the same proportion as the depth, notwithstanding that the preffure, whence the velocity arises, does increase in the proportion of the depth. But have the quantity of the matter is concerned in the quantity of motion, which is compounded of the ratio of the velocity and quantity of matter, is increased in equal times as the squares of the velocities.

2. The velocity of a fluid arising from the preffure of a superincumbent fluid, at any depth, is the same as that which a body would acquire in falling from a height equal to the depth: as is demonstrated both from mechanics and experiments. See Descent. See also Discharge of Fluids.

3. If two tubes of equal diameters, full of any fluid, be placed in any position, either erect, or inclined; provided they be of the same altitude, they will discharge equal quantities of the fluid in equal times.

That tubes, every way equal, shou'd, under the same circumstances, empty themselves equally, is evident; and that the bottom of a perpendicularly tube is preffed with the same force as that of an inclined one, when their altitudes are equal, ha's already been shewn. Whence it easily follows, that they must yield equal quantities of water, &c.

4. If two tubes of equal altitudes, but of unequal apertures, be kept confluently full of water, the quantities of water they yield in the same time will be as the diameters; and this, whether they be erect, or any way inclined.

Hence, if the apertures be circular, the quantities of water emptied in the same time, ought to be as a duplicate ratio of the diameter.

But this law, Mariotte observes, is not perfectly agreeable to experiment. If one diameter be double the other, the water flowing out of the less is found more than a fourth of what flows out of the greater. But this may have been owing to some accidental irregularities in making the experiments.

Voltaire however ascribes it principally to this, that the column of water directly over the aperture is shorter than that next the sides or parietes of the vessel: for the water, in its eflus, forms a kind of cavity over the aperture; that part immediately over it being evacuated first, and the other water not running fast enough from the sides to supply it. Now, this cavity, or diminution of altitude, being greater in the greater tube than in the less; hence the preffure, or endeavour to pass out becomes proportionally less in the greater tube than in the less.

5. If the apertures \( F \) of two tubes \( A, B \) and \( C, D \) (Hydraulics. Plate VI. fig. 1 and 2.) be equal, the quantities of water discharged in the same time will be as the velocities.

6. If two tubes have equal apertures \( E \) and \( F \), and unequal altitudes \( A, B \) and \( C, D \), the quantity of water discharged from the greater \( A, B \), will be to that discharged from \( C, D \), in the same time, in a subduplicate ratio of the altitudes \( A, B \) and \( C, D \).

Hence, 1. The altitudes of water, \( A, B \) and \( C, D \), discharged through equal apertures \( E \) and \( F \), will be in a duplicate ratio of the water discharged in the same time. And as the quantities of water are as the velocities, the velocities are likewise in a subduplicate ratio of their altitudes.

Hence, 2. The ratio of the water discharged by two tubes \( A, B \) and \( C, D \), together with the altitude of one of them, being given, we have a method of finding the altitude of the other, viz. by finding a fourth proportional to the three given quantities; which proportional, multiplied by itself, gives the altitudes of \( C, D \), required.

Hence, also, 3. The ratio of the altitudes of two tubes of equal apertures being given, as also the quantity of water discharged by one of them, we have a method of determining the quantity the other should discharge in the same time.

Thus, to the given altitudes, and the square of the quantity of water discharged at one aperture, find a fourth proportional. The square root of this will be the quantity of water required.

Suppose,
Support, e. gr. the height of the tubes as $9$ to $25$, and the quantity of water discharged at one of them, three inches; that discharged by the other will be $\sqrt{\frac{9^2 + 25^2}{9}} = \sqrt{\frac{81 + 625}{9}} = \sqrt{70.5} = 8.4$.

7. If the altitudes of two tubes $A$ and $C$ be unequal, and the apertures $E$ and $F$ be likewise unequal, the quantities of water discharged in the same time, will be in a ratio compounded of the simple ratio of the apertures, and the subduplicate one of the altitudes.

And hence, if the quantities of water discharged in the same time by two tubes, whose apertures and altitudes are unequal, be equal, the apertures are reciprocally as the roots of the altitudes, and the altitudes in a reciprocal ratio of the squares of the apertures.

8. If the altitudes of two tubes be equal, the water will flow out with equal velocity, however unequal the apertures be.

9. If the altitudes of two tubes, $A$ and $C$, as also their apertures, $E$ and $F$, be unequal, the velocities of the waters discharged are in a subduplicate ratio of their altitudes.

And hence, 1. As the velocities of waters flowing out at equal apertures, when the altitudes are unequal, are also in a subduplicate ratio of the altitudes, and as this ratio is equal if the altitudes be equal, it appears in the general, that the velocities of water flowing out of tubes, are in a subduplicate ratio of their altitudes.

Hence also, 2. The squares of the velocities are as the altitudes.

Mariotte found, from repeated experiments, that if a vessel $A$ $B$ $C$ $D$ have a tube $E$ $G$ fitted to it, there will more water be evacuated through the tube, than there could have been, in the same time, through the aperture of the vessel $E$ without the tube; and that the motion of the fluid is accelerated so much the more, as the tube $E$ $G$ is the longer.

E. gr. The altitude of a vessel $A$ $C$ being one foot, that of the tube $E$ $G$ three feet, and the diameter of the aperture three lines, no less than $\frac{41}{5}$ septiers of water were discharged in the space of one minute; whereas, upon taking off the tube, only four septiers were discharged.

Again, when the length of the tube $E$ $G$ was six feet, and the diameter of the aperture $G$ an inch, the whole quantity of water run out in thirty-six seconds; but cutting off half the tube, the vessel was not evacuated in less than forty-five seconds; and taking it quite away in less than fifty seconds.

10. The altitudes and apertures of two cylinders full of water being the same, one of them will discharge double the quantity of water discharged in the same time by the other, if both be kept continually full, while the other runs itself empty; for the velocity of the full vessel will be equally, and that of the other will be continually retarded. Now it is demonstrated, that, if two bodies be impelled by the same force, and the one projected equally, and the second equally retarded, by the time they have lost all their motion, the one has moved double the space of the other.

If two tubes have the same altitudes, and equal times wherein they will empty themselves, the squares of the altitudes are in the ratio of their rates.

Cylindrical and prismatic vessels, as $A$ $B$ $C$ $D$ (fig. 3), empty themselves by this law, that the quantities of water discharged in equal times decrease, according to the unities $1, \frac{1}{5}, \frac{1}{7}, \frac{1}{9}, \cdots$ taken backwards.

For the velocity of the descending liquid $F G$ is continually decreasing in the subduplicate ratio of the decreasing altitudes; but the velocity of a heavy body descending, increases in the subduplicate ratio of the increasing altitudes. The motion, therefore, of the liquid $F G$, in its descent from $G$ to $B$, is the same as if it were to descend in the inverse ratio of the altitudes; but if it descend from $B$ to $G$, the spaces, in equal times, would increase, according to the progression of the uneven numbers; consequently the altitudes of the level $F G$, in equal times, would decrease, according to the same progression inversely taken.

Hence, therefore, the level of water $F G$ descends by the same law, as, by an equal force impressed, it would ascend through an altitude equal to $B G$.

From this principle, many other particular laws of the motion of fluids might be demonstrated, which, for brevity sake, we here omit. See Discharge of Fluids.

To divide a cylindrical vessel into parts, which shall be evacuated in certain parts or divisions of time, see CLIPSIDRA.

13. If water, descending through a tube $H E$ (fig. 4.) spout up at the aperture $G$, whose direction is vertical, it will rise to the same altitude $G I$, at which the level of the vessel $L M$, in the vessel $A$ $B$ $C$ $D$, does stand.

For since the water is driven through the aperture $G$ by the force of gravity, if its velocity will be the same as that with which a body, by the same force impressed, would rise to the altitude $F I$; wherefore, since the direction of the aperture is vertical, the direction of the water spouting through it will be fo too; consequently the water must rise to the height of the level of the water $L M$ in the vessel.

Indeed, by the experiment, it appears, that the water does not rise quite so high as $I$: besides the aperture $G$ should be smaller, as the height of the level of the water is less; and even smaller when mercury is to be spouted than when water. But this is no objection to the truth of the theorem; it only shews that there are certain external impediments, which diminish the ascents.

Such are, the resistance of air, and the friction of the tube, &c. See Jet d'Eau.

14. Water, descending through an inclined tube, or a tube bent in any manner, will spout up, through a perpendicular aperture, to the height at which the level of the water in the vessel stands.

15. The lengths of spaces $D E$ and $D F$, or $I H$ and $I G$, (fig. 5.) to which water will spout either through an inclined, or an horizontal aperture $D$, are in a subduplicate ratio of the altitudes in the vessel or tube $A$ $B$ and $A$ $C$.

For since water, spouted out through the aperture $D$, endeavours to proceed in the horizontal line $D F$ and, at the same time, by the power of gravity, tends downwards in lines perpendicular to the same; nor can the one power hinder the other, inasmuch as the directions are not contrary; it follows, that the water, by the direction $D A$ will arrive at the line $1 G$ in the same time wherein it would have arrived at it, had there been no horizontal impulse at all. Now, the right lines $I H$ and $I G$ are the spaces which the same water would have described in the mean time by the horizontal impetus; but the spaces $I H$ and $I G$, inasmuch as the motion is uniform, are as the velocities; consequently the velocities are in a subduplicate ratio of the altitudes $A$ $B$ and $A$ $C$; and therefore the length or distances, to which the water will spout in apertures either horizontal or inclined, are in a subduplicate ratio of the altitudes.

That
FLUIDS.

That the velocities are in the subduplicate ratio of the altitudes may be shown by experiment; for, let two pipes, as C and g, of equal fixed bores, be fixed into the side of the vessel A B (fig. 6.) and let the pipe g be four times as deep below the surface of the water at h, in the vessel, as the pipe C is; and whilst these pipes run, let the water be constantly poured into the vessel, to keep the surface at the same height. Then a vessel, holding a pint, applied to the spout C, and another containing a quart at the spout g, will be filled at the same time. The horizontal distance, to which a fluid will spout from an horizontal pipe, in any part of the side of an upright vessel, below the surface of the fluid, is equal to twice the length of a perpendicular to the side of the vessel, drawn from the mouth of the pipe to a semicircle described upon the altitude of the fluid; and therefore, the fluid will spout to the greatest distance possible from a pipe whose mouth is at the centre of the semicircle; because a perpendicular to its diameter (supposed parallel to the side of the vessel) drawn from that point, is the longest that can possibly be drawn from any part of the diameter to the circumference of the semicircle. Thus, if the vessel A B (fig. 6.) be full of water, the horizontal pipe D be in the middle of its side, and the semicircle N eded be described on D as a centre, with the radius D e N, or D f b, the perpendicular D d to the diameter D N b is the longest that can be drawn from any part of the diameter to the circumference N eded. And if the vessel be kept full, the jet G will spout from the pipe D to the horizontal distance N M, which is double the length of the perpendicular D d. If two other pipes, as C and e, be fixed into the side of the vessel at equal distances above and below the pipe D, the perpendiculars C e and e, from those pipes to the semicircle, will be equal; and the jets F and H, spouting from them, will each go to the horizontal distance N K, which is double the length of either of the equal perpendiculars C e or e.

Hence, as every body, projected either horizontally or obliquely, in an unresisting medium, describes a parabola; water projected either through a vertical or inclined spout, will describe a parabola.

Hence we have a way of making a delightful kind of water arbores, or arches, &c., by placing several inclined tubes in the same right line.

On these principles are formed various hydraulic engines for the razing, &c., of fluids, as pumps, syphons, fountains, or jets d'eau, &c., which see described under their proper articles. Pump, Syphon, Fountain, Spiral, Screw, &c. For other particulars relating to this subject, and the difference between the deductions of theory and the result of experiments; see Discharge of Fluids. See also Contracted Jet and Jet.

For the laws of the motion of fluids, by their own gravity, along open channels, &c., see River and Wave, and Motion of Water.

For the laws of pressure and motion of air, considered as a fluid, see Air and Wind.

Fluids. Animals observed in fluids are of divers kinds; some are flat, others cell-like, but the greater part of an oval figure. Leewenboock gives a description of a very unusual shaped creature, fixed in a little fishbath or scuttle, which was fastened to some of the small green weeds found in ditches full of water. Phil. Trans. N. 220. p. 160.

Wonders of all kinds, that have flood a while exposed to the air, till they have grown a little putrid, or where putrefaction has been promoted by the admixture of other matters, abound in variety of animals, having each their peculiar characters, sizes, figures, colour, and method of life, not to say uses. In a small drop of the discolorated surface of rain water, which had flood two months in a window, Dr. Harris observed four sorts of animals: the clear part of the drop presented two kinds, both very small; the dril of the figure of antic-eggs; there were in a continual brisk motion. The second more oblong, three times as long as broad were exceedingly numerous, but their motion slow.

In the thick part of the drop there were also two sorts of animals. The first of the cell-like, resembling those in vinegar, but very much smaller, and with their extremities more sharp. These would wriggle out into the clear part, and then suddenly betake themselves back again, and hide in the thick and muddy part of the drop, much like common cells in the water. The second sort resembled a large maggot, which would contract themselves into a spherical figure, and then stretch out again. The end of the tail appeared with a forceps, like that of an ear-wig. They might be plainly perceived to open and shut their mouths, from whence air-bubbles were in quantity discharged. The number of these was not above four or five. The same four kinds of animals he also found in many other drops of the same corrupted water. Animals in fluids are generally found at the top. In the lower parts of the water, Dr. Harris affirms he could never find any, unless when the liquid had been disturbed, and the surface shaken down, and mingled with the lower parts. Dr. Harris examined some rain-water that had flood uncovered a little while, but had not contracted any thick or discoloured fume. And here, where the water was clear, he could not find any animals at all; but a little thin white fume, that, like gas, began to appear in its surface, he found to be a congeries of exceeding small animals of different shapes and sizes, much like those produced by steeping barley in water. Viewing a small drop of the green surface of some puddle water, he found it altogether composed of animalcules of several shapes and magnitudes; the most remarkable were those which gave the water that green colour, and were oval creatures, whose middle part were of a greenish-yellow, but each end clear and transparent. They could contract and dilate themselves, tumble over and over many times together, and then shoot away like flies. Phil. Trans. N. 220. p. 255.

Dr. Harris looked on the surface of some mineral chalybeate water, which flood in a viol untill for about three weeks. In it he saw two kinds of animals, one exceeding small, and the other very large, which latter fort had on the tail something that looked like fins. There were but very few of either sort. Phil. Trans. N. 220. p. 257.

Animals in fluids are easily destroyed by only separating them a while from their element. Naturalists have even found shorter ways. A needle-point dipped in spirit of vitriol, and then immersed into a drop of pepper-water, readily kills all the animalcules, which, though before feasting about with great liveliness and activity, no sooner come within the influence of the acid particles, than they spread themselves, and tumble down to all appearance dead. The like may be done by a fewt of salt, only with this difference; that by the application of salt, animals seem to grow vertiginous, turning round and round till they fall down. Tincture of salt of tartar used in the same manner kills them still more readily; yet not so, Vol. XIV.
but there will be apparent marks of their being sick first and convulsed. Liks destroy them as fast as spirit of vitriol, and human blood, by virtue of the salt contained in it, produces the same effect. Urine, fack, and sugars, do not all destroy them, though not so fast; besides, that there is some diversity in their figures and appearances, as they receive their deaths from this poison or that. The point of a pin dipped in spiritus nitricus, as Dr. Harris supposes it, will other animals of this kind. Phil. Trans. N. 203. p. 836, seq. and N. 220, p. 256.

We find in the waters of our ditches many species of small animals, both of the crustaceous and tellacous kinds. The legs of the creatures are short, they resemble those of crabs and lobsters, but are of a much more curious structure, they are less than a small flea, but they seem all breeders, carrying spawn at their tails, or in two small bags, one hanging from each side. These bags are often seen broked, and the spawn is then found to consist of globules very large in proportion to the size of the creature. There is another sort besides these, as beautiful, but much smaller than they; this in shape more resembles the shrimp, and carries its spawn as the shrimp does. These kinds both seem only to have one eye, and that placed exactly in the middle of the fore-head, without the least trace of a dividing line; and they are often so transparent, that the motion of their bowels, and pulsation of their heart, may be seen. Baker's Microscope, p. 93.

All who are acquainted with the microscope, know very well that in water, in which the best glasses can discover no animated particle of matter, after a few grains of pepper, or a small fragment of a plant of almost any kind, has been some time in it, animals full of life and motion are produced, and those so numerous as to equal the fluid itself in quantity.

A small quantity of water taken from any ditch in the summer months, is found to be full of little worms, seeming in nothing so much as fire to differ from these microscopic animals. Nay, water, without these, exposed in open vessels in the summer months, will be always found, after a few days, to abound with multitudes of them, visible to the naked eye, and full of life and motion.

These, we know, by their future changes, are the fly-worms of the different species of gnats, tipulcs, and multitudes of the other fly-species, and we can easily det rmine, that they have owed their origin only to the eggs of the parent fly there deposited. Nay, a closer observation will at any time give ocular proof of this; as the flies may be seen laying their eggs there, and those eggs may be followed in all their changes to the fly again.

Why then are we to doubt but that the air abounds with other flies and animalcules, as minute as the worms in these fluids? and that these last are only the fly-worms of the former, which, after a proper time spent in that state, will suffer changes like those of the larger kinds, and become flies like those of the whole eggs they owed their origin? Vide Reaumur, Hist. Infect. vol. iv. p. 431.

The differently medicated liquors, made by the infusions of different plants, afford a proper matter for the worms of different species of these small flies; and there is no reason to doubt but among these some are viviparous, others oviparous, and to this may be in a great measure owing the different time taken up for the production of the insects in different fluids. Those which are a proper matter for the worms of the viviparous fly, may be soonest found full of them, as probably the liquor is no sooner in a

FLU

plate to afford them a proper nourishment than their parents place them there: whereas those produced from the eggs of the little oviparous flies must, after the liquor is in a proper state, and they are deposited in it, in form of eggs, have a proper time to be hatched before they can appear alive.

It is easy to prove that the animals we find in these vegetable infusions were brought thither from some other place. It is not less easy to prove that they could not be in the matter infused, any more than in the fluid it is infused into.

Notwithstanding the fabulous accounts of salamanders, it is now well known, that no animal, large or small, can bear the force of fire for any considerable time; and by parity of reason we are not to believe that any insect, or embryo insect, in any state, can bear the heat of boiling water for many minutes. To proceed to enquiries on this foundation, if several tubes filled with water with a small quantity of vegetable matter, such as pepper, oak bark, truffles, &c. in which, after a time, insect is well discovered by the microscope; and other like tubes be filled with simple water boiled, with water and pepper boiled together, and with water with the two other ingredients, all separately boiled in it; when all these liquors come to a proper time for the observation of the microscope, all, as well those which have been boiled as those which have not, will be found equally to abound with insects, and those of the same kind in the infusions of the same kind, whether boiled or not boiled.

Those in the infusions which had sustained a heat capable of destroying animal life, must therefore not have subsisted either in the water, or in the matters put into it, but must have been brought thither, after boiling, and it seems by no way so probable, as by means of some little winged inhabitants of the air depositing their eggs or worms in those fluids.

It is a natural question on this to ask, why it is, that whilst we see myriads of the progeny of these winged insects in water, we seldom see the insects themselves? The answer is equally easy, viz., because we can always place a drop of this water immediately before the focus of the microscope, and keep it there while we at leisure examine its contents; but that is not the case with regard to the air inhabited by the parent flies of these our worms, which is of immense extent in proportion to the water proper to nourish these worms, and consequently, while the latter are clustered together in heaps, the former may be dispersed and scattered. Nor do we want influence of this even in the insects of a larger kind. In many of our gardens we frequently find vessels of water filled with the grat-worms, as plentifully in proportion to their size, as these our fluids with animalcules. Every cubic inch of water in these vessels contains many hundreds of these animals; yet we see many cubic inches of the air in the garden not affording any one of the parent flies. Id. loc. comm. 256.

FLUKE. in Ichthyology, a word used in some parts of England as a name for the flounder. See Anchor.

FLUKE, WORM, a sort of small flat worm, often found in the livers of sheep which have died of the rot. See Rot.
FLUMARI, in Geography, a town of Naples, in Principato Ultra; 21 miles S. E. of Ariano.

FLUMET, a town of France, in the department of Mont Blanc, seated on the Arly; 31 miles S. E. of Geneva.

FLUMMERY, a wholesome sort of vegetable jelly made of oatmeal.

The manner of preparing it is as follows: put in the proportion a three large handfuls of finely ground oatmeal, to steep for twenty-four hours or more, in two quarts of water; then pour off the clear water, and put two quarts of fresh water to it; strain it through a fine hair-net, and boil till it is as thick as a thin pudding, skimming it continually while it is boiling, so that it may be very smooth; some sweeten it with sugar, and add rose or orange-flower-water; and then eat it with white or Rhenish wine, cream, or milk.

FLUMS, in Geography, a town of Switzerland, in the county of Sargans, situated on the Mat; 3 miles W. of Seergans.

FLUOR, in Physics, &c. denotes a fluid; or, more properly, the state of a body, which, before hard and solid, but is now reduced by fume of fire, into a state of fluidity.

Gold and silver will remain a long time in flour, maintained by the intense heat, without losing anything of their weight. See Gold, Fertility, &c.

The word flour is applied to signify the habitual fluidity of any substance, or that property by which a substance cannot be rendered solid, and is employed as an epithet to distinguish such substances from others of the same kind, but which are habitually solid, or which may be rendered solid.

FLUOR, in Mineralogy, a species of the calcareous genus, being a combination of lime and fluoric acid, and known by the chemical appellation of FLUOR of lime. The more familiar names under which it passes in most countries are STONE and flower, denoting the use to which it is frequently applied as a flux of various ores. Besides these, there are a variety of other names that have originated in the similarity of its colours, (particularly those of the flourspar,) to the beautiful tints of several of the flowers called precious, such as topaz, topazes, kryz, eborulates, &c. Indeed there is no mineral that may equal flour in the varied beauty of its hues; the suit of its colours is almost sufficiently comprehensive to be formed into a chromatic scale. It is reserved for nicer chemical observation to discover the nature of this variously modified colouring principle, which is more fugacious in flour than in most other minerals, but probably always corresponding with the nature of the metallic substances that accompany flour in the bowels of the earth.

Flour has been divided by Werner into three sub-species, namely, earthy, compact, and saphiro flour. The first, 2100 known by the name of the phosphorescent earth of Marma-rosa, was clasped with the greenish earth by the authority of Pelletier; but the late analytical experiments of Klaproth, who found 32 parts of phosphoric to two of fluoric acid, showed the necessity of redating it to the phosphates of lime, to which it was first referred! Mr. Jamison appears to have had his doubts respecting this substance; he does not describe it as a sub-species of flour, nor does he enumerate it among the phosphates of lime. See PHOSPHORITE.

1. Compact flour. This is rather better understood; but it appears that mineralogists are very apt to confound the terms "compacta" and "malleous" also in speaking of flour: whereas malleous flour (spar has been described as Werner's compact flour. This latter occurs but rarely, having hitherto been found only at Stollberg and Strasburg in the Harz, and at Yttrum and Norberg in Sweden, to which habitus we may perhaps add Schlickerswald and Kirman in the Satz circle of Bohemia, and Schwarzeberg in Salzburg. The following external characters appear the most imporant:

Its colour is generally light grey, green, passing sometimes into greenish-white, sometimes into brownish-grey, approaching to yellow or green, and it is the found reddish. Not seldom several of these flours are mixed in spots in one and the same fragment, now and then with the addition of accidental yellowish and brownish spots.

It occurs malleous only. Fracture more or less even, approaching sometimes to flat conchoidal, sometimes to sphyntery, even to foliated. The fragments are indeterminately angular with pretty sharp edges, and more or less translucent in the same piece.

Its is feebly glittering, almost dull. Half-hard, scarcely scratched by fluor spar, brittle, entirely fragile. Its specific gravity, if Kirman's compact flour be the name as the one here described, is 3.120 to 3.165.

This sub-species, to a superficial observer, appears sometimes like horn-flour, sometimes like compact lime-stone; but the above external characters (to which may be added the physical one of its showing a weak phosphorescence when laid on ignited coal) keep it sufficiently distinct. Its geographical situation has been given above. Its geographical situation at Stollberg is in a vein, in greywacke; it is found with flour spar (its conlantine companion), fian copper pyrites and barytes. At Kirman in Bohemia it was found by Dr. Reuss in gneiss, in which it is sometimes seen as thin laminae between the layers of quartz and feldspar.

It is, together with flour spar, made use of as a flux.

2. The sparry flour, or flour spar, which, besides the above-mentioned general names, is also known under those of calcium flour, glass flour, phosphoroscent spar, spathites, &c.

Its principal colours are: 1. White, such as greyish, greenish, yellowish, and reddish-white, passing into 2. Red, particularly rote red of various intensity, carmine. 3. Grey, greenish, yellowish, smoke, and pearl-grey. 4. Blue, lavender, azure, smalt, sky-blue, Prussian and violet-blue, the two latter appearing sometimes nearly black. 5. Green, verdigris, faurado, mountain, emerald, grape-apple, leek, pythius, and olive green. 6. Yellow, wine, wax, honey-yellow. 7. Brown, yellowish, and clove-brown. All these colours will frequently pafs into each other, and even their shades related to each other are sometimes seen together in the same specimens in spots, and flakes, and in drapes that often appear like some kinds of alabaster, whence Roman de Pile called a variety of flour, albatrosites. The colouring matter of some of them is very fugacious, especially that of the sky-blue variety, which is often seen to fade merely by being exposed to the atmospheric air. Of the above colours, the white and violet blue are the most common.

Flour spar is found malleous and crystallized, and not commonly crystallized, but it has not been observed, except in one mine, to be malleous thence, in the 'magnetic shapes, (such as deutetform, branched, talcistanite.

4 S 2 &c.
FLUOR.

&c.), in which the carbonates and sulphates of lime, and other crystallizable earthy substances so frequently occur.

Its primitive form is the octaedron. As to the determination of the integral molecule some difficulty has arisen. The octaedron, we know, cannot be sub-divided into solids of the same form; the last term of mechanical division we arrive at is that into other octaedrons accompanied by tetraedrons; six of the former and eight of the latter being disposed in such a manner as to form in all directions acute rhomboheds. If we imagine either all the octaedral or all the tetraedral particles removed, those of the same kind that remain will still be in exact connection by means of their edges. Of the latter circumstance Haiy's has ingeniously availed himself to reconcile this resolution of the octaedral crystal into two kinds of solids, with that principle according to which all the integral molecules of a crystal must be necessarily similar. He supposes that, could we call a look into the primary constitution of the octaedral crystal, and sub-divide it to the utmost limits, we should find the whole sub-divided pervaded either by tetraedral or octaedral vacuities; if the former, the whole would be composed of octaedral elementary particles; if the latter, the tetraedron would exclusively constitute the integral molecule. Now, as, according to Haiy's doctrine, this molecule is constantly either the parallelo-piped, or the triangular prism, or the tetraedron, analogy has in this case decided in favour of the tetraedron, which is now considered as the integral molecule of fluorspar, instead of the octaedron. It was Werner who first observed the tetraedral and octaedral fragments which result (according to his terminology) from the fourfold cleavage presented by the foliated fracture of fluorspar.

The principal forms of the crystals of fluorspar, with their modifications, considered, not according to their origin, but to the manner in which they present themselves to the eye, are the following:

1. The perfect cube (chaux fluente cubique, Haiy.) It is sometimes elongated; passing from the cubic form into that of a rectangular four-sided prism, generally with two of its lateral planes narrower. We have seen specimens of this latter variety from Cumberland; it is also found at Schniititz and Nettiehau.

2. Cube with all the edges truncated (chaux fluante cube-dodecaedre, Haiy).

3. The preceding with planes of truncation so much increased that the rhomboidal or garnet-dodecaedron is formed (chaux fluante dodecaedre, Haiy).

4. Cube with all its edges bevilled (chaux fluante bordée, Haiy).

5. The preceding, with bevilling edges so much enlarged as to convert each plane of the cube into four triangular planes (chaux fluante hexoctaedre, Haiy). What has been described as perfect cube with convex planes, we suppose to be this modification indifferently formed.

6. Cube with all its solid angles flatly acuminated by three planes, placed on the lateral planes of the cube.

7. Cube having its angles acuminated by four planes, placed on the lateral planes. We do not know where the preceding and this variety occur; Emmelringer informs us, that in the latter the fix acuminating planes sometimes completely englobe the planes of the cube.

8. The cube truncated at all its solid angles (chaux fluante cube-octaedre, Haiy). If the triangular truncating planes do not meet, the planes of the cubes are octagons; if they meet exactly, those planes are squares; if all the truncating planes encroach on each other they become hexagons, while the planes of the cubes remain squares; when they encroach still more the

9. Octaedron, with fix truncated angles, is formed; in which the truncating planes are the fix planes of the cube; in the same manner as the truncations at the eight angles of the cube N° 8. are the eight planes of the octaedron. When the truncating planes of the modification N° 8. enlarge so much as to caufe the faces of the cube entirely to disappear.

10. The perfect octaedron, or double four-sided pyramid, is formed (chaux fluante primitiva, Haiy.)

11. Octaedron with truncated edges (chaux fluante emerginata, Haiy.)

12. Octaedron with both angles and edges truncated.

13. The elongated octaedron with four broader and four narrower planes, terminating in a ridge.

No. 1. is by far the most common of all the modifications of crystallized fluorspar. No. 3. is very rarely met with; it was found by M. Subrin between Brueil and Charecy on the way to Chalons. Of No. 4. the most interesting varieties occur in Cornwall. From the geometrical figure in plate 73. of that useful work "British Mineralogy," it appears, that Haiy's chaux fluente bordée occurs in Cornwall, with the eight angles truncated, parallel to the octaedron, by which a crystal of 38 faces is formed. Of No. 12, the perfect octaedron, the most beautiful variety is the rosecoloured one, found in the neighbourhood of Mont-Blanc. It also occurs in beautiful crystals in England, on Mount St. Gothard &c. and Mr. Sowerby is, we suppose, the first who has noticed the small violet variety of this modification found in Aberdeenhire.

To the above may perhaps in future be added the following unusual modifications. 1. The tetraedron with faintly truncated edges, mentioned by Mr. Muls as existing in the collection of Mr. Vonder Null; the truncating planes are flat to correspond to those of the cube. 

2. The rhomboid (one of the forms which fragments of fluorspar frequently exhibit, and which may be considered as an octaedron, with two tetraedrons applied to two of its opposite planes) is said to have been found as crystal. The third, mentioned by Emmelringer, is the double eight-sided pyramid, acuminated at both extremities by three planes placed on the alternate lateral edges. It is said to have been found in Saxony, and is in the collection of Count Wirna at Vienna.

The crystals of fluor spar are of various size; the perfect cubic is seen from five inches square to extremely minute, and scarcely distinguishable. They are found distinct and aggregated in various directions; sometimes globularly aggregated. Their surface is generally smooth and splendid; but sometimes perfectly dull. They are not seldom covered by an opaque crust of various colours, particularly blue or green; often they are drusy, and sometimes ornamented with a beautiful golden and pavonine tints: of which latter we have a fine specimen before us. Internal luster splendid, sometimes simply shining, according to the various degrees of perfection of the foliated fracture; it is vitreous, rather inclining to pearly; in some varieties even an adamantine luster has been observed.

Fracture more or less perfectly foliated, almost always straight, seldom curved-foliated, sometimes approaching to vitreous; it presents a four-fold equiaangular cleavage. The
FLUOR.

The form of the fragments has been mentioned in speaking of the integrant molecules. The massive is generally seen in granular distinct concretions of various bignesses; and sometimes it appears in columnar concretions, and radiated, interstratified by curved lamellar distinct concretions.

Degree of transparency according to the differences in the colour and fracture; some varieties, particularly the white or colourless, perfectly transparent; others entirely opaque; most commonly it is semi-transparent.

Its hardness is greater than that of calcareous spar; but it is scratched by iron; it is brittle, easily frangible, and not very heavy; its specific gravity is:

3.092 (from Stollberg) { 3.148 (from Freiberg) 4.
3.156 to 3.184. Muskau-brecc.
3.175 (the green var.) Blumenbach.
3.200 to 3.700. Gerhard.

Other physical characters are its phosphorescence when laid on ignited coal; the sky and violet blue and green varieties have been observed to emit the most vivid phosphoric light. The variety from Siberia, called chlorophane, when put on ignited coal, does not decrepitate, but emits a beautiful emerald green light, which has procured it its name. A flight of phosphorescence is likewise observed when two fragments are rubbed against each other in the dark.

As chemical characters of fluor-spar, we have to mention its deprecation before the blow-pipe, (which, however, is not the case with the Siberian chlorophane,) and subsequent loss of colour, and its melting, (particularly with addition of borax or phosphoric acid,) into a greyish white emanant; as also its emitting suffocating white vapours (fluoric acid) when acted upon by sulphuric acid.

The constituent part of fluor-spar, according to Sisold, the celebrated discoverer of a peculiar acid in this mineral, were stated to be:

Lime 57
Fluoric acid 16
Water 27

After him, Wenzel, Richter, and but lately Klaproth, have analysed this substance, and obtained the following results:

Fluoric acid 32.3
Calcareous earth 50.3
Iron and alum earth 10.3

100 Wenzel, 1783

Fluoric acid 55
Calcareous earth 65

100 Richter, 1785.

Fluoric acid 67.75
Calcareous earth 52.25

100 Klaproth, 1807.

With regard to the geographical situation of fluor-spar much is left to future observation. We know, however, that it does not only occur in veins, but likewise as beds in mountains of older formation. In Derbyshire it appears to form large irregular depositions in jet-like line, and also in Thuringia and at Zinnwald in Bohemia it occurs in beds. More frequently it is met with in veins of different relative ages, accompanied with several important metallic formations. The oldest, consisting principally of tin fluorspar, occurs at Zinnwald, and in other parts of the Bohemian and Saxony Erzgebirge; and a vein formation, equally old, is found in Switzerland, where the veins consist of fluor spar, feldspar, rock crystal, &c. The second in antiquity appears to be that which, accompanied with lead and silver ores, and sometimes with barytes, forms the substance of veins at Freiberg and other parts of the Saxony Erzgebirge, and also partly in Derbyshire. A third vein formation, found in the lower parts of the Hartz, consists chiefly of fluor spar with copper and iron pyrites, galena, sulphide iron, &c. The different ages of the venigenous fluor spar have first been examined into by Werner. We should also mention here that the variety of rock called chlorophane is found in a granitic rock in Siberia; and Andrada speaks of a variety he saw in Sweden (in the district of Norberg) mixed in large masses with mica flake.

A list of localities of fluor-spar may be found in all books on mineralogy; indeed, it is met with in most parts of Europe, though in some it is found in no considerable quantity. England and Saxony are the principal native places of this interesting mineral substance. In Scotland it is very scarce; the only localities known to Mr. Jameson are Aberdeen-firth and the Shetland islands. We know of no specimens from any part of America or Africa; in the northern parts of Asia, Patria found it in small quantities in two mines, viz. in the silver mine of Zmeof, in the Atlas mountains, where it occurs mixed with the other vein materials; in the lead mine in Dauria, near the river Amur, where it found it in small cavities of the vein stone, in the shape of a thick botryoidal crust.

The uses to which fluor-spar is applied, though not manifold, are not unimportant. The cheaper kinds are used as fluxes to metallic ores, particularly copper, iron, and silver. Chemists obtain fluoric acid from it. The use of it in this country, (particularly of the variety called blue jack by the Derbyshire miners,) for ornamental vases, columns, &c., is generally known. Mr. Mawe, in his "Mineralogy of Derbyshire," has given an account of the mode of working it. Several attempts have been made in France to manufacture the fluor spar of Auvergne into similar articles of ornament; but it appears as if the nature of its fracture renders it less fit for the lathe.

Fluoric smerc is seldom seen to constitute the substance of organic remains. We find influences of this concretion mentioned in Mr. Martin's "Outlines," the remains are chiefly those of retrochitae. Allo Dr. Kidd, in his "Outlines, &c." describes a bivalve shell in the Oxford collection, converted into fluor spar with imperfect crystals of nearly colourless fluor in the interior.

We should not omit mentioning in this place those corroded cubic crystals of fluor spar, of a yellowish-grey colour, found near the surface of the earth in some parts of Derbyshire: their texture is more or less porous throughout. Halé, who calls this variety chauss fluorspar aluminiferous, thinks that the ferruginous clay which it is laid to contain has the same relation to the fluor spar which the quartz grains have to the carbonate of lime in the crytalized lodestone of Fontainebleau. But this analogy does not appear to be founded in reality (See Sandstone.) Dr. Kidd concludes that the corroded appearance of these crystals may have been produced by some form of time.

Fluoric spar sometimes exhibits traces of decompositions. The singular variety from Boermalton, Devonshire, is octahedral crystals of a pale salmon green colour, and caked, as it were, in one another, is encrusted with a white earthy substance, which, if we may judge from the gradual transitions
transition into the perfect sublimate observable in a specimen before us, can only be the result of a disintegration of the constituent parts. Mr. Sowerby has given a good figure of this variety. It is probable that much of the sublimate described as earthy fluor is nothing but fluor in a decomposed state.

Fluorspar, in Minera, a colourless discharget from the female vagina, popularly termed the vitrioli, and by the schoolmen lavericles, an application of the same figuration, derived from the Greek. See Lecorrhrea.

FLUORIC Acid, in Glaebuli. This acid was discovered by Scheele more than thirty years ago, and the sub-fec spum of the diamonds, from being the first to be detected, it has also been found in the animal kingdom, viz. in the enamel of the pettish teeth of an elephant; also in the enamel of the human teeth, and ivory.

We have seen that the constituent parts of fluor spar, independently of the water in combination, are fluoric acid and lime. To obtain this acid we must put one part by weight of the spar coarsely powdered into a leaden retort, and pour over it three parts of concentrated sulphuric acid. An effervescence is immediately excited; the sulphuree acid exerting a stronger attraction for the lime of the spar, unites with it, and the fluoric acid goes off in the form of gas, which may be collected in receivers over mercury.

When water had been previously introduced into the receiver, the gas would have been absorbed, and the acid would, in that case, be exhibited in the liquid state. Hence fluoric acid can sublimate in the liquid form, and likewise under that of gas, which has the common properties of the atmospheric air, being elastic and invisible. But it is somewhat heavier than common air; it extinguishes combustion, and is utterly incapable of supporting animal life. Exposed to the atmosphere it combines very greedily with its moisture, and appears in the form of vapour or white fumes. It has a penetrating pungent smell; reddens vegetable blues, and corrodes the skin. If a lighted candle be introduced into it, the flame becomes green, and then is extinguished.

The most remarkable property of the fluoric acid gas is that of corroding glass in consequence of its strong affinity for glass. This property has rendered it extremely useful in etching or engraving on glass vessels, which operation is performed by a very simple and easy process: the glass is covered with wax, or a strong solution of tinctures, the figures are then traced with a common graver, or steel point, and then the vessel is exposed to the action of the fluoric acid in a flat of gas; those parts that are exposed are soon corroded, and the impression is more or less deep, according to the time employed. This art, though adopted as new at the time of Scheele's and Priestley's discoveries, was, according to the account given by Beckman in the second volume of his History of Inventions, known and practiced a century before.

Light and caloric have no effect on fluoric acid; its properties are not the least altered by being passed through a red-hot porcelain tube. It will not unite with oxygen, which is the great difficulty that exists between this and the muriatic acid. Air has no action on azote, hydrogen, carbon, phosphorus, or sulphur. By these, or by some of them, almost all the other acids have been decomposed, and their constituents detected, and hence its base was, till very lately, wholly unknown; and it was, from analogy only, that chemists assumed that it must contain oxygen in combination with an unknown base. Mr. Davy has, however, thrown some light on this subject, by subjecting the fluoric acid-gas to the action of potash, one of his newly discovered metals. In this gas potash, when heated, burns, and there is a great absorption of the gas. Either the whole, or part of the acid, according to the quantity of the potash used, is destroyed or absorbed, and the residual elastic fluid is found to be hydrogen, which is in less proportion as the fluoric acid gas has been more perfectly freed from water. After the combustion, a chocolate coloured mass remains at the bottom of the retort, and also a sublimate, partly chocolate coloured, and partly yellow, is found about the sides, and at the top of the retort. This sublimate, when examined by a magnifier, appeared to consist of different kinds of matter; and when thrown into water it effervesced very violently, and the gas evolved was inflammable. When heated in contact with air it burnt slowly, lost its brown colour, and became a white false sublimate.

The water which had acted on this sublimate was examined, the solid particles separated by a filter, and the filtrate was found to contain a mixture of potash and pot-spar. The solid residuum was heated in oxygen gas, it burnt before it came to a red heat. The brown colour was changed to white; oxygen was absorbed, and acid matter was produced. The inflammable sublimate thus produced from the action of potash on the fluoric acid is supposed to be the base of the acid. Perhaps the decomposition of the fluoric acid by potash is analogous to that of the sulphuric and phosphoric acids; in which the base ates is not evolved, nor even the bases in their common form, but new compounds formed of the base with potash, with a smaller proportion of oxygen. This subject has engaged also the attention of the French chemists, M. M. Gay Lussiac and Thenard, who employed the agency of potash, and the results of their investigations were very similar to those of Mr. Davy. From which we infer that since little or no hydrogen gas is evolved in the combustion of potash, the effect cannot be ascribed to the agency of water. The acid must therefore be decomposed, or it must combine undecomposed with the metallic base, which is not even oxidated. It is probable, therefore, that the acid is decomposed, and the product is a combination of the fluoric base with potash, analogous in constitution to a phlogurture.

Fluoric acid combines with alkalies and earths, and the salts so formed are named fluorites. They are generally deliquescent, and can be crystallized with difficulty. They are decomposed by the sulphuric or muriatic acid, which, as we have seen, dissolves the fluoric. The alkaline fluorites are decomposed also by lime, as is evident by the following table.

Table of Affinities,

| Lime | Barites | Strontites | Magnesia | Potash | Soda | Ammonia | Glucina | Albunus | Zoncon | Schea |

The fusing power of this acid exceeds that of all the others.
others, a given quantity of it saturating a larger quantity of any base. On this account, it is regarded as the most powerful of the acids, and its felsic energy must be attributed partly to the weak state of concentration in which it can be obtained, and partly to its not affording oxygen in a direct way.

There are eight fluates known, viz. of pot-ash, soda, ammonia, lime, barytes, magnesia, alumine, and silica. Some of these we shall briefly notice. The fulate of pot-ash is obtained by fusing in a platina crucible, a mixture of fluor spar, and carbonate of pot-ash. The mass, digested in water, yields a solution, which, filtered and evaporated, leaves a fulate of pot-ash. It does not crystallize, but forms a gelatinous mass with scarcely any taste, that attracts moisture from the air. It readily dissolves in water.

F. of soda is formed like the last; if the solution is evaporated till a pellicle forms on its surface, it yields anBS6 small cubical crystals of fulate of soda. These are bitter and aromatic; they do not deliquesce in the air, and are but little soluble in water. They decrystallize and melt into a transparent globule when exposed to the action of the blow-pipe. F. of ammonia is obtained by the application of heat to a mixture of sulphate of ammonia and fluor spar. The fluates sublimes; but if it is prepared by fusing the acid with ammonia, the solution, by evaporation, yields small crystals of fulate of ammonia. F. of lime is the fluor spar on which we have already treated; as it is found in nature, this salt may be artificially prepared by adding fluates of ammonia to nitrate of lime; the fluate of lime falls to the bottom, and when properly treated is very pure. It is insoluble in water, phosphoric acid when laid on a hot iron, is in its nitrate, unalterable by exposure to the air, and at a heat equal to 51°F of Wedgwood, it melts into a colourless transparent glass. Fluoric acid obtained in glas vessels always contains a portion of silica; if this solution is allowed to remain a considerable time in a vessel not quite closed, it deposits small brilliant transparent crystals, which have been ascertained to be the fluate of silica. This salt is soluble in alkalies, and gives out fluoric acid by mere heat, or by the action of any of the strong mineral acids. Felspar, and all minerals that contain silica, are probably acted on without difficulty by the fluoric acid in a state of gas, but those that contain no alkali are least liable to its action. The following table, taken from Dr. Thomson's chemistry, vol. ii. exhibits the results of the experiments and calculations of Richter on the several fluates.

FLURRY-Brige, in Geography, a small post-town of Ireland, in the county of Louth, on the borders of Armagh.

FLUSH, signifies to draw off, or let go a stream of water from any period.

FLUST. Deo. De Creek.

FLUSHER, in Ornithology, the common name of the better butcher-bird, called by authors the lanius minor, and the lanius tertius of Aldrovand. See Lanius Cullu-rio.
thee creatures is in general white, and in the night-time, or when placed in the dark, they occasionally emit a phosphorescent light.

Species.

**Truncata.** Foliacese, sub-divided, with linear truncated sub-divisions. Müll.

Native of the European seas, and five inches in length; cells oblong-square, and pale yellow-brown.

Inhabits European and Mediterranean seas, six inches long; colour yellow-brown.

**Filoza.** Foliacese, variously branched, with a fe- tacous ciliate on the lower part of each pore. Müll.—*Allelopura membranacea plana, punctis quincuncialibus,* A. Moen. Acad.

Whitish, porous, incrusting marine plants; and inhabits European seas.

**Carbasea.** Foliacese, sub-divided, with a single layer of cells. Ellis.

Yellow-brown. Inhabits the coast of Scotland.

**Characea.** Papparaceus, with cells on both sides, the tops of the branches truncated, like the edge of an axe. Ellis.

Adheres to shells, and of a pale straw colour; native of Europe.

**Bombycina.** Frondescent, with obtuse branches, divided into two or three parts, growing together in tufts, forming forth small radical tubes, and having a single layer of cells. Soland.

Inhabits the Bahama islands.

**Verticillata.** Parastallic, with flattish linear branches, narrower at the base, and rows of top-shaped ciliated cells disposed in whorls one above another. Soland.

Native of the Mediterranean.

**Dentata.** Parastallic, foliacose, with thinning oval cells in a single layer, the mouth surrounded by sharp inflected teeth. Ellis.

On fuci, and inhabits the European seas.

**Bullata.** Parastallic, with ovate projecting white cells, the mouths of which are round, and armed with small spines. Ellis.

Found in the European seas adhering to fuci.

**Tomentosa.** Parastallic, soft, woolly, with invisible cells. Müll.

Inhabits the North and Baltic seas.

**Denticulata.** Parastallic, with oval distinct cells, three-toothed at the opposite margin, and the mouth margined. Müll.

Inhabits the North seas, on fuc I and shells.

**Turbita.** Parastallic, membranaceous, with single oblong-ovate cells, and tubular erect mouths. Soland.

Deep yellowish, semi-transparent, and adheres to fuci; found in the seas of St. Domingo.

**Hispa.** Frondescent, spongy, the fronds branched and mucilaged on the upper side with very rough belts. Pallas.

About an inch long, of a pale grey colour, and extremely rare. The species inhabits the Mediterranean sea.

**Frondiculosa.** Frondescent, with obtuse crowded branches thrice divided, and a single layer of cells. Seba, Pallas, &c.

Native of the Indian ocean.

**Pappacea.** Frondosceous, frondescent, with a manycleft finely lamellate frond; cells oblong-ovate, and ringlet at the top. Pallas.

Yellowish and rough on the surface. Inhabits the Mediterranean.

**Hirta.** Parastallic, flat, coriaceous, with contracted distal cells. *Fiohra bipi~ida,* Fabr. Fin. Grouw.

Fuscous with narrow cells, adhering to fuci, in the Greenland seas.

**Membranacea.** Parastallic, membranaceous, with oblong-quadangular cells pointed at the upper projecting angles. Soland.

Inhabits the British and North seas.

**Lineata.** Parastallic, flat, foliacose, undivided, with oval cells in transverse rows. Fabr. Fin. Grouw.

Found on fuci in the North seas.

The fruticosa are no of Gmelin is excluded, as it cannot be considered of this genus; it is an escorial of Pallas, and millipora of Ellis.

**FLUT, in Geography, a river of Bohemia, which runs into the Egro, opposite to Libeshein.

**FLUTA, in Ichthyology, a name given by Gara and some authors to the common thars, distinguished by Arctedi by the name of the plain yellow thars, with a large annular black spot near the tail. See *Parus Annulatus.*

**FLUTA** is also a name given by Columbus to the murana of Aritcle and the ancient authors in general, as well Greek as Roman. It makes only one species of the murana, according to Arctedi; but being with him a general name which comprehends all the ech-kynds, the serpens marinus and the like, among them. This, which was anciently called simply the murana is distinguished by that author under the name of the murana having no pectoral fins; which being peculiar to this species, evidently and obviously distinguishes it at first sight from all the red. See *Murana.*

**FLUTE, an instrument of music, the simplest of all those of the wind-kynd; played, by blowing it with the mouth; and the tones or notes formed and changed by flapping or opening holes disposed for that purpose all along it. Those of common use are either the flute after, i.e. a beaked or common English flute, and the traverse, Helvetian, or German flute, the invention of which is ascribed by Galileo and Merfunne to the Helvetians; but the antique flute of the piping faun, and a telescoped pavement of Fortuna Virili, erected by Sylla at Rome, in which is a representation of a young man playing on a traverse pipe, with an aperture to receive his breath, shaw that it is of more ancient original.

The Latin call it *floutas,* and sometimes *tibias,* pipe; from the former of which some derive the word flute; though Borel will have it derived from *flouta,* a lamprey, thus called a *fluvium in fluvius,* in regard the flute is long, like the lamprey; and has seven holes all along it, like that fish. Grallinian.

The ancient fialtw, or flutes, were made of reeds; afterwards they were of wood; and at length of metal. But how they were blown, whether as our flutes, or hautboys, does not appear.

Mons. Cassillon apprehends that they were founded by means of a rned; and that there were two sorts of them, in one of which the reed was visible, as in our hautboy, but concealed in the other. (Berlin Mem. 1774, vol. v.) It is plain some fime had holes, which at first were but few; but afterwards were increased to a greater number; and some had none. Some were finge pipes, and some a combination.
FLUTE.

of several, particularly Pan’s syrinx, which consisted of seven reeds, joined together sideways.

These seven reeds had no holes, each giving but one note, in all seven distinct notes; but at what intervals is not known; perhaps they were the notes of the natural, or diatonic scale.

The Gorgon flute is different from the common one; it is inserted into the mouth, by the end, as the ordinary ones are; the end is flapped up with a plug or tampon, but the lower lip is applied to a hole a little way distant from it.

It is made equally big every where, and perforated with six holes, licks that of the mouth, and that opened by the key.

The flute was of such importance in antiquity, that among the Divi minorum gentium, some of the female divinities laid claim to a share in musical discoveries. Of this number was Minerva, or Pallas, the daughter of Jupiter, who is sometimes called Muses, or the musician; a name she acquired from a statue made by Demetrius, in which, when the serpent of the Gorgon were struck, they reformed like a flute. She is also honoured with the invention of chariots, together with having first used trumpets, and invented the flute. The vouchers for her musical talents are Paninius, Plutarch, and Pulfentius, among the prose writers; and Pindar, Nonnus, Ovid, Hyginus, Propertius, and Claudian, among the poets. The flute that she invented is said by Ovid to have been made of box, and by Hyginus of bone. Toramina rara, with few holes, it is natural to suppose.

Indeed the Syrinx, see plate IV. N° 6, said to have been invented by Pan, was found inconvenient. It consisted of a number of pipes of different lengths, tied together, or fastened by wax, which were played on, according to Lucertius, by blowing in them one after the other, moving the instrument sideways, for the admission of wind into the several tubes; and it was by the facility and penetration of Minerva, that it was found practicable to produce the same variety of tones with a single pipe, by means of ventages or holes, which had the effect of lengthening or shortening the tube, by a quick alteration of the column of air which was forced through it.

Two other circumstances are related of Minerva with respect to the flute; she is said by Hyginus to have found herself laughed at by her mother and sister, Juno and Venus, whenever she played the flute in their presence; this suggested to her the thought of examining herself in a fountain, which serving as a mirror, convinced her that she had been justly derided for the deficiency of her countenance, occasioned by swelling her cheeks in the act of blowing the flute. This is one reason given for her throwing aside that instrument, and adopting the lyre. However, a better cause, and one more worthy of her wisdom, is assigned for her throwing aside the flute, upon seeing Apollo perform on the lyre; for by having his mouth at liberty, she found that it enabled him to sing at the same time as he played, which afforded an opportunity of joining instruction to pleasure.

The invention of the flute having been given by the poets to Apollo, Mercury, Minerva, and Pan, is a proof of its high antiquity as well as importance. There are several flutes represented in sculpture of all forms: curved, straight, small, middle-sized, fipple, double, right, left, equal, unequal, &c.; these instruments were made of all kinds of wood and metal. They had different names alligned them, according to the country where they were made, or were chiefly in use: as the curved flute was called Pyrgian.

Vot. XIV.

or Tyrian, its name in Magna Grecia, or the Phoenician of the Egyptians, which was termed Monaulus. The flute had, indeed, so many different names in the Classics, and is applied to so many different purposes, that M. le Ferre, who had undertaken their explanation, ended his father's labours by a copy of Latini verba in præcis of Minerva, for throwing the flute into the sea, and anathematizing that he should take it out. But far from intriguing M. le Ferre, and without having the fear of Minerva before our eyes, we shall try if we cannot give some satisfaction by explanation of the terms equal and unequal flutes, right and left flutes, Sarracen flutes, Phrygian, Lydian, or Tibiafloris, Tibia impares, Tibia farrane, Phrygian, Lydian, &c., of which mention is often made in comedies preferred at Rome; we shall give what has been said, which was most probable and ingenious on this curious subject of antiquity.

In the comedies of Terence the flute-player is played on double flutes, or two flutes at the same time, that which they held in the right hand was called the right flute, and that with the left, for the same reason, the left. The right hand had few holes, and produced the higher, or lowest sounds; the left had many holes, and produced the grave or high notes. When the musician played two flutes of different sounds, it was said that the piece was accompanied tibia imparibus, with unequal flutes; or tibia dextris et sinistris, with right and left flutes; and when they played on two flutes of equal sound (or in unison), either right or left, as often happened, it was called the piece was played tibia paribus ductibus, with equal flutes, producing two sounds; or tibia paribus ductibus, equal left-handed flutes, producing a single note.

Donat pretends, that when the subject of a piece was grave and serious, the right-hand or base flutes only were used, which were called Lydian; that when the drama was gay and playful, the left-hand or high flutes were used, which were called Tyrian or Sarracen, which having high sounds were more proper for joy; and finally, when the subject was mixed, or as we should say, tragic-comedy, unequal flutes were employed, that is to say, right and left, which were called Phrygian.

At the Panathenaeum games, instituted at Athens in honour of Minerva, the patrons of that city, premiums were given to players on the flute, an instrument then in the highest estimation throughout all Greece, but in particular request at Athens; perhaps from the legendary account of its invention by Minerva, the protectress of that city.

Aristotle tells us, (de Land. S.p.) that the flute, after its first invention, was used by mean people, and thought an ignoble instrument, unworthy of a free man; till after the invention and defeat of the Persians, when ease, effusion, and luxury, found its use to become common, that it was disgrace to a person of birth not to know how to play upon it. Callias and Critias, celebrated Athenians, Archias of Tarentum, Phileolaus and Epaminondas, were able performers on the flute.

The Thebans in general piqued themselves much on being great performers on the flute. This is manifest from a passage in Dion Chrysostom. "The pre-eminent," says he, "which all Greece unanimously allows to the Thebans, in this particular, has been constantly regarded by them as a point of great importance, of which I shall give an instance. After the total ruin of their city, which has never yet been rebuilt, no part of it being now inhabited but the small quarters, called Edynus, they gave
FLUTE.

themselves but little trouble in restoring any of the public monuments that had been thrown down or destroyed, one statue only of Mercury excelled, which they took great pains to dig out from among the rubbish, and to erect again, on account of the following inscription: Ἐκλεκ μὴ ἔνεκ τόποις περιγραπτόμεθα. — "Greece has declared that Thebes wins the prize upon the flute." So that this statue is still standing in the old public square, among the ruins."

Pronomus, a Thespian, according to Pausianias, invented a flute, upon which he could play in three different modes. Before his time, there was a particular flute for every mode or key: and so out of tune are the generality of modern flutes, it were almost to be wished that the custom had still continued. The words and music of a hymn, composed by Pronomus for the inhabitants of Chalcis, when they went to Delos, were sung in the time of Pausianias, as was likewise the statue of this musician, erected by the citizens of Thebes, near that of Epaminondas.

Pericles, who had invited Antigenides to Athens, and who had undertaken the superintendence of the education of Alcibiades, his nephew, appointed Antigenides for his flute-master. But Aulus Gallus relates, from the History of Mitha, in thirty books by Pampilla, that his scholar Alcibiades feigned up for a fine gentleman, and taking the utmost care of his person, was soon disfigured with his instrument, as Minerva herself had been before; for happening to see himself in a mirror, while he was playing, he was so shocked at the distortion of his sweet countenance, that he broke his flute in a transport of passion, and threw it away, which brought this instrument into great disfavour among the young people of rank at Athens. However, this disfigurement did not extend to the sound of the flute itself, since we find by Plutarch, that the great performers upon it continued long after to be much followed and admired.

Horace speaks of bands of female flute players, which he calls "Ambobabaurum Collegia," and of whom there were still colleges in his time. But the followers of this profession became so numerous and licentious, that we find their occupation prohibited in the Theodosian code; however, with little success; for Procopius tells us that in the time of Justinian, the officer of the empress Theodora, who was a Tiberian, appeared on the stage without any other drefs than a flight scarf thrown loosely over her. And those performers were become so common in all private entertainments, as well as at public feasts, obtunding their company, and placing themselves at the table, frequently unasked, that, at the latter end of this reign, their profession was regarded as infamous, and utterly abolished.

Dorion is mentioned by Plutarch as a flute player who had made several changes in the music of his time, and who was head of a sect of performers, opponents to another sect of practical musicians, of which Antigenides was the chief; a proof that these two masters were cotemporaries and rivals. Dorion, though much celebrated as a great musician and poet, by Athenæus, is better known to posterity as a voluptuary. Both his music and poetry are lofty; however, many of his paeans are preferred. Being at Milo, a city of Egypt, and not able to procure a lodging, he enquired of a priest who was sacrificing in a chapel, to what divinity it was dedicated, who answered, to Jupiter and to Neptune. How should I be able, says Dorion, to get a lodging in a place where the gods are forced to lie double? Supping one night with Nicoereon, in the island of Cyprus, and admiring a rich gold cup that was placed on the fide-board, the goldsmith will make you jest such another, says the prince, whenever you please; he'll obey your orders much better than mine, sir, says Dorion; so let me have that, and do you bespeak another. The remark of Athenæus upon this reply is, that Dorion acted against the proverb, which says, that "To flute-players, nature gave brains there is no doubt, but alas! 'tis in vain, for they soon blow them out."

Upon hearing the description of a temple, in the Nauplius of Timothetus, Dorion said, he had seen a better in a boiling cauldron.

Having left a large shoe at a banquet, which he wore on account of his foot being violently swelling by the gout, "the only harm I with the thief, said he, is, that my shoe may fit him."

His wit and talents made amends for his gluttony, and he was a welcome guest wherever he went. Philip of Macedon, in order to enliven his parties of pleasure, used frequently to invite him with Aristophanes the citizen.

The importance of the flute is manifested in innumerable passages in ancient authors; among which there is one in Pliny that is diverting and curious. In speaking of comets, Pliny says that there were some in the shape of flutes, which were imagined to forebode some ill to music and musicians. (Tibianum specie, musicæ arti portendere), and Montfacon proves by several inscriptions from ancient marbles, that the fictacular Tibicen at Athens was always chosen, and his name recorded with the officers of flute, (Supple. tom ii. cap. 25.)

After speaking of so many flute players of the male sex, it is but just to say that they did not monopolize the whole glory arising from the cultivation of that instrument; as the performing upon it was ranked, in high antiquity, among female accomplishments. Its invention was ascribed by the poets to a goddess; it was the symbol of one of the Muses; and it was never omitted in the representation of the Sirens. However, the same reason which provoked Minerva to throw it aside, has luckily inclined modern ladies to cultivate instruments, in performing upon which, their natural charms, instead of being diminished, are but rendered still more irrefrangible.

The most celebrated female flute-player in antiquity was Lamia; her beauty, wit, and abilities in her profession, made her regarded as a prodigy. The honours she received, which are recorded by several authors, particularly by Plutarch and Athenæus, are sufficient testimonies of her great power over the passions of her hearers. Her claim to admiration from her personal allurements does not entirely depend, at present, upon the fidelity of historians; since an exquisite engraving of her head, upon an amulet, with the veil and bandage of her profession, is preferred in the king of France's collection, which, in some measure, authenticates the accounts of her beauty.

As she was a great traveller, her reputation soon became very extensive. Her first journey from Athens, the place of her birth, was into Egypt, whither she was drawn by the fame of the flute-players of that country. Her person and performance were not long unnoticed at the court of Alexandria; however, in the conflict between Ptolemy Soter, and Demetrius, for the island of Cyprus, about 312 years B.C. Ptolemy being defeated in a sea engagement, his wives, domestics, and military stores fell into the hands of Demetrius.

Plutarch, in his life of this prince, tells us, that "the celebrated Lamia was among the female captives taken in this victory. She had been universally admired, at first, on
on account of her talents, for she was a wonderful performer on the flute; but afterwards her fortune became more splendid by the charms of her person, which procured her many admirers of great rank." The prince, whose captive she became, and who, though a successful warrior, was said to have vanquished as many hearts as cities, conceived to violate a passion for Lamia, that, from a sovereign and a conqueror, he was infantly transformed into a flave; though her beauty was now on the decline, and Demetrius, the handomest prince of his time, was much younger than herself.

At her invitation, he conferred such extraordinary benefits upon the Athenians, that they rendered him divine honours; and as an acknowledgment of the influence which she had exercised in their favour, they dedicated a temple to her, under the name of "Venus Lamia."

The flutes of the ancients alone have furnished Bartholinus with materials for a very learned and instructive work (De Tibia Veterum), in which he has collected all the classic descriptions of the different instruments included in the class of flutes, and pointed out all the allusions to them in Greek and Roman authors, furnishing subsequent modern writers with a body of information on the subject, which has enabled them to appear very learned with very little trouble. So many different kinds of ancient wind instruments under the denomination of flutes are represented in sculpture, some plain without holes, some with two, some with three, and some with five holes, others with plugs, Ropans, or, as Merianus calls them, tuberculi (nipples) at the sides, some double, and some so large, that they must have been an octave below the others. Horace speaks of flutes with few holes, as well as lyres with few strings:

"Tibia non ut nunc orichales vineta tuberque
"Æmula, fed tensis, simplexque foraminis paene."

Ovid has the same remark:

"Prima terebro per rara foraminis luxuro,
"Ut daret effect, tibia longa fons."

Sidonius gives the flute seven holes; but Avienus gives it a thousand.

"Foraminibus tibia mille sunt."

The learned are very discordant in their opinions and explanations of the flutes used in the comedies of Terence; nor does any one discover the least knowledge of modern practical music, sufficient to lead them to intelligible discoveries on the subject. Bianchini "De tribus generibus instrumentorum musicarum veterum organis," and Bonani, in his "Gabinetto Armonico," have copied the antique representations of ancient musical instruments, but we have long seen that there is no dependence to be placed on their fidelity. Sometimes ignorance, and sometimes picturesque convenience, have occasioned blunders and deviations from truth in the original sculptors. In the supplement to the folio edit. of the Fr. Encyclopédie, it is suppos’d that all the ancient flutes had reeds; but of two kinds: one visible and the other invisible, like those in children’s trumpets; the oblique flute, or flauto traversiere, commonly called the German flute, was unknown to the ancients. According to the author of this article, the ancients had no real flute à bec, or traversiere; but all were played with reeds, like the modern hurtnois. The plugs, or flappes at the sides of ancient flutes, which served instead of keys, are imagined to have been used occasionally to stop certain holes which, in changing the mode, would not be wanted.

In this long article concerning flutes, or rather the hautbois, not a word is said of double flutes. Our belief how ever is, that the tibicines were two tubi in unison with each other; and that the tibicines were tuned all ottava. We can conceive no other harmonical use that could be made of them, as it is now generally believed that the ancients had never cultivated counterpoint, or figurative harmony. But something must still be said in this article, as long as it is already, concerning modern flutes.

The common flute, or flute à bec, from the upper end, or mouth-piece, resembling the beak of a bird, at the beginning of the last century, till the works of Corelli came out, was far more general use as a concert instrument than the violin. Sonatas for two flutes, and a thorough bass, violoncello or theorbo, were innumerable; with solos, duets, and concertos for the same instrument; nor was there a ballad then printed which was not thrown for the flute at the bottom of the page; as in the middle of the same century, almost every long and tune was set for the guitar. The concert flutes for which this music was composed were generally F and C. There is an imitative flout in the organ, called the flute, composed of open wooden pipes in unison with the principal; but much more soft and tender. This flout is always in the choir organ. The flute is shown by Mr. Maxwell, in his "Effays on Tune," p. 17, to belong to the class of imperfect instruments, vide Perfect Instruments.

Flute traversiere, Fl. Flauto traversiere, It. horizontal.

Flute Allemande, or German flute, a wind instrument of wood or ivory, consisting of four pieces, or joints, inserted one in the other. In the Fr. Encyclopédie a minute a description is given of the several parts of this instrument, its joints, holes, or perforations, keys, tenons, and bung at the top of the mouth-piece, that in ingenious turner who never saw a German flute would find little difficulty in making one; but we shall lay no more on the mechanism of the instrument, but confine our instructions to its use.

To become a good performer on this instrument, the student must begin by acquiring a good embouchure, or by procuring a clear, full, and sweet tone; a talk far more difficult than is generally imagined. Every one can produce a tone on a common flute, but few are able, without teaching, to make the German flute speak. The instrument being blown at the side, whereas it has its name of traversiere, must be held parallel to the shape of the mouth, that the stream of air issuing from the breath of the performer may enter in part at theingle orifice in the upper piece. Whoever can whistle in the pipe of a key, will soon produce a tone in the German flute, which will be harsh at first, but must be smoothed and refined by degrees, never forgetting in every day’s practice to make that a principal consideration. Whether sitting or standing, the performer must be erect in his carriage, the head rather above than below its usual position, and a little inclining to the left shoulder; the hands high, without raising the elbows or the shoulders; the left hand bent out, and the name arm near the body. If the player is standing, the attitude should be firm, the left foot advanced, the body resting on the right hip, and the whole performer free from constraint. The greatest care should be taken not to move the head or body, as many do, in order to mark the time. The attitude should have no irregularities, nothing awkward or affected to attract the attention, or prejudice the audience against the performer. With regard to the position of the hands, the left is to be at the top of the flute, which is held between the thumb of that hand and the fore finger, which ought to stop the upper hole, marked 1 in the figure, the second hole with the middle finger, and the third by the ring-finger. The right hand is to hold the lower part of the instrument; the thumb of this hand, which must be a little bent.
best inwards, supports the flute below, and the three fingers of this hand, the fore finger, the middle finger, and ring finger, flop the holes marked 4, 5, 6; the little finger serves to press down the key at the tail piece, or lowed joint, which key opens a hole out of the reach of the fingers. The flute must be held horizontally. No instructions for the lips in blowing the flute can suit the form of all mouths; but when the student can make the instrument speak easily and freely, he must turn it in and out, by small degrees, till he gets the best tone possible; and then, beginning with the chief well filled with wind, as left as possible to swell by minute degrees any note to its utmost power, and then to diminish it by the same degrees to a thread. We shall give among the plates a complete scale of every sound that can be produced on the instrument. Having worked upon one and the same note till a full and clear tone can be produced on a short notice, begin on the lowest found D, to swell and diminish each note in the same manner as the first, and let alone rapid passages and execution, till certain of the tone of the instrument: as fingers are obliged to follow, going no further than a hexachord for a long time; swelling each note to the utmost power of the breath and lungs, ascending and descending, to acquire steadiness in sustaining a note perfectly in tune, and free from all tremulous uncertainty during the most crude and violent accompaniment. See Musical Plate.

The tablature contains seven ranges of black and white indications of the seven holes that are to be occasionally stopped and opened on the flute. The black represent the fingers, and the white or open circles the holes unstopped. The compass of the German flute at present extends to three octaves, from the lowest D in the treble, to the octave above what used to be the highest D. [A C % or D below the D natural, has lately been acquired, by blowing very softly and turning the instrument inward.] It is to be observed that the higher the notes on this instrument are, the wind must be encreased, and the orifice of the lips somewhat more closed. Most of the notes are broken into octaves by a little additional force in blowing. The B, C, D, of the third octave cannot be produced upon all flutes; with middle pieces which lower the tone of the whole instrument, they are easier to be produced; the lower the better. There are sometimes seven middle pieces in use for flattening the pitch. These amount to about a tone; so that by their aid the same instrument may accommodate itself to any pitch. Not only all the semitones are given in the general scale on the first plate, but the flats on a second plate, which are indicated by the black and white ciphers. The finger over the white open cipher is to be closed, and the semitone is to be produced. There are nine flats in the language, accents, flats, &c. must be practiced separately.

Flute, or Organ, is a range of pipes, constructed to imitate the notes of the common flute or flageolet: it is softer than the principal in its tone: its pitch is an octave above the notes of the diapasons, or in unison with the principal flageolet.

Flute, or Fluy, is also a kind of long vellum, with flat ribs, or floor timbers, round behind, and swelled in the middle: serving chiefly for the carrying of provisions in fleets, or squadrons of ships: though it is often used in merchandise.

The word flute, taken for a fort of boat, or vellum, is derived, according to Borel, from the ancient flute, a little boat. In the verbal proverbs of the miracles of St. Catherine of Sweden, in the 12th century, it is used in "Unus equum form una cum transuse in magia ponders introductit super instrumentum de lignis fabricatum, vulgariter dictum fluta." Upon which the Hollandists observe, that in some copies it is read flotta, an instrument called by the Latins rotellis; and that the word flotta, or flotta, arose from flotto or flutten, to float.

Flute, in weaving tapestry. See Tapestry.

Flutes, or Flutings, are longitudinal concavities depress'd in the surface of a piece of architecture, generally of a circular or elliptical section, meeting each other in lines, or separated with a part of the surface from which the excavation is made left standing between. The surface separating every two flutes is called a fillet; if the flutes are parallel or diminuith according to any law, the fillets are also made parallel or to diminish in the same law.

And if the flutes run in a straight line, or in a curve at right angles to the section, the fillets follow the same direction. When fillets separate the flutes from each other, each fillet is in breadth from one-third to one-fifth of the breadth of the flute. That species of fluting where the flutes meet each other without the intervention of fillets, is generally applied to the shaft of the Doric order, and the other with fillets to the shafts of Ionian and Corinthian. Flutes frequently terminate semicircularly on the face or with spheric heads, and sometimes their terminations are planets at right angles to their longitudinal direction. The Greeks never applied fluting to any member of the Doric order, except to the shaft, which was almost a universal practice, there only being two known examples to the contrary, nor even to the Ionic. The Romans frequently overcharged all the plain and cylindrical members. For a more particular description of fluting, see Doric and Ionic Orders.

Flutes, or Flutings, are also used, in Botany, to denote the stems and fruits of certain plants, which have furrows analogous to those of flute columns.

Flutter, or Majic, is a term applied by Dr. Robert Smith (Harmonics, p. 97.) to the fluctuating roughnesses in the found of two notes which are discords to each other: a phenomenon very distinct from the beats of imperfect consonances; the latter being, because the succession of their short cycles are periodically confused and interrupted, whereas discords have this characteristic fluctuating, when their ratios are quite perfect, and when concords, under the same circumstances, cease to have any beats, but produce a perfect consonance, or uniformity of sound. See Concord.

Fluvanna, in Geography, a county of Virginia, bounded N. by Albemarle, N. E. by Louisa, E. by Goochland, W. by Amherst, and S. by Fluanna or James river, which divides it from Buckingham. It is about 22 miles long and 20 broad, and contains 2,703 free inhabitants, and 3,936 others. There is great pled of ore, and some inferior white and variegated with blue, red, and purple veins found in this county, on James river at the mouth of Rockfish; where it forms a large precipice overhanging a navigable part of the river.

Fluviana, in Geography, a river of Spain, in Catalonia, which runs into the Mediterranean, in the gulf of Roses. N. lat. 42° 10'. E. long. 2° 56'.

Fluvialites Cochlearis, fresh-water shell-fish, a term used by naturalists to express those kinds of shell-fish which never inhabit the sea, but are found in our ponds, rivers, and ditches. These, though much less numerous than the species of sea shells, are yet of a greater variety and beauty than is usually supposed. See Conchology.

Flux, in Enamel, is that glossy body that forms the basis of all enamels, whether transparent, semi-transparent, or opaque. Now as the painting on enamel is performed with vitreous colours, which to speak truly can be nothing more
FLUX.

or left than coloured enamels, it must be evident that flux likewise forms a principal part in the composition of enamel colours.

FLUX. Enameller's, is a sort of enamel principally used for the upper surfaces of plates intended for enamel painting. It differs from the common enamels, in being of a more mellow and rich quality, whilst its properties facilitate the fusion of those colours which are employed in painting on it. The best kinds having been generally brought from Venice, have acquired the name of Venetian flux, and are commonly imported in the form of small beads, hence called lead-flux, or short pipes about three-eighths of an inch in diameter, and from three quarters of an inch to an inch in length: the latter is called pipe-flux. The fluxed plates, when prepared as described under Enamelling, have a rich yellow hue, or cream colour; by which they are rendered of particular utility in paintings where much of the naked figure is exposed. The flux must always be laid upon hard enamel; as the properties of glass enamel are inimical to effective cohesion, the flux cracking in circles, or flying off in pieces as the plates cool.

In order to give a clear idea of the nature of fluxes, it will not be improper previously to inquire more particularly into the nature of the ingredients, their operations on each other in a state of composition, as well as the power which each exerts in producing a proper effect; since by this means such an initiative knowledge may be obtained, as will enable persons unacquainted with the art to conduct their experiments with more certainty, than they possibly could by any particular recipes, however good they might be.

There are two kinds of substances which enter into the composition of enamel fluxes; the one, the proper matter of the flux, being principally such bodies as are by their nature endowed with a strong propensity to run into the vitreous fusion, and be converted into glafs, at the same time that they affimilate and change other bodies in combination with them into their own vitreous nature. This kind consists principally of fusible substances, lead, and arsenic. The other kind consists of the correctives of these proper fluxings, which without their admixture would be found to have qualities that would deprive them for enamelling or the fluxes for paintings. For all kinds of fluxes, when vitrifled by themselves, or with a small proportion of other bodies, are still liable to be dissolved by aqueous moisture; and flux, made of such ingredients only, would be corroded even by the common air, and turn black and dull on its surface; hence it becomes necessary to add some other bodies as correctives to prevent these bad tendencies, and render the flux more durable. Lead and arsenic, when formed into glafs, of which they compose the principal ingredients, are particularly liable to be thus corroded; to prevent which, when using these fluxes, it is necessary to add considerable proportions of the corrective matter. The truth of these remarks may be readily ascertained by the appearance of the enamel door-plates about this town, in many of which the lead, having been used in too great a proportion as a flux for the black colour, has been so far corroded as to have admitted the air to come in contact with the colouring matter, in which case the whole writing is almost obliterated.

The most common of these corrective bodies of the proper matter of the flux, and which therefore make the second kind of substances of which enamel fluxes are composed, are calcined clints, and Lynn sand, or what is generally known by the name of silver sand, which being perfectly white, and refilling when vitrifled the corrective and decomposing action of all menitrus, give body and hardness to the fluxes, without any other disadvantage than that of diminishing, in a certain degree, their inclination to vitrify, and on that account rendering them somewhat weaker as fluxes than they would be if used alone.

The most active kind of salt as a general flux is borax, which possesses the greatest power of any simple body hitherto known. Lead, which is the next, vitrifies with a very slight heat, and at the same time analogous to other bodies to its own nature, such as earths, stones, the oxides of metals, &c. Arsenic is likewise a powerful fluxing substance; but whenever this is used it should be, with bodies that have been previously vitrifled and ground tolerably fine, otherwise it is apt to sublimate and fly off from the composition with which it is mixed, and which of course must render any recipe, where a certain proportion of this is to be used, very liable to error without such precautions. Several kinds of salts possess the next degree of fluxing power, the principal of which is sea salt; but it must be evident from what has been mentioned, that they are not sufficiently strong to form an enamel flux by themselves, yet as they are perfectly colourless when vitrified, which is not the case with lead, they will be found very useful in composition with lead, or when used in place of that substance, allied by borax, especially where any tinge of yellow would be detrimental to the colouring matter that is to be used with the flux.

Having endeavoured to give the reader an idea of the nature of the fluxes that are used in the formation of enamels, we shall next endeavour to explain the method of compounding them before they are fused, and also some observations upon that part of the process.

When the materials are procured, taking care that they are of the best quality, each should be separately levigated either in an agate mortar, or one made of the same kind of glass as the common wine bottles are made of; the pestle in either case should be of flint or agate. The proportions of each substance, having first been thoroughly mixed, the whole must be put into crucibles of a proper size, and placed in an air furnace, or what is more commonly called a wind hole, where the heat should be increased till the matter is perfectly vitrified, which may be known by its becoming clear and transparent. The heat must be sufficiently powerful, yet not too violent, for though a great heat may accelerate the vitrification, yet it at all times hardens the composition, and greatly reduces the fluxing power. The simplest method of dipping the end of a tobacco pipe in the flux while in a state of fusion, and examining the small quantity that adheres to it, will enable a person to form an accurate judgment of the whole; for if it appears clear and transparent it may be concluded that the vitrification is complete, but if any cloud of parts appear including opaque specks, it is evident that a longer continuation of heat is necessary. When the quantity is small it becomes very difficult to get the whole out of the pot; the best method perhaps is to hold the edge of the pot with a convenient pair of tongs, and at the same time scrape the matter out with a small piece of iron, the edge of which should be previously made to at the bottom of the crucible. Whoever would have flux in the greatest degree of purity, must previously prepare the clints of lead to be ready at all times for use, for although lead might be mixed with the other ingredients for common purposes, yet it will be better in all cases to prepare it previously by the following means.

Take of the bell-minium, or, as it is commonly called, red lead, four pounds; of Lynn sand, or calcined clints, two pounds and a quarter; these two substances should be thoroughly
thoroughly mixed, and be put into a very found crucible. One that has had flux or a little flint glafs melted in it before would be preferable, for when a new pot is used, the lead is very liable to strain through the pores, and thus occasion an uncertain refult, although the quantities should have been ever fo nicely adjusted. This is to be vitrified in the fame manner as directed for flux, and when perfect will be of a beautiful topaz or transparent gold colour. When the matter is cold, it should be ground in the mortar before defribed, and then kept perfectly free from durt.

In molt large concerns in the glafs busines is fond greatly preferable to flints, as the trouble of calcining and grinding the latter, where large quantities are wanted, is a ferior objection to their ufe. But in the cafe of flux, where quality is of more confequence than quantity, flints are certainly preferable.

The method of preparing the flints for ufe, is to place them in a clear fire, in which they fhould continue two or three hours; the fire fhould then be increafed till they attain a white heat, at which time they fhould be taken very quicfly from the fire and plunged into cold water, which will caufe them to crack and faw in innumerable parts; they muft then be broken into pieces, and if they are of an uniform whitenefs throughout, they may be considered as fit for grinding; but if any black and discolourd places appear, they muft be again submitted to the fire, and the immersion in water repeated; the calcination being then completed, they muft be broken as small as poaffe with a steel-faced hammer, and ground very fine in the glafs or agate mortar.

A very important advantage attending this preparation of the glafs of lead, is the ease with which a very perfect vitrification of the fand or flints is effected without the aid of intense heat; at the fame time the mixture is rendered more capable of affimilating with a larger proportion of flints, which will in all cafes add greatly to the foftnefs of the flux.

Very little hope is entertained that any more of the Venetian hard enamel or flux for grounds will be imported into this country, as we are affured that Bertolini, the celebrated maker of thofe fubfiances, perifhed in the hands of the French at Naples, on account of his political opinions. We feel much pleafure in being able to fay, however, that Mr. Griffiths of Broad Court, Long Acre, London, after many years spent in making enamel colours, has fucceeded in making flux for grounds equal to any of the Venetian, which he has confantly for fale. He has likewise, within the laft three years, brought to perfedion a beautiful white, hard enamel, which is fo neary equal to the Venetian, that the one might be mistaken for the other, the colour and fracture being fo much alike.

The firft recipe for the formation of a flux, and which we shall call N. 1, is the white glafs enamel, which, containing a large proportion of arfenic in a femi-vitrified state, requires to be broken into small pieces, and fufed till the matter becomes quite clear and transparent; the arfenic will by this means be completely vitrified, and convert the glafs into a foft and ufeful flux, fit to be mixed with molt of the earths that may be ufed as colours. And likewise, with the oxys of all the metals, gold and filver excepted; for it must be remembered, that lead and arfenic are both apt to injure the beauty of the colours that are produced by gold and filver: therefore, whenever they are ufed, it must be with a flux that is compofed without either of these ingredients; or if they do enter the compofition, it muft be in very fmall proportions.

Composition of a fopter flux for common purpofes, where the glafs may be found too hard, N. 2.—Take of the glafs of lead one pound; of pearl afhes, five ounces; of borax, five ounces; and of arfenic, half an ounce. This flux is fuitcd, by its foftnefs, to be mixed with colours that are to be ufed in glazing over others, where a harder flux has been ufed, and in moft cafes, where burning the colours with a flight heat is advantageous.

Composition of a flux perfectly pellicid and very foft, N. 3.—Take of common fint glafs, powdered very fine, seven ounces; of borax, one ounce and a half; of pearl afhes, two ounces; and of fciafi, one ounce. This flux, by its foftnefs and cleareftry, will be found very ufeful for the oxys of gold and filver; likewife in all cafes where a tinge in the flux might be detrimental to the colouring fubfance that is to be ufed.

These fluxes, in the proportion here given, have been found to answer the purpofes for which they are intended extremely well; but as the ingredients fometimes vary in their quality, it is evident that much muft at all times be left for the ingenuity of the operator to supply. Indeed, when the difficulties that every perfon muft meet with in attempts of this nature, without a previous knowledge of chemistry, are confidered, we cannot do better than ad- vife a ftudy of that fcienee as an introduction to the art of enamelving and enamel painting, by which means a complete theory of the various fubfiances may be obtained, which, in the course of practice, may lead to ufeful dif- coveries; or, to lay the leaft, will many times prevent ufe- less experiments being made.

We muft not omit noticing in this place, that plate-plate enamellers found great inconvenience in the fads of the Venetian white hard enamel, as that fubfance was principally ufed for the bottoms or backs of plate-plates manufactured of the English glafs enamel; for the expansion of these two fubfances is fo exadly fuitcd each other, that it was very rare that any of them cracked in the fire. This, however, was not the cafe with all the kinds that were brought from Venice, and particularly a blue fort, famped on the cafes with the figure of a monkey, and commonly called monkey-enamel. This fort was very apt to crack the plates in circles, after they had been made a few weeks, unlefs it was ufed in compofition with other fubfances, whose fluxes, being fottcr, contributed to counteract this disagreeable property.

These obervations tend to confirm what we have before flated respecting the neceffity of laying flux for grounds on hard enamel, becaufe the English glafs enamel, being much harder from the nature of its compofition, does not run into fusion with the fame heat as the flux; consequently a perfect addition cannot take place between these two fub- fances. For a further account of the proportions of flux ufed in enamel colours, see Painting on Enamel. Hand- maid to the Arts, vol. i. and ii.

Flux, in Hydrography, a regular, periodical motion of the sea, happening twice in twenty-four hours; wherein the water is rafed, and driven violently against the fhores. The flux, or flow, is one of the motions of the tide, (see Tide); the other, whereby the water raps and retires, is called the reflux, or ebb.

There is also a kind of refl, or ceafation of about half an hour, between the flux and reflux; during which time the water is at its greatest height, called high-water.

The flux is made by the motion of the water of the sea, from the equator towards the poles; which, in its progrefs, striking against the coasts in its way, and meeting with opposition from them, rakes, and where it can find passage, as in flats, rivers, &c. rifes up, and runs into the land.

This motion follows, in fome measure, the course of the
the moon; as it rises or comes later every day by about three quarters of an hour; or, more precisely, by forty-eight minutes: and by so much is the motion of the moon slower than that of the sun. It is always highest and greatest in full moons, particularly those of the equinoxes. In some parts, as at Mount St. Michael, it rises eighty or ninety feet, though the general height above a foot or two, and in some places, as about the Morea, there is no flux at all. It runs up some rivers above a hundred and twenty miles. Up the river Thames it only goes eighty, viz. near to Kingston in Surrey.

Above London-bridge, the water flows four hours, and ebbs eight; and below the bridge, flows five hours, and ebbs seven. See Tides.

**FLUX.**

In Medicine, often called also bloody flux, the popular appellation of Disenteroty, which see.

**FLUX.** in Metallurgy. All those substances which have been employed to facilitate the separation of metals from their ores, or to give greater fluidity in the fusing or melting of metals, have by manufacturers been denominated fluxes.

Fluxes employed in separating metals from their ores have the effect of rendering the substances with which the metal is combined, capable of fusion. The whole is, by this addition of the flux, rendered fluid; the metal, being the heaviest fluid, sinks to the bottom; while the fluid mafes, arising from the earthy matters of the ore, combined with the flux, floats on the surface: the latter, on cooling, puts on a vitreous appearance, and is, by manufacturers, called *forin.* Hence it will appear, that the flux employed must be such a substance as may be best calculated to render those substances more fusible with which the metal is combined.

If the ore abounds with *filex,* potash or soda is best calculated to separate it from the metal. Tartar, which contains the tartaric acid united with the potash, and frequently abounds with much vegetable matter, is employed to great advantage in the small way. The hydrogen and carbon present, take the oxygen from the metal; while the potash combines with the *filex,* forming a fluid vitreous mass, more or less coloured by the oxides of the metal.

The fluxes known by the names of black flux and white flux are generally used in the smaller experiments. The former is made by detonating one part of nitre with three of tartar, so that it contains at least an excess of carbonaceous matter, which is fitted for the reduction of the metallic oxide, while the potash, derived from the nitre and tartar, combines with the earthly products.

That called white flux, is formed by detonating equal parts of nitre and tartar, by projecting the mixture, by a small quantity at a time, into a red-hot crucible. In these proportions the whole of the carbonaceous matter of the tartar is destroyed by the oxygen of the nitre, and nothing more is obtained than a sub-carbonate of potash. It will appear evident to every chemist, that common tartar, or for nice experiments, that super-tartar of potash, will answer all the purposes of the black flux, and the sub-carbonate of potash is equally well taken for the latter. Some have recommended the nitre and tartar to be used together; but this will always be improper where the oxidizing action of the sub-ultramundine is intended. Nitre possesses a power so much the contrary, that it is capable of oxidizing gold.

In the large way, on account of cheapness, lime is employed to separate the *filex.* Barytes, if it could be found more plentifully, might be used to more advantage for separating *filex,* particularly from iron ore.

Lime is found to be the best flux for smelting the alumino-ous iron ores, from the great fusibility of due proportions of those two earths. Should the ore abound with *filex,* its reduction is found more difficult. It might be an advantage, where ores of this kind occur, to use some cheap compound of barytes, such as the sulphate of that earth.

From what has been observed, it will appear that it is of the greatest importance to be acquainted with the nature of the earthly matter in the different ores. Whether the ore contain alumina, lime, or both these substances, a certain quantity of one of them should be added, as will make the most fusible compound of the two. If the alumina be in excess, lime must be added, but if the ore be calcareous, which is sometimes the case, it is found necessary to add flux. In the smelting of iron ores, however, the fusibility of the earths is much increased by the oxides of iron, which always, more or less, colours the scoria. The oxides of iron is found to exert a much stronger affinity upon *filex* than upon any of the other earths, and hence those iron ores abounding with *filex,* when smelted, afford more coloured scoria, and in consequence are less productive.

In the smelting of copper ores, which contain *filex,* it is common to add some substance which contains oxide of iron; pyrites is generally used to afford this substance. But many copper ores contain iron, and add the addition of this substance as a flux. The oxide of iron combines with the *filex,* forming a dark coloured fusible compound, which floats on the surface, leaving the copper free from both those substances.

Most of the fluxes used in fusing or smelting those metals liable to oxidate by the presence of the oxygen of the atmosphere are such, as by fusing, when the metal would begin to oxidate, envelope the metallic surface, and prevent the combination of the oxygen. Of these ashes are many saline bodies, such as borax, potash, soda, tartar, muriate of soda, &c. In short it should be such a substance as may fuse before the body becomes very hot. It should have no action upon the metal itself, and it should possess so much fixity as not to be volatilized by the heat required for the fusion of the metal. If the flux be at all liable to fly off, a fresh quantity should be frequently added.

Another species of fluxes act by reducing the oxides as fall as it may be formed. The fusible metals are generally treated with those inflammable bodies, which combine with oxygen, with great facility, and at the same time involve the metallic surface. Roof and fatty substances are mostly employed for lead, tin, antimony, and bismuth, or their alloys. Zinc requires to be treated in a close vessel with charcoal powder, or pounded pit-coal.

The vitreous and saline fluxes which act by preventing oxidation, are employed for cast iron, copper, brass, &c. Pounded glas, or a mixture of lime and clay, may be employed for cast iron; potash or tartar for copper and brass.

The scoria of blast furnaces is generally used in the fusing of steel which is to be cast into ingots. If too much of these fluxes be used, the firmness of the crucible will be endangered. Muriate of ammonia has a very peculiar property of freeing the surfaces of metals from oxygen. This has been explained, by supposing that the ammonia is decomposed; the hydrogen of which combines with the oxygen. This does not, however, clearly explain the fact, for the muriate of ammonia is not decomposed by this process, and much less by the ammonia. It is well known to those who manufacture this muriat, that if any metallic oxide be present when this salt is sublimed, the oxide fuses with it, forming a triple salt. Indeed the substance, known in medi-
cine by the name of *floria martialis*, is formed in this
way, and is a triple mixture of iron and ammonia.

The great utility of this fact in the folding of metals, therefore, consists in carrying off the oxygen from the surface, at the time it hardens.

Rough and flat substrates used in folding give great fluidity and brightness to the folder, and clear the surfaces to be united, by their carbon and hydrogen taking the oxygen which may be present.

The fluid employed in folding iron, brass, and copper, are generally borax, (ful-horat of fola.) After the folder and the surfaces are once made clean, this borax acts, by preventing oxidation, till the folder fuses, and unites the two surfaces.

That this is the true explanation of the action of a flux, in folding, we have abundant proof, in folding one noble metal with another. When fine gold is employed for folding platinum, the gold is observed at the time of fusion to assume a degree of fluidity far superior to any folder made of oxidable metals, although the latter be assisted with the bell-flux.

In the fusion of these metals liable to oxidate, whether the fusion may be for the purpose of folding or casting, certain fluxes are found to be indispensable. The fluidity is so much improved, that in the latter process, without a flux, the folder would not be able to run between the surfaces to be united, independent of its action in preventing the oxidation of the surfaces. In the casting of metals, the fluidity would sometimes be so imperfect, without the presence of the flux, that impressions taken from the mould would be exceedingly defective, and small articles, such as needles and fish hooks, could not be cast at all.

We shall conclude this article by giving a short explanation of the cause of increase of fluidity by the agency of fluxes.

Although an idea is entertained by chemists, that there is no medium between that pulpyulent plate called the oxidated and the metallic plates, it will be found that the oxidable metals combine with oxygen when exposed to the air in a plate of fusion, without losing their metallic form. They however lose much of their luire and fluidity. Of this fact we have a striking proof in silver, which in the act of refining has been long exposed to a current of oxygen for the purpose of freeing it from the hafer metals. At the time the silver affinates the fold form, the oxygen is given out in the form of gas. Mr. Lucas, a refiner of Sheffield, by throwing the liquid silver into water, collected an abundance of pure oxygen gas.

The partial loss of luire and fluidity from the combined oxygen, is soon very apparent in melted zinc, both of which may be completely restored, by treating it in a close vessel with charcoal powder. All the oxidable metals are more or less susceptible of this change, proportionate to their affinity for the said substance.

From what has been observed we may infer, that it is highly injudicious to expose much of the melted surface of metals to the air. Hence the iron ladles used for the fusible metals, as well as crucibles, ought to be as narrow as possible at the top, at the same time that fume fusilbute should be employed, which will either prevent the oxidation, or reduce the oxyd as it is formed.

FLUXES, in the Manufacture of Glass, are red-lead, pearl-ashes, nitre, tea-salt, borax, arsenic, the fever of forges, commonly called clinkers, and wood-ashes. See Glass.

FLUXION, was a term, in Surgery, much employed by the ancient writers and practitioners to signify the motion by which, according to theories now exploded, the humours were spontaneously determined, with a certain velocity, towards any particular part of the body, so as to occasion there a tumour, attended with heat. When the humours were deposited in a flower and more gradual way, the old medical writers used to say, that the tumour was produced by congestion.

FLUXION, in the Newtonian Analysis, denotes the velocity with which a flowing quantity is increased by its generative motion; by which it stands contradistinguished from fluent or the flowing quantity, which is gradually, and indefinitely increasing, after the manner of a space which a body in motion describes.

Or, a fluxion may be more accurately defined, as the magnitude by which any flowing quantity would be uniformly increased in a given portion of time, with the generating celerity at any proposed position, or instant, supposing it from thence to continue invariable.

Thus, if the point $m$ move from $A$, and generate the right line $Am$, (Plate VII. Analysis fig. 1.) and the celerity at $R$ be such as would be sufficient, supposing it to continue uniform from that point, to describe the line $Rr$ in the given time; then $Rr$ represents the fluxion of the variable line $A m$ in that position. The rectangle $A S$, $Sg$, 2 may be conceived to be generated by the parallel motion of the invariant line $m n$ between $A F$ and $B g$; and since $R r$ is the fluxion of $A m$, the rectangle $R r S$ will be the space which would be uniformly described by $m n$, whilst $A m$ would be uniformly increased by $m r$, and it is, therefore, the fluxion of the generated rectangle $A B S R$. Farther, if the curve line $A m$, $m f$, 3 be generated by the parallel motion of $m n$, considered as variable, and $R r$ be the fluxion of $A m$, the rectangle $R r S$ would be uniformly generated with the celerity, with which it begins to be generated, and with which the space $A m$ is increased in the position $R s$, when the length and velocity of $m n$ are supposed to continue invariable from that position, and, therefore, agreeably to the definition, will be the fluxion of the generated space $A m$.

From this definition it appears, that the fluxions of quantities are, always, as the celerities by which the quantities themselves increase in magnitude.

Mr. Simpson observes, that there is an advantage in considering fluxions, not as mere velocities, but as the magnitudes which those velocities would, uniformly, generate in a given finite time; the imagination is not here confined to a single point, and the higher order of fluxions are rendered much more easy and intelligible. And though Sir Isaac Newton defines fluxions to be the velocities of motions, yet he hath recourse to the increments or moments generated in equal particles of time, in order to determine those velocities, which he afterwards teaches us to expand by finite magnitudes of other kinds. Simpson’s Fluxions, vol. 1. prof. p. 6, and p. 7, &c.

FLUXIONS, Method of, is the arithmetical and analysis of fluxions and fluents, or flowing quantities.

Foreigners usually define the method of fluxions as the arithmetic, or analysis, of infinitely, or rather indefinitely, small variable quantities; or the method of finding an infinite, or indefinitely small quantity, which, being taken an infinite number of times, becomes equal to a given quantity.

Sir I. Newton, and after him, the English authors, call these indefinitely small quantities moments; considering them as the momentary increments, or decrements, of variable quantities, e. g. of a line considered as generated by the flux
FLUXIONS.

flux of a point, or of a surface generated by the flux of a line.

Accordingly, the variable quantities are called fluent, or flowing quantities; and the method of finding either the fluxion, or the fluent, the method of fluxions.

M. Leibnitz considers the same infinitely small quantities as the differences, or differentials, of two quantities; and calls the method of finding these differences the differential calculus. (See Calculus.) Each of these ways of considering and denominating, has its advantages, which the retainers to this or that method strenuously affect.

Flowing quantities, i.e. such as, in the genesis of figures by local motion are continually increasing and diminishing, are certainly very properly denominated fluents; and as all figures may be conceived as so generated, the infinitely small increments or decrements of such quantities are very naturally denominated fluxions.

Beside this difference in the name, there is another in the notation.

Sir I. Newton expresses the fluxion of a quantity, as $x$, by a dot placed over it, as $\dot{x}$; and M. Leibnitz expresses his differential of the same $x$, by prefixing a $d$, as $dx$; each of which methods of notation has likewise its advantage.

Setting aside these circumstances, the two methods are the same.

The method of fluxions is one of the greatest, most subtle, and sublime discoveries of this, or, perhaps, of any age: it opens a new world to us, and extends our knowledge, as it were, to infinity; it carries us beyond the bounds that seemed to have been preferred to the human mind, at least infinitely beyond those to which the ancient geometry was confined.

The history of this important discovery, as fresh as it is, is a little dark and embroiled. Two of the greatest men of this age do both of them claim the invention, viz. I. Newton, and M. Leibnitz; and nothing can be more glorious for the method itself, than the zeal wherewith the partisans of either side have asserted their respective title.

To give the reader a just view of this noble dispute, and of the pretensions of each party, we shall lay before him the origin of the discovery, and mark where each claim commenced, and how it was supported.

The first time the method made its appearance in public, was in 1684, when M. Leibnitz gave the rules thereof in the Leipsic Acts of that year; but the demonstrations he kept to himself. The two brothers, the Bernoullis, were previously struck with it, and found out the demonstrations, though very difficult; and published the calculus with surpassing success.

However, M. Leibnitz began to propose his differential method in a letter, dated 21 Jan. 16, 5, in which he exactly pursues Dr. Barrow's method of tangents, published in 1677, and Sir I. Newton communicated his method of drawing tangents to Mr. Collins, in a letter dated 16 Dec. 1672; which letter, together with another dated 13 June 1676, was sent to M. Leibnitz by Mr. Oldenburgh, in 1676. So that there is a communication that he might avail himself of the information contained in these letters, and other papers transmitted to him. But also if he, before the publication of his own letter, containing the hint of his differential method, had sufficiently appeared that Sir I. Newton had invented his method before the year 1669, and that he actually made use of it in his Compendium of Analysis and Quadrature of Curves before that time. His attention seems to have been directed thereto, even before the plague which happened in London 1665, and 1666, when he was about twenty-three years of age; and, therefore, there is no foundation for the hint suggested by the authors of the Encyclopaedia Art. Differentiel, that Sir Isaac borrowed the differential method from Dr. Barrow.

This is all we hear of it, till the year 1687, when Sir Isaac Newton's admirable Principia came forth, which is almost wholly founded on the same calculus.

The common opinion, at that time, was, that Sir Isaac, and M. Leibnitz, had each invented it about the same time; and what co.ined it was, that neither of them made any mention of the other; and that, though they agreed in the substance of the thing, yet they differed in their ways of conceiving; called it by different names, and used different characters.

In effect, M. Leibnitz's character was supposed, by foreigners, to be somewhat more commodious than that of Sir Isaac Newton; accordingly, the method soon spreading itself, throughout Europe, M. Leibnitz's character went with it; by which means the geometricians were insufficiently accustomed to look on him as the sole, or principal inventor.

The two great authors themselves, without any seeming concern, or dispute, as to the property of the invention, enjoyed the glorious prospect of the progress continually making under their auspices, till the year 1699, when the peace began to be disturbed.

M. Fatio, in a treatise "Of the Line of swift Fluxions," declared, that he was obliged to own Sir Isaac Newton as the first inventor of the differential calculus, and the first by many years; and that he left the world to judge whether M. Leibnitz, the second inventor, had taken anything from him. This precise distinction between first and second inventor, with the suspicion it insinuated, raised a controversy between M. Leibnitz, supported by the editors of the Leipsic Acts, and the English geometricians, who declared for Sir Isaac Newton. Sir Isaac himself never appeared on the scene; his glory was become that of the nation; and his adherents, warm in the cause of their country, needed not him to animate them.

Writings succeeded each other; but slowly on either side; probably on account of the distance of places; but the controversy grew still hotter and hotter; till, at length, it came to such pass, that in the year 1711, M. Leibnitz complained to the Royal Society, that Dr. Keill had accused him of publishing the method of fluxions invented by Sir Isaac Newton, under other names and characters. He informed, that nobody knew better than Sir Isaac himself, that he had found nothing from him; and required, that Dr. Keill should publicly disavow the ill construction which might be put on his words.

The society here applied to as a judge, appointed a committee to examine all the letters, papers, that had passed among the several mathematicians relating to the point; and, after a strict examen of all the evidence that could be presented, gave in their report to this purpose: That M. Leibnitz was in London in 1693, and had a correspondence with Mr. Collins, by means of Mr. Oldenburgh; that he returned from Paris to Leipsic; and that he returned from London, and Amsterdam, in the year 1711, when the dispute was carried to such a state of the difference, that the Leipsic Academy, after the 2nd June, 1711, was a great matter of the 3rd July, of another letter, written by Sir Isaac Newton, in the year 1712, and published, in which the same circumstances were communicated to him, and the same was answered. M. Leibnitz, on his part, proposed to communicate that letter, but an answer which, after the first method of fluxions was extremely established, the controversy would be better decided. The
of his sagacity into the whole matter: and that Sir I. Newton had even invented his method before the year 1669, and, of consequence, fifteen years before M. Leibnitz had given any thing on the subject in the Leipsic Acts." And thence they concluded, that Dr. Keill had not at all injured M. Leibnitz in what he had said.

The society printed this cenasure of theirs, together with all the pieces and materials relating thereto, under the title of "Commerciuni Epistolica de Analyte Promota," Lond. 1712. This book was carefully distributed through Europe, to vindicate the title of the English nation to the discovery; for Sir Isaac, as already hinted, never appeared in it: whether it were that he trusted his honour with his compatriots, who were zealous enough in the cause; or whether it were that he was even superior to the glory thereof.

M. Leibnitz and his friends, however, could not shew the same indifference: he was accused of a theft; and the whole Commerciium Epistolica either express it in terms, or intimates it. Soon after its publication, a broad sheet was printed, at Paris, in behalf of M. Leibnitz, then at Vienna. It is written with great zeal and spirit; and maintains, boldly, that the method of fluxions had not preceded that of differences: and even intimates, that it might have been taken from it. The detail of the proofs, on each side, would be too long, and could not be underlined without a large comment, which must enter into the deep and geometry.

M. Leibnitz had begun to work upon a Commerciium Epistolicum, in opposition to that of the Royal Society; but he died before it was completed.

A second edition of the Commerciium Epistolicum was printed at London in 1722; where Sir Isaac Newton, in the preface, account, and annotations, which were added to that edition, particularly answered all the objections which M. Leibnitz and M. Bernouilli were able to make since the Commerciium first appeared in 1712. See also Raphson's Hill. Fluxion. From the last edition of the Commerciium, and the various original papers contained in it, it evidently appears that Sir Isaac Newton had discovered his method of fluxions many years before M. Leibnitz's pretensions.

It must be owned, that there are strong presumptions in favour of M. Leibnitz: presumptions, we mean, that he was no plagiarist: for that Sir Isaac Newton was the first inventor, is past all dispute; his glory is secure; the reasonable part, even among the foreigners, allow it: and the question is only, whether M. Leibnitz took it from him, or fell upon the same thing with him; for, in his "Theory of Abstract Notions," which he dedicated to the Royal Academy, 167, before he had been any thing of Sir Isaac Newton's, he already supposes infinitely small quantities, some greater than others; which is one of the great principles of the system.

The doctrine consists of two parts, viz. the Direct method of fluxions, called also Calculus differentialis; and the Inverse method of fluxions, or Calculus integralis. The latter is directly opposite to the former, and is a sequel of it: both of them are adopted into the new geometry, and make reigning methods therein.

The first depends from finite, to infinite; the latter advances from infinitely small, to finite: the one de-compounds a magnitude; the other re-establishes it.

The foundation of the direct method of fluxions amounts to this problem: the length of the space described being continually (that is at all times) given, to find the velocity at any time proposed.

The foundation of the inverse method of fluxions amounts to this problem; the velocity of the motion being continually given, to find the space described by it at any time proposed.

Direct method of fluxions.—All finite magnitudes are here conceived to be resolved into infinitely small ones, supposed to be generated by motion, as a line by the motion of a point, a superflicus by a line, and a solid by a superflicus; and they are the elements, moments, or differences thereof.

The art of finding these infinitely small quantities, or the velocities by which they are generated, and of working upon them, and discovering other infinite quantities, by their means, makes the direct method of fluxions.

What renders the knowledge of infinitely small quantities of such signal use and extent is, that they have relations to each other, which the finite magnitudes, whereof they are the infinitesimals, have not.

Thus, e. g. in a curve, of any kind whatever, the infinitely small differences of the ordinate and absciss have the ratio to each other, not of the ordinate and absciss, but of the ordinate and subtangent; and, of consequence, the absciss and ordinate alone being known, give the subtangent unknown; or, which amounts to the same, the tangent itself. See the Inverse method of fluxions.

The method of notation in fluxions, introduced by the inventor, Sir I. Newton, is thus: The variable, or flowing quantity, to be uniformly augmented, as suppose the absciss of a curve, he denotes by the final letters a, x, y, z, and their fluxions by the same letters with dots placed over them, thus, x, y, z. And the initial letters a, b, c, d, &c. are used to express variable quantities.

Again, if the fluxions themselves are also variable quantities, and are continually increasing, or decreasing, he considers the velocities with which they increase, or decrease, as the fluxions of the former fluxions or second fluxions; which are denoted by two dots over them, thus, x x, y x, z x. After the same manner one may consider the augment, and diminutions of these, as their fluxions, also; and thus proceed to the third, fourth, fifth, &c. fluxions which will be noted thus, x x x, x x y, x x z, &c. We may observe, in general, that the fluxions of all kinds and orders whatever, are contemporaneous, or such as may be generated together, with their respective celerities, in one and the same time.

Lastly, if the flowing quantity be a curved, as so = a - b; he notes its fluxion, \[ y = \frac{d}{dx} (a - b) \]; if a fraction \( \frac{x}{y} \) he notes it, \( \frac{x}{y} \). Vide Wallis's Algebra, p. 392; and Oper. vol. ii. See Fluxent.

The chief scope and business of fluxions is, from the flowing quantity given, to find the fluxion; for this we shall lay down one general rule, as stated by Dr. Wallis, and afterwards apply and exemplify it in several cases. "Multiply each term of the equation separately by the several indices of the powers of all the flowing quantities contained in that term; and in each multiplication change one root or letter of the power into its proper fluxion; the aggregate of all the products connected together by their proper signs, will be the fluxion of the equation desired."

The application of this rule will be contained in the following
FLUXIONS.

Following cases. 1. To express the fluxions of simple variable quantities, as already mentioned, you need only put the letter, or letters, which express them, with a dot over them: thus, the fluxion of $x$ is $\dot{x}$, and the fluxion of $y$ is $\dot{y}$, and the fluxion of $x + y + u + z$, is $\dot{x} + \dot{y} + \dot{u} + \dot{z}$, &c.

2. To find the fluxions of the products of two or more variable or given quantities multiply the fluxion of each simple quantity by the factors of the products, or the product of all the reals and connect the last products by their proper signs: then the sum, or aggregate, is the fluxion sought.

Thus, the fluxion of $xy$, is $\dot{x}y + x\dot{y}$. For let two right lines, $DE$ and $FG$, move parallel to themselves from two other right lines, $BA$ and $BC$, (Plate VII. Analysis, fig. 4) and generate the rectangle $DF$. Let them always intersect each other in the curve $BHR$, and let $Dd$ of $\dot{e}$ and $Ff$ of $\dot{g}$ be the fluxions of the sides $BD$ and $BF$; and draw $dm$ and $fn$ parallel to $DH$ and $FH$. The fluxion of the area $BDF$ (see the beginning of this article) is $m\dot{y} + x\dot{r}$, and that of the area $BDF$ in $x$ or $x$, and therefore the fluxion of the whole rectangle $EF = x\dot{y} + y\dot{u} + y\dot{u} + u\dot{v} + u\dot{v} + v\dot{r}$; for if $x$ be put $= u$, then $y\dot{u} + u\dot{v} = y\dot{x} + x\dot{y}$; but $x = u = 1$ and $\dot{x} = \dot{u}$. $y\dot{x} + y\dot{y} + y\dot{y} + y\dot{y}$, by substitution, will be $= y\dot{x} + y\dot{y} + y\dot{y} + y\dot{y}$. And the fluxion of $x + y + z$ is $\dot{x} + \dot{y} + \dot{z}$ (the common product being $x\dot{y} + y\dot{u} + u\dot{v} + v\dot{r}$ and the fluxion of $a + b + c - d - e - f$, the fluxion of $a\dot{b} + \dot{b}e + d\dot{e} + b\dot{d} + e\dot{a} + a\dot{e}$).

3. To find the fluxion of a fraction. — Multiply the fluxion of the numerator by the denominator, and from this product subtract the fluxion of the denominator drawn into the numerator; this will be the numerator, and the square of the denominator will be the denominator of the fraction expressing the fluxion of the given fraction.

Thus, the fluxion of $\frac{x}{y}$ is $\frac{\dot{x}y - xy\dot{y}}{y}$. For suppose $\frac{x}{y} = z$, then will $x = yz$, which equal quantities must have equal fluxions; therefore $\dot{x} = \dot{y}z + \dot{z}y$, and $x - z = \dot{z}y$; and dividing all by $y$, $\frac{\dot{x} - \dot{z}y}{y}$. (because $\frac{x}{y} = z$) $\frac{\dot{x} - \dot{z}y}{y} - \frac{\dot{y}z - \dot{z}y}{y} = \frac{\dot{x}y - xy\dot{y}}{y}$, wherefore this last is the fluxion of the fraction $\frac{x}{y}$. $\dot{z}$, because $\dot{z}$ will be equal to the fluxion of $\frac{x}{y}$.

And the fluxion of $\frac{a}{x}$ will be $\frac{-a\dot{x}}{x}$; for the constant quantity $a$ having no fluxion, there can be no product of the fluxion of the numerator into the denominator, as there would have been, had $a$ been $x$, $z$, or any other variable quantity.

4. To find the fluxion of a power. — Multiply the fluxion of the root by the exponent of the power, and the product by that power of the same name, whose exponent is less by unit than the given exponent; and likewise by the variable quantity and co-efficient, if there be any.

Thus, the fluxion of $x^2$ will be $2x\dot{x}$; for $x = 2^x$. But the fluxion of $x^2 = x\dot{x} + 2\dot{x}x$, &c. and the fluxion of $x$ will be $2^x$. Then $\dot{x}$ will be $8x\dot{x}$, &c. and that of $\dot{x}$ will be $25^x\dot{x}$, &c. that of $y = 12^x\dot{x}$ &c.

Or, if $m$ expresses the index of any power, as suppose $x^m$, its fluxion will be $x^m\dot{x}$.

If the power be produced from a binomial, &c. as suppose $x + y$, or $x^2 + 2xy + y^2$, its fluxion will be $2x\dot{x} + 2x\dot{y} + 2y\dot{y}$.

If the exponent be negative, as suppose $\frac{1}{x}$, or $-x$, its fluxion will be $-\dot{x}$.

Or, if you would do it by way of fraction, $\frac{m}{x^m}$. (for the square of $x^n$ is $x^{2n}$), $-\frac{m}{x^m}$: $\dot{x} = -\frac{m}{x^m} \cdot \dot{x}$ as before; =, removing $x^{m-2}$ to the denominator, by changing the sign of the exponent, $\frac{m}{x^{m-2}}$.

If the power be imperfect, i.e. if its exponent be a fraction, as suppose $\sqrt[n]{x^{m-1}}$; or in the other notation $\frac{m}{n}$, suppose $\frac{m}{n} = z$; then if you raise each member to the power of $n$, it will stand thus, $x^m = z^n$: the fluxion of which will be, by this general rule, $m\dot{x} = n\dot{x}\frac{n}{n-1}$. $\dot{x}$.

Wherefore $\dot{z}$ will be $\frac{m}{n\dot{x}}$, (by dividing both parts by $n\dot{z}$) and $m\dot{x} = n\dot{z}$; or $\frac{m}{n}$: $\dot{x}$; putting, instead of $z^{n-1}$, its value $x\frac{m-n}{m}$, and the above expression will become $\frac{m}{n} \dot{x} = \frac{m}{n} \dot{x} = \frac{m}{n} \dot{x}$.

$\frac{m-n}{m} = \frac{m}{n} \dot{x} \frac{m-n}{m}$; or, more briefly, according to the rule, the fluxion of $\sqrt[n]{x^n}$ or $\frac{m}{n}$ will be $\frac{m}{n} \dot{x} = \frac{m}{n} \dot{x}$, &c.

5. To find the fluxions of several quantities. — Suppose it required to find the fluxion of $\sqrt[2]{x^n - x^n}$, or $\sqrt[n]{x^n - x^n}$.

Suppose $\frac{2}{2} = \frac{x screamed when you reach $2^x$, then $2^x = 2^x$, and consequently $r^x = x^z$; &c. and by division, $\frac{r^x}{z} = \dot{z}$; (by substitution) $\frac{r^x}{z} \dot{z} = \dot{z}$, to the fluxion of $\sqrt[2]{r^x - x^n}$.

Or, by the preceding rule, the fluxion of $\sqrt[2]{r^x - x^n}$, will be $\frac{r^x}{z} \dot{z} = \frac{r^x}{z} \dot{z} \dot{r} = \frac{r^x}{z} \dot{r} \dot{z}$, &c. See Power.
If it be required to find the fluxion of \( a y - x^2 \); put \( z = \frac{a}{y - x} \), and \( y = \frac{a}{x} \), and \( a y - 2 x = z \).

Multiplying by \( z \), \( 3 a y - 6 x = \frac{a}{x} = \frac{z}{3} \), and therefore, \( 3 a = \frac{z}{x} = \frac{a}{x} \).

Substituting \( a y - x^2 = \frac{a}{x} \) equal to \( \frac{3 a^2}{a} y^2 - 6 a x^2 y \), and \( x^2 = 6 a x^2 y + 2 a x^2 x = 6 a x^2 y + 2 a x^2 x = 6 a x^2 y \), and \( x^2 = 6 a x^2 y \).

To find the fluxion of quantities compounded of rational and several quantities: Let us be required to find the fluxion of \( b x^2 + a x^2 + a^2 x + \sqrt{x^2 + a} \), and \( \sqrt{x^2 + a} = \frac{a^2}{x} \). Then the given quantity is \( \frac{a^2}{x} \), and the fluxion thereof is \( \frac{\sqrt{x^2 + a}}{x} \).

To find the fluxion of a logarithm: The fluxion of the hyperbolic logarithm of any quantity is equal to the fluxion of that quantity divided by the quantity itself; e.g., the fluxion of the hyperbolic logarithm of \( x \) is \( \frac{1}{x} \); for let

\[ L, Q, \text{Plate VII. Analysis, fig. 5.} \]

be an hyperbola, whose asymptotes are \( O \) and \( S \), whose parameter is \( A \), \( \frac{AO}{1} \); draw an ordinate \( P M \) parallel to \( A L \), and the space \( A P M L \) will be the hyperbolic logarithm of the line \( O P \). Therefore, the fluxion of the space \( A P M \) will be equal to the fluxion of \( x \) the hyperbolic logarithm of the line \( O P \). But the fluxion of this line, \( O P \) being \( x \), and \( P M = \frac{1}{x} \), \( y \), \( O P \). \( A O \). \( L : A : P M \) by the nature of the curve; \( i.e., \( x \) : \( i : 1 ; \ y = \frac{1}{x} \),

therefore \( y = \frac{x}{x} \).

Then, from the nature of the logarithms, the hyperbolic logarithm of \( 10 \) (viz. 2,30258, &c.) is to the common logarithm of \( 10 \) (viz. 1) as the hyperbolic logarithm of any number \( n \) to the common logarithm of the same number \( n \); \( i.e., \) \( L \) being made \( 2,30258 \), &c., \( L \). \( 1 : 1 \) the hyperbolic logarithm of \( n \); common logarithm of \( n \); and therefore \( L \). \( 1 : 1 \); the fluxion of the hyperbolic logarithm of \( n \); the fluxion of the common logarithm of \( n \); \( i.e., \) \( L \). \( 1 : 1 \); \( \frac{x}{x} \), \( n \). \( L \), which is the fluxion of the common logarithm of \( n \); or because \( \frac{x}{x} = 0.43429 \), &c., the modulus of the Bragon or common form of logarithms, if \( \frac{x}{x} = \frac{M}{n} \), the fluxion of the common logarithm of \( n \) (viz. \( \frac{x}{x} \)) will be \( \frac{x}{x} \times M \); cr, the fluxion of the hyperbolic logarithm of any number multiplied by \( M \) or

\[ 0.43429 \text{, &c.} \]
FLUXIONS.

The base of a parallelogram multiplied by the infinitely small element of its altitude, gives an infinitely small parallelogram; which is the element of the finite parallelogram, and is repeated an infinity of times therein, i.e. as many times as there are points in the height of the parallelogram.

To have the finite parallelogram, therefore, by means of its element, the element must be multiplied by the altitude; which is the inverse method of fluxions, re-ascending from the infinitely small quantity to the finite.

Such a circuit of infinitesimals, it is true, would be impertinent, in so simple a cafe; but when we have to do with surfaces terminated by curves, the me hod then becomes necessary, or at least superior to any other.

Suppose, e.g., in a parabola, the space included between two infinitely near ordinates, an infinitely small portion of the axis, and an infinitely little arc of the curve; it is certain, this infinitely small surface is no parallelogram; since the two parallel ordinates which terminate it on one side are not equal; and the arc of the curve, opposite to the little portion of the axis, is frequently neither equal nor parallel thereto; and yet this surface, which is no parallelogram, may be considered, in the strictest geometry, as if it really were one, because it is infinitely small; and the error, of consequence, infinitely little, i.e. none.

So that, to measure it, there needs nothing but to multiply an ordinate of the parabola by the infinitely small portion of the axis corresponding thereto. Thus we have the element of the whole parabola; which element being raised, by the inverse method, to a finite magnitude, is the whole surface of the parabola.

This advantage, so peculiar to the geometry of infinites, of being able, without any error, to treat little arcs of curves as if they were right lines; curvilinear spaces, as if rectilinear ones, &c. enables it not only to go with more ease and readiness than the ancient geometry to the same truths, but to reach a great number of truths which were inaccessible to the other.

Its operations, in effect, are more easy, and its discoveries more extensive; and simplicity and univercity are its distinguishing characters.

The preceding observations are more properly applicable to the method of infinites and indivisibles than to the Newtonian method of fluxions, in which magnitudes of various kinds are capable of increase, not by a repeated accession of parts, but by a continued motion or flux. See the sequel of this article.

Fluxion, given, to find the flowing quantity belonging to any. — To have the doctrine of the inverse method correspond and keep pace with that of the direct, we will apply it in the same cases.

1. In the general, to express the variable quantity of a fluxion, there needs nothing but to write the letters without the dots, or to substitute the variable or flowing letter for its fluxion. Thus, the fluxions of \( x, y, z \), are \( \dot{x}, \dot{y}, \dot{z} \).

2. To find the fluent of a compound fluxional expression consisting of the products of two or more flowing quantities drawn into their fluxions; or which consists of the fluxion of each quantity drawn into the other, or product of the rest of the quantities.

Multiply the flowing quantities together; and the product is the fluent required. E.g., the fluent of \( xy + x \dot{y} \) is \( \dot{x}y + x\dot{y} + \dot{x}y + \dot{x}y \); is \( xy + a + b \), &c.

3. To find the fluent of a fraction. The following rule will serve in many cases. Divide the last term in the numerator by the fluxion of the negative square root of the denominator; then divide this quotient by the affirmative square root of the denominator for the required fluent.

Thus, the fluent of \( \frac{\dot{x}y - \dot{x}}{y} \) is \( \frac{\dot{x}y}{y} \).

4. To find the fluent of an expression compounded of different fluxional terms connected together by the signs + and —

Find the separate flucents of the different terms, and connect them together by the signs of their respective fluciones.

Thus, the fluent of \( ax + x \dot{y} + x^2 - \frac{\dot{x}y - \dot{x}}{y} \) is \( a + \dot{x} + \dot{y} \).

5. To find the flowing quantity belonging to the fluxion of any power, either perfect or imperfect. Take the fluxional letter, or letters, out of the equation; then augment the index of the fluxion by 1, or multiply; lastly, divide the fluxion by the index of its power so increased by unity.

Thus, suppose \( 3x^2 \) proposed; by taking away \( x \), will be \( 3x \); and by increasing its index by unity, it will be \( 3x^3 \); then dividing it by \( 3 \), its new (augmented) index, the quotient will be \( x^2 \); the flowing quantity required.

Again, the fluent of \( \frac{x^3}{m} \) will be \( \frac{x^2}{m} \). In compound fluxional expressions, if the fluxional part is equal, or in an invariable ratio to the fluxion of the quantity under the vinculum, the fluent may be had by adding 1 to the index of the power, and dividing by the index of the quantity under the vinculum drawn into the power thus increased. E.g., the fluent of \( x + x^\frac{1}{3} \times 3 \dot{x} + 6x \dot{x} \) is \( x + x\dot{1} + \frac{3\dot{x} + 6x\dot{x}}{3\dot{x} + 1} = x + \dot{x} \); the fluent of \( \frac{a + c\dot{z} + m\dot{z}}{n\dot{z} + m + 1} \times d\dot{z} \) is \( \frac{a + c\dot{z} + m\dot{z}}{n\dot{z} + m + 1} \); and the fluent of \( a + z^{n-1} \) is \( a + z^{n-1} + 1 \).

By these methods the fluent is found when fluxion is given; and the rules are derived from those of the direct method; as the rules in division and evolution in algebra are deduced from those of multiplication and involution. As when a fluent consists of a variable and invariable part, the latter does not appear in the fluxion; so when any fluxion is proposed, it is only the variable part of the fluent that can be derived from it. If \( \dot{a} \) represent any fluxion that may be proposed, the variable part of the fluent will be equal to \( \dot{a} \); for supposing \( y \) to be any variable quantity, if \( x + y \) could represent the fluent of \( x \), then \( x + y \) would be equal to \( \dot{a} \), and \( \dot{a} = \dot{x} \), or \( y \) would be invariable, against the supposition. But supposing \( K \) to represent any invariable quantity, then \( x + K \) may generally represent the fluent of \( x \). If it be required to find such a fluent of \( x \) as shall vanish when \( x \) is supped to vanish, it can be no other than \( x \); and if it be required that the fluent should vanish when \( x \) is equal to any given quantity, \( a \), then by supposing \( x + K \) to vanish when \( x \) becomes equal to \( a \); we shall have \( a + K = a \); or \( K = - a \); whence the fluent is \( x = a \). In the same manner, the fluent of \( - \dot{x} \) may be generally represented by \( K \). When a fluxion that is
propose coincides with any of those which were deduced from their fluents in the preceding articles, the variable part of the fluent required must coincide with that which was there proposed. As division in algebra leads us to fractions, and evolutions to roots; so the inverse method of fluotions leads us often to quantities that are not known in common algebra, and that cannot be expressed by common algebraic symbols. Maclaurin’s Flux. art. 355.

We cannot here pretend to enter into a detail of the rules of the inverse method of fluotions. We shall only observe in general, that a fluxion being proposed, its fluent may sometimes be found accurately in algebraic terms; but this is far from being always possible; and recourse must sometimes be had to a converging series. Thus, if \( \frac{\alpha}{x} \) were proposed, the variable part of the fluent is found by adding only to the exponent of the power, dividing by the exponent thus increased, and by the fluxion of the root; that is, the variable part of the fluent of \( \frac{\alpha}{x} \) will be

\[
\frac{\alpha x^m + \frac{\alpha}{x}}{n + 1} = x^n.
\]

But in many cases this fluent requires the addition or subtraction of some constant quantity to render it complete, which can only be known from the nature of the problem under consideration: e.g., the fluent of \( \frac{\alpha}{x} \) may be either represented by \( \frac{\beta}{x} \) or by \( \frac{\beta}{x} + \gamma \), because being constant, the fluxion of \( x^n + a \), as well as of \( x^n \), is \( \frac{\beta}{x} \). To find this variable quantity that must be added or subtracted, is to correct the fluent. In order to do this, the best way is to consider how much the variable part of the fluent, first found, differs from the truth, in that particular circumstance when the required quantity which the whole fluent ought to express, is equal to nothing; then, that difference added to or subtracted from the variable part, as occasion requires, will give the fluent truly corrected. For, since the difference of two quantities flowing with the same celerity, or having equal fluxions, is either nothing at all, or constantly the same, the difference in that circumstance will likewise be the difference in all other circumstances; and, therefore, being added to the other quantity, or subtracted from the greater, both become equal at the same time: e.g., \( x = a \) to \( x + \frac{a}{x} \), the fluent will be \( y = \frac{a^2}{x} \); if \( x = a \), \( a^2 \frac{x}{2} \) vanishes, because \( x \) is also \( a \), and the fluent needs no correction.

2. Let \( y = a + \frac{a}{x} \times \frac{x}{2} \); and \( y \) will be equal \( \frac{a^2}{x} \) ; but when \( x \) is equal to \( a \), \( a + \frac{a}{x} \) becomes \( \frac{a^2}{x} \); and, therefore, \( \frac{a^2}{x} \) always exceeds \( y \) by \( \frac{a}{x} \), and the fluent properly corrected will be \( y = \frac{a^2}{x} + \frac{3 a^2}{2} + a \times \frac{x}{2} + \frac{x}{4} \). But this fluent may be found without correction, by expanding \( a + \frac{a}{x} \) in the original equation, which will become \( y = a^2 x^2 + 3 a^2 x^3 + \frac{3 a^2 x^4}{2} + a x + \frac{x}{4} \). Let \( y = \frac{a^2}{x} \times \frac{x}{2} \); then \( y = \frac{-a^2}{x} \), and \( y \) being

\[
\left(1 - \frac{a^2}{x^2} \right) \text{ becomes } = - \frac{a^2}{3} \text{, therefore } - \frac{a^2}{3}.
\]

This is too little by \( \frac{a^2}{3} \); and the fluent corrected will be \( y = \frac{a^2}{3} - \frac{a}{x} \) ; &c.

In the solution of other problems, the value of \( y \) will be equal to nothing, when that of \( x \) is equal to any given quantity \( a \). E.g., Let \( y = a + \frac{a}{x} \), and \( y = \frac{a}{x} \), but then

\[
y = \frac{a}{x} \text{ is } \frac{a}{x}, \text{ by supposition; therefore the corrected fluent will be } \frac{a^2}{x^2} \text{. 2. Let } y = - \frac{a}{x} \text{, then } y = - \frac{a}{x} \text{, which corrected becomes } y = \frac{a^2}{x^2}.
\]

If the proposed fluent were \( a + \frac{a}{x} \), we cannot find its fluent by the rule above given; however, we may throw the fluent into an infinite series by dividing \( a \) by \( x \) in the usual method, and we shall find the quotient

\[
\frac{a}{x} = \beta = \frac{a x^2 + 3 a x^4 + \frac{3 a^2 x^6}{2} + \frac{a^2 x^8}{4}}{n + 1}, \text{ &c. hence } \frac{a}{a} = \beta + \frac{a x^2 + 3 a x^4 + \frac{3 a^2 x^6}{2} + \frac{a^2 x^8}{4}}{n + 1}, \text{ &c.}
\]

Now the fluent of each term of this series may be found by the foregoing rule; and therefore the fluent of \( \frac{a}{x} \frac{a^2}{x} \) will be expressed by the series

\[
\frac{a^2}{x} + \frac{a^2}{x^3} + \frac{3 a^2 x^4}{2} + \frac{v}{4}, \text{ &c. which may be of use for determining the fluent when } x \text{ is very small in respect to } a \text{, because in that case, a few terms at the beginning of the series will be nearly equal to the value of the whole. But it often happens that the series deduced in this method converges too slowly, as to be of little or no ufe. Or, because the fluent of the hyperbolic logarithm of any quantity is equal to the fluent of that quantity divided by the quantity itself, the fluent of } \frac{a}{a} \text{ will be } \frac{a}{a} \frac{a}{a} \times \text{ hyp. log. of } a \times \text{. For the fluent of } a + x \text{ is } x \text{, which divided by } a - x \text{ is } \frac{a}{a} \text{. See Maclaurin’s Tr. of}
\]

Mathematicians do not always immediately recur to infinite series, when it does not appear that a fluent can be aligned in a finite number of algebraic terms. The arcs of a circle, and hyperbolic areas or logarithms cannot be aligned in algebraic terms, but have been computed with great exactness by several methods. By these with algebraic quantities, any segments of conic coëfficients, and the arcs of a parabola, are easily measured; and when a fluent can be aligned by them, this is considered as the second degree of resolution. When it does not appear that a fluent can be measured by the areas of conic sections, it may however be measured in some cases by their arcs, and this may be considered as the third degree of resolution. If it does not appear that a fluent can be aligned by the arc of any conic section (the circle included), it may however be of some use to align the fluent by an area or are of some other figure, that is easily constructed or described; and it
is often important, that the proposed fluxion be reduced to a proper form, in order that the series for the fluxion may not be too complex, and that it may not converge at too slow a rate.

We may, therefore, constitute three orders or classes of fluxions. First, such as can be accurately assigned in finite terms by common algebraic expressions. Secondly, those which can be reduced to circular arcs and logarithms. Thirdly, such as can be assigned by hyperbolic or elliptic arcs. The first two classes (considering triangles and circles as conic sections) may therefore be measured by the areas of conic sections: and the third class by their perimeters, or lines that bound them.

The fluents of \( \frac{x}{\sqrt{1 + x^2}} \) are of the first class; that of \( \frac{x}{\sqrt{1 + x^2}} \), or of \( \frac{x}{1 + x^2} \), of the second; but the fluents of \( \frac{x}{\sqrt{1 + x^2}} \), \( \frac{1 + x^2}{\sqrt{1 + x^2}} \), \( \sqrt{1 + x^2} \), \( \frac{x}{\sqrt{1 + x^2}} \), and \( 1 + x^2 \) are of the third class, and as far as has appeared hitherto, cannot be reduced to the former. See Maclaurin's Fluxions. Look ii. chap. iii. art. 755. 798, &c.

It is to be observed, as to the fluent of \( \frac{x}{\sqrt{1 + x^2}} \) or of \( \frac{x}{1 + x^2} \), that it does not appear possible to represent them by any hyperbolic and algebraic quantities. But by affixing an elliptic arc likewise, they may be constructed. See Maclaurin, lib. cit. art. 802.

Solikewise to represent the fluent of \( \frac{x}{\sqrt{1 + x^2}} \) or of \( \frac{x}{1 + x^2} \), we must have recourse to both the hyperbolic and elliptic arcs. Maclaurin, lib. cit. art 805.

The fluent of \( \frac{x}{\sqrt{1 + x^2}} \) is assignable by the arcs of conic sections, when \( r \) is an integer number; that is, by right lines, when \( r \) is equal to four, or to any multiple of 4; by circular and parabolic arcs (reducible to logarithms) with right lines, when \( r \) is any other even number; by arcs of an equilateral hyperbola with right lines, when \( r \) is any number of the series 3, 7, 11, 15, &c. and by arcs of the hyperbolas and right lines, with arcs of an ellipse, that has its excentricity equal to the second axis, when \( r \) is any of the numbers 1, 3, 5, 7, 9, 13, &c. See Maclaurin, libid. art. 809. See ELEMENT and FUNCTION.

We presume, upon the whole, that few will be so scrupulous as to deny the Newtonian doctrine of fluxions to be intelligible and accurately demonstrated. But on the other hand it must be confessed, that the introduction of the notions of motion and velocity, which are mechanical, seems not to have thrown any light on this part of geometry. The consideration of the limiting ratios of variable quantities, and that of the limiting polygons of curves, so it requires no other knowledge but what depends on the common properties of number and magnitude, so it seems, in all respects, the most clear and unexceptionable manner of considering the subjects treated of in the higher geometry. An eminent mathematician seems to declare himself of this opinion, when he says, that quadrature by limiting polygons is one of that kind which requires no other knowledge but what depends on the common properties of number and magnitude; and so may serve as an influence to shew, that no other is requisite for the establishment of principles for arithmetic and geometry; a truth which, though certain in itself, may perhaps seem doubtful from the nature and tendency of the present inquiries in mathematics. For among the moderns none have thought it necessary, for the investigation of the relations of quantities, to have recourse to very hard hypotheses; such as that of numbers infinite and indeterminate; and that of magnitudes in \( \frac{a}{b} \), existing in a potential manner, which are actually of no signification. And others, whose names are truly to be revered, on account of their great and singular inventions, have thought it requisite to have recourse even to principles foreign to mathematics, and have introduced the consideration of efficient causes and physical powers, for the production of mathematical quantities; and have spoken of them, and used them, as if they were a species of quantities by themselves. Vide Machin, in Phil. Trans. N. 447.

The elements of the doctrine of fluxions have been delivered by its great author in so concise a manner, as to give occasion to one of the most ingenious writers of the last age to represent it as founded on inconceivable principles, and full of fable reasonings. This author in a letter, under the title of the "Analysis," published in the year 1733, has been at great pains to convince his readers that the objects, principles, and inferences of the modern analysis by fluxions, are not more difficultly conceived, or more evidently deduced, than religious mysteries and points of faith. He says he does not controvert the truth of the conclusions, but only the logic and method of mathematicians. He asks how they demonstrate, what objects they are conversant with, and whether they conceive them clearly; what principles they proceed upon, how found they may be, and how they apply them; declaring himself not concerned about the truth of the theorems, but only about the way of coming at them, whether it be legitimate or illegitimate, clear or obscure, scientific or tentative. He considers the conclusions not in themselves, but in their premises; not as true or false, useful or insignificant, but as derived from such principles, and by such inferences. And for as much as it may seem an unaccountable paradox, that mathematicians should deduce true propositions from false principles, he right in the conclusion, and yet err in the premises, he endeavours particularly to explain how this may come to pass, and how error may bring forth truth, though it cannot bring forth science. His solution of the paradox is, that in the application of the method of infinitesimals and fluxions, two errors are committed, which being equal and contrary, destroy each other. We cannot enter into a detail of all he says on this and many other heads, nor of all that has been said on the other side, in defence of the method of fluxions; and of its inventor, Sir Isaac Newton. An answer to the "Analysis," under the title of "Geometry no Friend to Infinitesimals," appeared very early under the name of Philosophica Catechismi, supposed to be Dr. Jurin; a second, by the same hand, in defence of the first, intitled, "The Minute Mathematician, or the Free-thinker no Jovil Thinker," published in 1755; a Discourse of Fluxions, by Mr. Robins, issued in 1755 (see his Collection of Tracts, by Wilfon, vol. ii.); a Treatise of Sir Isaac Newton's, with a commentary by Mr. Colton; and several other pieces were published on this subject; particularly a very full and excellent treatise of fluxions, by
FLUXIONS.

by Mr. Maclaurin, late professor of mathematics in the university of Edinburgh, containing not only a most distinct account of the principles of fluxions, but also of the chief discoveries in geometry, and mathematical philosophy of this age. The curious may find an elegant account of this treatise in the Philosophical Transactions, No. 4, 8, 469.

We premise that Mr. Maclaurin's demonstrations are sufficient to satisfy the most scrupulous; it would exceed the bounds of our design to insert them at length here; but we cannot omit mentioning what seems necessary to explain and illustrate the notion of fluxions; and the principles on which this method of computation is founded. In the doctrine of fluxions, magnitudes are conceived to be generated by motion; and the velocity of the generating motion is the fluxion of the magnitude. Lines are supposed to be generated by the motion of points; the velocity of the point that describes the line, is its fluxion, and measures the rate of its increase or decrease. When the motion of a point is uniform, its velocity is constant, and is measured by the space described by it in a given time; when the motion varies, the velocity at any term of the time is measured by the space which would be described in a given time, if the motion was to be continued uniformly, from that term, without any variation. And this is analogous to the general doctrine of powers, or may be considered as a particular application of it. As a power which acts continually and uniformly is measured by the effect that is produced by it in a given time; so the velocity of a uniform motion is measured by the space that is described in a given time. If the action of the power vary, then its exertion at any rate of the time is not measured by the effect that is produced after that term in a given time, but by the effect that would have been produced if its action had continued uniform from that term; and in the same manner, the velocity of a variable motion at any given term of time is not to be measured by the space that is actually described after that term in a given time, but by the space that would have been described, if the motion had continued uniformly from that term. If the action of a variable power, or the velocity of a variable motion, may not be measured in this manner, they must not be susceptible of any measurement at all. When it is supposed that a body has some velocity or other at any term of the time, during which it moves, it is not therefore supposed, that there can be any motion in a term, limit, or moment of time, or in an indivisible point of space; and as velocity is always measured by the space that would be described by it, continued uniformly for some given finite time, it cannot surely be said, that geometers pretend to conceive motion or velocity without regard to space or time, as the author of the Analyst often suggests. This is a short view of the nature and tendency of the doctrine of fluxions, which we shall now proceed to explain more particularly.

We have already said that lines may be conceived as generated by the motion of points; in like manner surfaces may be conceived as generated by the motion of lines; solids, by the motion of surfaces; angles, by the rotation of their sides; the flux of time being supposed to be always uniform. The velocity with which a line flows, is the same as that of the point which is supposed to describe or generate it. The velocity with which a surface flows, is the same as the velocity of a given right line; that, by moving parallel to itself, is supposed to generate a rectangle which is always equal to the surface. The velocity with which a solid flows, is the same as the velocity of a given plain surface, that, by moving parallel to itself, is supposed to generate an erect prism or cylinder that is always equal to the solid. The velocity with which an angle flows, is measured by the velocity of a point, that is supposed to describe the arch of a given circle, which always subtends the angle, and measures it. In general, all quantities of the same kind (when we consider their magnitude only and abstract from their position, figure, and other affections) may be represented by right lines, that are supposed to be always in the same proportion to each other as the quantities. They are represented by right lines in this manner in Euclid's Elements, in the general doctrine of proportion, and by right lines and figures in the data of that accurate geometer. In this method likewise, quantities of the same kind may be represented by right lines, and the velocities of the motions by which they are supposed to be generated, by the velocities of points moving in right lines. All the velocities we have mentioned are measured, at any term of the time of the motion, by the spaces which would be described in a given time, by these points, lines, or surfaces, with their motions continued uniformly from that term.

A fluxion being the velocity with which a quantity flows at any term of the time while it is supposed to be generated, is therefore always measured by the increment or decrement that would be generated in a given time by this motion, if it was continued uniformly from that term without any acceleration or retardation; or it may be measured by the quantity that is generated in a given time by an uniform motion, which is equal to the generating motion at that term.

Time is represented by a right line that flows uniformly, or is described by an uniform motion; and a moment or termination of time is represented by a point or termination of that line. A given velocity is represented by a given line, the same which would be described by it in a given time. A velocity that is accelerated or retarded, is represented by a line that increases or decreases in the same proportion. The time of any motion being represented by the base of a figure, and any part of the time by the corresponding part of the base; if the ordinate at any point of the base be equal to the space that would be described, in a given time, by the velocity at the corresponding term of the time continued uniformly, then any velocity will be represented by the corresponding ordinate. The fluxions of quantities are represented by the increments or decrements, described in the foregoing paragraph, which measure them; and instead of the proportion of the fluxions themselves, we may always substitute the proportion of their measures.

When a motion is uniform, the spaces that are described by it in any equal times are always equal. When a motion is perpetually accelerated, the spaces described by it in any equal times that succeed after one another, perpetually increase. When a motion is perpetually retarded, the spaces that are described by it in any equal times that succeed after one another, perpetually decrease.

It is manifest, conversely, that if the spaces described in any equal times are always equal, then the motion is uniform. If the spaces described in any equal times that succeed after one another perpetually increase; the motion is perpetually accelerated; for it is plain, that if the motion was uniform for any time, the spaces described in any equal parts of this time would be equal; and if it was retarded for any time, the spaces described in equal parts of this time that succeed after one another would decrease; both of which are against the supposition. In like manner it is evident, that a motion is perpetually retarded, when the spaces that are described in any equal times that succeed after one another, perpetually decrease. The following axioms are as evident as that a greater or
FLUXIONS.

acceleration, different generated from given not the exprcfsly the.

motion Tiie in body and but quantitv, the reftangle radius the Maclaurin's.

Axiom; 3. The space described by a retarded motion is less than the space which would have been described in the same time if the motion had not been retarded, but had continued uniform from the beginning of the time.

Axiom 4. The space described by a motion while it is retarded is greater than the space which is described in an equal time by the motion that remains after that retardation, continued uniformly.

From these axioms, general theorems concerning motion, of use in the doctrine of fluxions, may be demonstrated. Thus, when the spaces described by two variable motions are always equal, or in a given ratio, the velocities are always equal, or in the same given ratio; and conversely, when the velocities of two motions are always equal to each other, or in a given ratio, the spaces described by those motions in the same time are always equal, or in that given ratio; that when a space is always equal to the sum or difference of the spaces described by two other motions, the velocity of the first motion is always equal to the sum or difference of the velocities of the other motions; and conversely, that when a velocity is always equal to the sum or difference of two other velocities, the space described by the first motion is always equal to the sum or difference of the spaces described by the two other motions. See Mr. Macaulay's Treatise of Fluxions, book i. chap. 1.

The main point, in the method of fluxions, is to obtain the fluxion of the rectangle, or product of two indeterminate quantities, since from thence may be derived rules for all other products and powers, be the co-efficients, or the indices, what they will, integers, or fractions, rational or surds; according to the manner of sir Isace Newton, in the second lemma of his second book of Principles.

Mr. Macaulay has therefore been very full in establishing this point; and after what he has said, we presume that no reasonable objection can lie either against the clearness and distinctness of the notion of fluxions, or against the truth of the principles, or accuracy of the demonstrations by which their measures are determined. We cannot here impart his demonstrations at length; but as many readers may, perhaps, be desirous of seeing the argument contracted into a narrow compass, we shall here give a summary of it, from the Philosophical Transactions, N° 468, p. 331, or Martin's Abridg. vol. viii. p. 31, &c.

A triangle that has two of its sides given in position, is supposed to be generated by an ordinate moving parallel to itself along the base. When the base increases uniformly, the triangle increases with an accelerated motion, because its successive increments are trapezia, that continually increase; therefore if the motion with which the triangle flows, was continued uniformly from any term for a given time, a less space would be described by it than the increment of the triangle, which is actually generated in that time by axiom 1; but a greater space than the increment which was actually generated in an equal time preceding that term, by axiom 2. And hence it is demonstrated, that the fluxion of the triangle is accurately measured by the rectangle contained by the corresponding ordinate of the triangle, and the right line which measures the fluxion of the base. The increment which the triangle acquires in any time, is resolved into two parts; that which is generated as a consequence of the motion with which the triangle flows at the beginning of the time, and that which is generated in consequence of the acceleration of this motion for the same time. The latter is justly regulated in measuring that motion (or the fluxion of the triangle at that term), but may serve for measuring its acceleration, or the second fluxion of the triangle. The motion with which the triangle flows, is similar to that of a body descending in free spaces by an uniform gravity, the velocity of which, at any term of the time, is not to be measured by the space described by the body in a given time, either before or after that term, because the motion continually increases, but by a mean between these spaces.

When the sides of a rectangle increase or decrease with uniform motions, it may be always considered as the sum or difference of a triangle and trapezium; and this fluxion is derived from the last proposition. If the sides increase with uniform motions, the rectangle increases with an accelerated motion; and in measuring this motion at any term of the time, a part of the increment of the rectangle that may be determined, is rejected, as generated in consequence of the acceleration of that motion.

Those who have well understood what precedes will not be at a loss to conceive, that the fluxions of a curvilinear area, whether generated by an ordinate moving parallel to itself, or by a radius revolving round a given centre, may be determined by demonstrations of the same kind. When the ordinates of the figure increase, the increment of the area may be resolved in like manner into two parts, one of which only is to be retained in measuring the fluxion of the area, the other being rejected as generated in consequence of the acceleration of the motion with which the figure flows.

What has been hitherto said will set the difference between the notion of fluxions and that of infinitesimals in a clear light. Fluxions may always be represented by finite quantities. The supposition of an infinitely little magnitude is too bold a postulate for such a science as geometry. Nor have authors accounted explicitly for the truth and perfect accuracy of the conclusions derived from this consideration. When they determine what is called the difference, but more accurately the fluxion of a quantity, they tell us, they reject certain parts of the element, because they become infinitely less than other parts. But this is no proper reason, not only because a proof of this nature may leave some doubt as to the accuracy of the conclusion, but because it may be demonstrated that these parts ought to be neglected by them at any rate, or that it would be an error to retain them. If an accountant, that pretends to a scrupulous exactness, should tell us, he had neglected certain articles, because he found them to be of small importance; and it should appear that they ought not to have been taken into consideration by him on that occasion, but belong to a different account, we should approve his conclusions as accurate, but not his reasons. See Macaulay's Treatise of Fluxions in the preface, and book i. chap. 12, where the method of infinitesimals is expressly treated of. Mr. Macaulay, in the first part of his treatise, considers fluxions in a merely geometrical form, and has demonstrated the value of the method with all possible accuracy and rigour; but as the great improvements made by this doctrine are chiefly to be ascribed to the facility, conciseness, and great extent of the methods of computation, or the algebraic part, it is necessary to add some account of these methods also.
FLUXIONS.

Any quantities produced from each other by an algebraic operation, or whose relation is expressed by any algebraic form, being supposed to increase or decrease together, some will be found to increase or decrease by greater differences, or at a greater rate, others by less differences, or at a less rate; and while some are supposed to increase or decrease at one constant rate by equal successive differences, others increase or decrease by differences that are always varying. These rates of increase or decrease may be determined by comparing the velocities of points that always describe lines proportional to the quantities as before mentioned, but they may also be determined without having recourse to such supposition, by a jujt restoring from the simultaneous increments or decrements themselves.

When a quantity A increases by differences equal to \( a \), \( 2A \) increases by differences equal to \( 2a \), and manifestly increases or decreases at a greater rate than \( A \) in the proportion of \( 2a \) to \( a \) or \( 2 \) to \( 1 \); and if \( m \) and \( n \) be invariable, \( \frac{m \Delta A}{n} \) increases or decreases by differences equal to \( \frac{m}{n} \), and therefore at a greater or less rate than \( A \) in proportion as \( \frac{m}{n} \) is greater or less than \( a \), or \( m \) is greater or less than \( n \). This seems to be easily conceived, without having recourse to any other considerations than the relation of the differences by which the quantities increase or decrease. In order therefore to avoid figurative expressions in the algebraic part, it will be proper to substitute in the place of the definition and axioms before mentioned, others that are rather of a more general import, but are perfectly consistent with them: Thus,

"Fluxions of quantities are any measures of their respective rates of increase, or decrease, while they vary or flow together.

There can be no difficulty in determining these measures when the quantities increase or decrease by successive differences, that are always in the same invariable proportion to each other. While \( A \) by increasing becomes equal to \( A + a \), or by decreasing equal to \( A - a \), \( 2A \) becomes equal to \( 2A + 2a \), or to \( 2A - 2a \); and as \( 2A \) increases or decreases at a greater rate than \( A \) in the proportion of \( 2a \) to \( a \); so the fluxion of \( A \) being supposed equal to \( a \), the fluxion of \( 2A \) must be equal to \( 2a \).

In the same manner the fluxion of \( \frac{m}{n} \times A \), or of \( \frac{m}{n} \) 

\[ A \neq a, \text{ (supposing } m, n, \text{ and } e \text{ to be invariable) is } \frac{m}{n} \times a; \]

and since \( m \) may be to \( n \) in any invariable ratio, a quantity may be always assigned that shall increase or decrease at a greater or less rate than \( A \) in any proportion, or that shall have its fluxion greater or less than the fluxion of \( A \) in any ratio. In such cases, the ratio of the fluxions and that of the differences, by which the quantities increase or decrease, are the same.

But while \( A \) is supposed to increase at a constant rate by any equal successive differences, if \( B \) increase or decrease by differences that are always varying, \( B \) cannot be said to increase or decrease at any one constant rate; and it is not so obvious how the fluxion of \( A \) being supposed equal to its increment \( a \), the variable fluxion of \( B \) is to be determined. It cannot be supposed that the fluxions and differences are always in the same proportion in this case; but it is evident that if \( B \) increase by differences, that are always greater than the equal successive differences by which \( \frac{m}{n} \times A \) increases, it cannot increase at a less rate than \( \frac{m}{n} \times A \); and it cannot increase at a greater rate than \( \frac{m}{n} \times A \), while its successive differences are always less than those of \( \frac{m}{n} \times A \). The fluxion of \( A \) being still represented by \( a \), the fluxion of \( B \) therefore cannot be less than \( \frac{m}{n} \times a \) in the former case, or greater than \( \frac{m}{n} \times a \) in the latter. The following propositions are consequences of this, and will enable us to determine at what rate \( B \) increases, when its relation to \( A \) is known.

The successive values of the root \( A \) being represented by \( A - a, A - 2a, \) &c., which increase by any constant difference \( a \), let the corresponding values of any quantity produced from \( A \), by any algebraic operation (or that has a dependence upon it so as to vary with it) be \( B - b, B - 2b, \) &c. Then if the successive differences \( b, b, \) &c., of the latter quantity always increase, how small soever \( a \) may be, then \( B \) cannot be said to increase at a greater rate than \( b \); or to a small rate as any quantity that increases uniformly by equal successive differences greater than \( b \), or at a small rate as any quantity that increases uniformly by equal successive differences less than \( b \). In like manner, if the relation of the quantities is such, that the successive differences \( b, b, \) &c. continually decrease; then \( B \) cannot be supposed to increase at the same rate as a quantity that increases uniformly by equal successive differences greater than \( b \), or less than \( b \).

Therefore the fluxion of \( A \) being supposed equal to the increment \( a \), the fluxion of \( B \) cannot be greater than \( b \) or less than \( b \), when the successive differences \( b, b, \) &c. continually increase; and cannot be greater than \( b \) or less than \( b \), when these successive differences always decrease.

In the same manner, if the latter quantity decrease while the former increases, and its successive values be \( B + b, B + 2b, \) &c. then if the decrements \( b, b, \) &c. continually increase, \( B \) cannot be said to decrease at a greater rate as a quantity that decreases uniformly by equal successive differences greater than \( b \), or at a small rate as a quantity that decreases uniformly by equal successive differences less than \( b \). Therefore in this case the fluxion of \( A \) being supposed equal to \( a \), the fluxion of \( B \) cannot be greater than \( b \) or less than \( b \). And in the same manner if the successive decrements \( b, b, \) &c. continually decrease, the fluxion of \( B \) cannot be greater than \( b \), or less than \( b \). Vide Maclaurin's Flux. book ii. chap. i. tom. i. p. 579. seq.

As the fluxions of quantities are any measures of the respective rates, according to which they increase or decrease; so it is of no importance how great or small those measures are, if they be in the just proportion or relation to each other. Therefore if the fluxions of \( A \) and \( B \) may be supposed equal to \( a \) and \( b \) respectively, they may be likewise supposed equal to \( \frac{1}{3} \) \( a \) and \( \frac{1}{3} \) \( b \), or to \( \frac{m}{n} \times \frac{m}{n} \) and \( \frac{m}{n} \times \frac{m}{n} \).

Prop. 1. The fluxion of the root \( A \) being supposed equal to \( a \), the fluxion of the square \( A^2 \) will be equal to \( 2A \times a \).

To demonstrate this, let the successive values of the root
FLUXIONS.

be $A - u, A, A + u$, and the corresponding values of the square will be $AA = 2A u + u^2, AA, A + 2A u + u^2$, which increase by the differences $2 A u + u, 2 A u + u^2$; &c. and because those differences increase, it follows from what has been said, that if the fluxion of $A$ be represented by $u$, the fluxion of $AA$ cannot be represented by a quantity that is greater than $2 A u + u$, or $u$s than $2 A u + u u$. This being premised, suppose, in the proposition, that the fluxion of $A$ is equal to $a$; and if the fluxion of $AA$ be not equal to $2 A a$, let it be first be greater than $2 A a$ in any ratio, as that of $2 A + a$ to $2 A$, and consequently equal to $2 A a + a u$. Suppose now that $u$ is any increment of $A$ less than $a$, and because $a$ is to $u$ as $2 A a + a u$ is to $2 A u + u a$, it follows, that if the fluxion of $A$ should be represented by $u$, the fluxion of $AA$ would be represented by $2 A u + u a$, which is greater than $2 A u + u$. But it has been shown, that if the fluxion of $AA$ be represented by $u$, the fluxion of $AA$ cannot be represented by a quantity greater than $2 A u + u$. And there being contradictory, it follows, that the fluxion of $A$ being equal to $a$, the fluxion of $AA$ cannot be greater than $2 A a$. If the fluxion of $AA$ can be less than $2 A a$, when the fluxion of $A$ is supposéd equal to $a$, let it be less than in any ratio of $2 A - a$ to $2 A$, and therefore equal to $2 A a - a a$. Then because $a$ is to $u$ as $2 A a - a u$ is to $2 A u - a u$, which is less than $2 A u - u a$ (as before) it follows, that if the fluxion of $A$ was represented by $u$, the fluxion of $AA$ would be represented by a quantity less than $2 A u - u a$, against what has been shown. Therefore the fluxion of $A$ being supposéd equal to $a$, the fluxion of $AA$ must be equal to $2 A a$.

The fluxion of $A$ and $B$ being supposéd equal to $a$ and $b$, respectively, the fluxion of $A + B$ will be $a + b$, the fluxion of $A + B$, or of $A A + 2 A B + B B$, will be $2 A + B + a + b$, or $2 A a + 2 b B a + 2 A b$, by the law of addition. The fluxion of $A A + B B$ is $2 A a + 2 b B a + 2 A b$, by the same; consequently the fluxion of $2 A B$ in $2 A a + 2 b B a + 2 A b$, and the fluxion of $A B$ is $B a + A b$. Hence if $P$ be equal to $A B$, and the fluxion of $P$ be $p$, then $p$ will be equal to $B a + A b$, and dividing by $B$, or $A$, we find $p = A + B$. When any one of the quantities decreases, its fluxion is to be considered as negative.

The rule for finding the fluxion of a power is usually deduced from the binomial theorem of Sir Isaac Newton. But as this theorem, though easily found by induction, is not so easy to demonstrate, it is proper to proceed upon a principle, the truth of which may be shewn from the first algebraic elements, with more facility and perspicuity. This principle is, that if $n$ be any integer number, and the sum of the terms $E^m, E^m + F^m, E^m + F^m$, &c continued till their number be equal to $n$, be multiplied by $E - F$, the product will be $E^n - F^n$. But the terms being formed by dividing coiningly from the index of $E$, and adding it to the index of $F$, the last term will be $F^n$. The product of the sum of the terms multiplied by $E$ will be $E^n + F^n + F^n + F^n$, &c.

If $n$ be integers, their sum multiplied by $- F$ gives $E^n - F^n - F^n - F^n$; and the sum of these two products is $E^n - F^n$. Supposing $E$ to be greater than $F$, $E^n - F^n$ will be less than $n E^n - 1 \times F - 1$, but greater than $n E^n - 1 \times E - F$. For each of the terms $E^n, E^n - F, E^n - F$, is greater than the succeeding term in the same ratio that $E$ is greater than $F$, and $E^n - F$ is the greatest term; consequently the number of terms being equal to $n$, $E^n - F$ is greater than their sum, and $n E^n - 1 \times E - F$ is greater than their fluxions multiplied by $E - F$, or (by the last paragraph) greater than $E^n - F^n$. Because the last term $F^n$ is less than any preceding term, $n E^n - 1 \times E - F$ is less than the fluxion of the terms multiplied by $E - F$, or less than $E^n - F^n$. When $n$ is any integer positive number, the root $A$ being supposed to increase by any equal successive differences, the successive differences of the power $A^n$ will continually increase. For let $A = a, A, A + a$ be any successive values of the root, and $A = a, A, A + a$ will be the corresponding values of the power. But $A + a - A^a$ is greater than $n A^n - a$, as appears by substituting in the last paragraph $A + a$ for $E, A$ for $F, a$ for $E - F$. In like manner, $n A^n - a$ is greater than $A^n - A^a$. Therefore $A + a - A^a$ is greater than $A^n - A^a$, and the successive differences of the power continually increase.

Prop. II. The fluxion of the root $A$ being supposed equal to $a$, the fluxion of the power $A^n$ will be $n a A^n - 1$. For if the fluxion of $A^n$ can be greater than $n a A^n - 1$, let the excess be equal to any quantity $r$; suppose $a$ equal to the excess of $\sqrt[n]{A^n} + r$ above $A$, and consequently $A + a = A + \sqrt[n]{A^n} + r$, $n a A^n + a$. Then $n a A^n + a$ will be equal to $n a A^n - 1 + r$, the fluxion of $A^n$. Let $u$ be any increment of $A$ less than $a$; and because $a$ is to $u$ as $n a \times A^n + u$ to $n a \times A^n + a$, it follows (from what has been said) that if the fluxion of $A$ be now represented by the increment $u$, the fluxion of $A^n$ will be represented by $n a \times A^n + u$, which is greater than $n a \times A^n + u$; and this last is itself greater than $A^n - A^n - A$. But when the successive values of the root are $A = u, A, A + u$, those of the power are $A = u, A$, $A + u$, the successive differences of which continually increase: consequently if the fluxion of $A$ be represented by $u$, the fluxion of $A^n$ cannot be represented by a quantity greater than $A^n + u - A^a$, or less than $A^n - A - u$. And these being contradictory, it follows, that when the fluxion of the root $A$ is supposéd equal to $u$, the fluxion of $A^n$ cannot be greater than $n a A^n - 1$; if it can be less than $n a A^n - 1$, let it be equal to $n a A^n - 1$, or (by supposing $u$ equal to $A = \sqrt[n]{A^n} + r$) then $n a \times A^n - a$. Then $n a \times A^n - a$.
FLUXIONS.

posed equal to \( a \), the fluxion of \( A^n \) must be equal to \( n a A^{n-1} \).

Prop. III. The fluxion of \( A \) being supposed equal to \( a \), the fluxion of \( A^n \) will be \( \frac{m}{n} a \times A^{n-1} \).

First, let the exponent \( \frac{m}{n} \) be any positive fraction what
soever, suppose \( \frac{m}{n} A^n = K \); consequently \( A^{m-n} = K^{n} \); and the fluxion of \( K \) being supposed equal to \( k \), \( ma A^{m-1} = n k K^{n-1} \), and \( k \), or the fluxion of \( A^{n-1} \), will be equal to \( \frac{ma K}{n K^{n-1}} = \frac{m}{n} a \times A^{n-1} \). When \( \frac{m}{n} \) is negative, let it be equal to \(-r \); and suppose \( A^{-r} = K \), or \( s = A^{-K} \), then taking the fluxions, \( r A^{-r-1} a K = \frac{m}{n} a \times A^{n-1} \).

Prop. IV. Supposing \( P \) to be the product of any factors \( A, B, C, D, E, \) \&c, and the fluxions of \( P, A, B, C, \) \&c, respectively equal to \( p, a, b, \) \&c, then will \( \frac{dp}{P} = \frac{a}{A} + \frac{b}{B} + \frac{c}{C} + \frac{d}{D}, \) \&c.

Let \( Q \) be equal to the product of all the factors of \( P \), the first \( A \) excepted, that is, suppose \( P = A \cdot Q \). Suppose \( R \) equal to the product of all the factors, the first two, \( A \) and \( B \) excepted; that is, let \( P = A \cdot B \cdot R \), or \( Q = B \cdot R \). In the same manner, let \( R = C \cdot S \cdot D \cdot T \), and so on.

Then the fluxions of \( Q, R, S, T, \) \&c, being supposed respectively equal to \( q, r, s, \) \&c, it follows that \( \frac{dp}{P} = \frac{a}{A} + \frac{q}{Q} = (\text{because } q = \frac{b}{B} + \frac{r}{R}) \frac{a}{A} + \frac{b}{B} + \frac{r}{R} = (\text{because } r = \frac{c}{C} + \frac{s}{S}) \frac{a}{A} + \frac{b}{B} + \frac{c}{C} + \frac{s}{S} = (\text{because } s = \frac{d}{D} + \frac{t}{T}) \frac{a}{A} + \frac{b}{B} + \frac{c}{C} + \frac{d}{D} + \frac{t}{T} \), and so on. Therefore \( \frac{dp}{P} \) is equal to the sum of the quotients when the fluxion of each factor is divided by the factor itself.

If the factors be supposed equal to each other, and their number be equal to \( n \), then \( P = A^n \), and by the last proposition \( \frac{dp}{P} = \frac{n}{n} a \); consequently \( p = \frac{n}{n} A = n a A^{n-1} \), as was before demonstrated.

Prop. V. If \( P = A \cdot B \cdot C, \) \&c, and the fluxions of the respective quantities be expressed by the small letters \( p, a, b, c, \) \&c, as before, then \( \frac{dp}{P} = \frac{a}{A} + \frac{b}{B} + \frac{c}{C} - \frac{k}{K} - \frac{l}{L} - \frac{m}{M} \), \&c.

For \( PKLM, \) \&c, \( = ABC, \) \&c, and \( \frac{dp}{P} = \frac{k}{K} + \frac{l}{L} + \frac{m}{M} \), \&c. what may by transposition \( \frac{dp}{P} = \frac{a}{A} + \frac{b}{B} + \frac{c}{C} - \frac{k}{K} - \frac{l}{L}, \) \&c. Maclaurin, ibid.

The notation we have hitherto used is the same as for Isaac Newton's, in the second lemma of the second book of his Principles. But it is generally more convenient to distinguish fluxions from other algebraic expressions, and in such manner, that the second and higher fluxions may be represented so as to preserve the original fluent in view. Hence sir Isaac Newton, in his last method, represented variable or flowing quantities by the final letters of the alphabet, as \( x, y, z; \) their first, second, \&c. fluxions, respectively, by \( x, y, z; \) \&c. But as this doctrine has been contested and represented by the author of the Analytical, as inconceivable and sophistical, we thought it proper more fully to explain and demonstrate the principles thereof, from Mr. Maclaurin's excellent treatise on this subject.

It is to be observed, that the fluxions of powers are commonly delivered in an algebraic form; but this is not necessary. The same may be done geometrically, by supposing a series of lines in geometric progression, the first term of which is variable. Then if the second term be supposed to increase uniformly, all the subsequent terms will increase with an accelerated motion. The velocities of the points that describe those lines being compared, it may be demonstrated from common geometry, that the fluxions of any two terms, are in a ratio compounded of the ratio of those terms, and of the ratio of the numbers that express how many terms precede them respectively in the progression. Thus, if \( A, B, C, D, E, \) \&c. represent any lines in geometric progression, the first term \( A \) of which is variable, then will the fluxion, for instance, of \( E \) be to the fluxion of \( D \) as \( 4 \) \( E \) is to \( 3 \) \( D \), and the fluxion of \( E \) will be to the fluxion of \( B \) as \( 4 \) \( E \) to \( B \). The analogy between powers in algebra and lines in geometric progression is sufficiently known. Thus \( A \) being variable may be called unity, or \( 1 \); let \( B = x \), then will \( C = x^2, D = x^3, E = x^4 \), \&c. and consequently the fluxion of \( E \), if \( x \) is variable, will be to the fluxion of \( B \) or \( x \), as \( 4 \) \( x^4 \) is to \( x \), or as \( 4 \) \( x^4 \) is to \( 1 \). Therefore if the fluxion of \( x \) be expressed by \( x \), the fluxion of \( x^4 \) will be expressed by \( 4x^3 \), according to the common algebraic method of expression. Vide Mr. Maclaurin's Flux. book i. chap. 6. See also the Preface of the Rep. of Let. Oct. 1735, p. 248, 249, \&c.

If the fluxion of \( B \), or the second term of the progression be variable, every term of the progression will have fluxions of as many degrees as there are terms that precede it in the progression. And the increment of any term, generated in a given time, may be resolved into as many parts as it has fluxions of different orders; and each part may be conceived to be generated in consequence of its respective fluxion. Hence fluxions of all orders may be illustrated and measured.

As to the higher order of fluxions, it is to be observed, that when a motion is accelerated or retarded continually, the velocity may itself be considered as a variable or flowing quantity, and may be represented as a line that increases or decreases continually. When a velocity increases uniformly, so as to acquire equal increments in equal times, its fluxion is measured by the increment which is generated in any given time. In this case the velocity is represented by a line that is described by an uniform motion; and its fluxions by the constant velocity of the point that describes the line, or by the space which this point describes in a given time. When a velocity is not accelerated uniformly, but acquires increments in equal times, that continually increase or decrease, then its fluxion at any term of the time is not measured by the increment which it actually acquires.
acquires, but by that which it would have acquired, if its acceleration had been continued uniformly from that term for a given time. And in the same manner, when a motion is retarded continually, the quantity by which it would be diminished in a given time, if its retardation was continued uniformly for any term, measures its fluxion at that term. While the point M describes the line E, let the point Q describe the line I', so that I Q may be always equal to the space that would be described by the motion of M, if it was continued uniformly for a given time. Then I Q shall always represent the velocity of M, and the velocity of the point Q shall represent the fluxion of the velocity of M; which therefore is measured, at any term of the time, by the space which would be described by Q, with its motion at that term continued uniformly for a given time. The velocity of M is the fluxion of E M; and therefore the velocity of Q represents the fluxion of the fluxion of E M. (See the beginning of this article.) Thus, when a fluxion of a quantity is variable, it may be considered itself as a fluent, and may have its fluxion which is called the second fluxion of that quantity. This may also have its fluxion, which is called the third fluxion of the first fluent; and motions may be easily conceived to vary in such a manner, as to give ground for admitting second fluxions, and those of any higher order. And as the first fluxion of a variable quantity, at any term of the time, is measured by the increment or decrement, which would be produced, if the generating motion was continued uniformly from that term, for a given time; so its second fluxion may be measured by twice the difference between this increment, or decrement, and that which would be produced, if the acceleration, or retardation, of the generating motion was continued uniformly from that term for the same time. Maclaurin, lib. cit. book i. chap. 1. § 70. 75. and chap. 5. 6.

See a farther illustration of second and third fluxions, in the same author (chap. 3, and 4.) deduced from the consideration of the fluxions of solids.

The author of the Analysis has represented the notions of second and third fluxions as inextricable mysteries; and, indeed, when some speak of the velocities of velocities, &c. it is not easy to say what they mean. But it is to be observed, that the first fluxion of any fluent is not the velocity of that fluent, but the velocity of the motion by which the fluent is conceived to be generated. And in like manner, the second fluxion of that fluent is not the velocity of the velocity of this fluent, but the velocity of the motion by which the quantity is generated that always represents its first fluxion; and so of the rest.

When the fluxion of a quantity is variable, it may be considered as a fluent; and its fluxion, which is the second fluxion of the proposed quantity, may be determined by the preceding propositions. Thus the fluxion of A being supposed equal to a, the fluxion of A A is 2 A a; and if A be supposed to increase at an uniform rate, or its fluxion a to be invariable, 2 A a will increase by equal successive differences; consequently its fluxion, or the second fluxion of A A, will be equal to any of these differences, as 2 a A a + 2 A a, or 2 a a. If a be variable, let its fluxion be equal to z, and the fluxion of 2 A a (or second fluxion of A A) will be 2 A a + 2 A z. In the same manner the fluxion of A being constant, the fluxion of A A⁻¹, or the second fluxion of Aⁿ, is n a x n − 1 × Aⁿ−². a, or n × n − 1 × a Aⁿ−²; the fluxion of this, or third fluxion of Aⁿ, is n × n − 1 × n − 2 × a Aⁿ−³, &c. x a Aⁿ−ᵣ, where the factors in the coefficient are to be continued till their number be equal to m. When n is in any integer positive number, the fluxion Aⁿ, of the order n, is invariable and equal to n × n − 1 × n − 2 × n − 3, &c. x a. The quantities that represent the first fluxions of Aⁿ depend on a, which represents the fluxion of A. When A remains of the same value, the first fluxion of Aⁿ is greater or less in the same proportion, as a is supposed to be greater or less; the second fluxion of Aⁿ, is in the duplicate ratio of a; and its fluxion of the order m, is as aᵐ. If a be variable, then the fluxion of A, or the second fluxion of A, be constant, then the fourth fluxion of A A will be constant and equal to 6 a 2, for we found that the second fluxion of A A was 2 a A; the fluxion of this is 4 a 2 + 2 A a, or 6 a a; and the fluxion of this is 60 a². In like manner, the fifth fluxion of A⁻¹ will be constant in this case, and equal to 90. The second differences of any quantity B are the successive differences of its first differences; and as the fluxion B increases when its successive differences increase; so its second differences, or its fluxions of any higher order increase when its second or higher differences increase. If we arrive at differences of any order that are constant, the fluxion of the same order is constant, and is expressed by that difference. Thus, when A is supposed to increase by constant differences equal to a, and its fluxion is supposed equal to a, the second difference of A A (or A + a² - 2 A A + A - a) is 2 a a, which is likewise its second fluxion; and the third difference of A is 6 a², which is its third fluxion. When n is a integer and positive number, the fluxion of Aⁿ of the order n is equal to the fluxion of any of its first differences of the order n − 2, and so on. For the fluxion of A + a² - Aⁿ (one of the first differences of Aⁿ) of the order n - 1 is n × n - 1 × n - 2, &c. x A + a² - Aⁿ - aⁿ⁻² - A x a⁻¹ = n × n - 1 × n - 2, &c. x a⁻¹, where the coefficients are supposed to be continued till their number be n - 1, so that the last term will be the fluxion of A⁻¹ of the order n, in the preceding paragraph. In the same manner the fluxion of A + a² - 2 A A + A - aⁿ⁻² (the second difference of Aⁿ) of the order n − 2, is equal to the fluxion of A + a² - A of the order n − 1, and consequently equal to the fluxion of Aⁿ of the order n. These fluxions are invariable and equal to the last or invariable differences. But in other cases the fluxions of Aⁿ of any order are less than its subsequent differences of the same order, but greater than the preceding differences, as before mentioned. Maclaurin’s Flux. art. 720. 721.

By supposing one of the variable quantities to flow uniformly, it will have no second or higher fluxions, and the higher fluxions depending on it will be expressed in a more simple manner. Thus the fluxion of x being supposed constant, the first fluxion of xⁿ being xⁿ⁻¹ x, its second fluxion will be n × n − 1 × xⁿ⁻² xⁿ⁻¹, and its fluxion of any order m will be n × n − 1 × n − 2 × n − 3, &c. x Aⁿ−ᵣ, where the factors in the coefficient are to be continued till their number be equal to m. The second or higher fluxions of quantities may be found by particular theorems (without computing those of the preceding orders) as may be seen by the last example. See further

FLIES, Eyes of. See Eye.

FLIES, Legs of. See Leg.

FLIES, Rings of. See Rings.

FLY, St. Mark, the name of a species of fly, which makes its first appearance every year about St. Mark's day, and is then seen in vast numbers; it is somewhat smaller than the large blue fleet-fly, and has no truck, but a mouth without teeth; notwithstanding this seemingly innocent organization, the creature does great mischief, and every gardener knows the effects of it at one time or other.

FLY, in Mechanics, is an apparatus employed to equalize and regulate the velocity and power of many machines which require such regulation from the inequality either of the moving power, or of the resistence it has to overcome. A fly acts upon the principle that any body, being put in motion with a certain velocity at a certain expense of power, will continue to move until its motion is checked by a resistence equal to its momentum or ham of the power and velocity which first caused its motion. This principle is carried into effect by various forms of the apparatus; the main being generally made to revolve upon a centre, and the parts on the opposite sides of the centre being balanced. Two, four, or any other number of equal weights, placed on the opposite ends of arms or radii which are affixed to an axis, will, if the weights be supposed to touch each other, or a hoop or ring of one piece be fastened, its form will be much improved; and it is now termed a fly-wheel, and is the manner in which the fly is most generally used.

The friction or resistence which the air opposes to any body in motion, and the friction of the pivots which support the axis of a fly-wheel, are considerable deductions from the power communicated to it; so that instead of a fly-wheel gaining power, as some imagine, it requires a constant exertion of power to keep it in motion, even when no other resistence is applied to prevent it. For this reason a mechanic should never introduce a fly-wheel into a machine, unless the advantages to be derived from its action are greater than the actual loss of power it occasions. As an instance, we will suppose a heavy flamer or hammer to be raised by a water-wheel: the action of the water upon the wheel is constant and uniform, and whilst the machine is lifting the hammer, this action is nearly balanced; but the instant the hammer falls, the principal resistence or load to the water-wheel is removed, and the water urges it rapidly forwards, until it meets the hammer again, when it is suddenly checked, and moves with diminished velocity, until it again looses its load.

In such a case as this the fly-wheel is of great service, for in the interval while the resistence to the water-wheel is not in action, it prevents its acceleration, the power of the water-wheel being employed to give a momentum to the fly-wheel; and as soon as the velocity of the water-wheel is at all diminifhed, by the return of its load, the momentum of the fly-acts to carry it forwards, and continue the motion with the same velocity until the momentum is expended in displating the water-wheel. By this time the hammer has fallen, and the water-wheel left at liberty to communicate a new impulse to the fly.

In this, and many other similar cases, the power expended in giving motion to the fly is trifling, compared with what it pretends from complete loss during the interval in which the resistence of the water-wheel is inactive. If the water-wheel had been applied to raising a flamer, the equalization might, have been made by using three or four flapers in place of one, and adapting the machine to raise them successively: by this means, the load being divided and applied continually, the motion would be rendered nearly as uniform as by a fly-wheel, and without its inconveniences.

In this manner in many machines where fly-wheels are introduced, they are not absolutely necessary, as mills, pump mills, &c., where a single machine which only acts in one direction is to be moved, all these might be improved by dividing the load, and causing its parts to act in succession; and for pump mills the double acting pumps may be substituted, to great advantage, in lieu of a single one with a fly-wheel.

It is a great object in constructing flies to form them so as to present the smallest resistence to the air. For this purpose a wheel should always be used, and should be smooth and truly circular without any projecting nuts, &c.; the radii should be made to present a thin edge to the air, and the whole should be made of metal, that the greatest weight may be contained under the smallest surface; and for this purpose, if the section of the ring is a circle, the smallest surface will be exposed to the resistence to the air, the radii should be of an elliptic figure, the narrowest edge meeting the air.

This form of a fly-wheel is used by Messrs. Murray and Wood in the steam engines which they ereft, and in included in a patent they have for steam engines, and have been applied to the steam engines, and is not original, as Mr. Sully gave that form to his watch balances many years ago.

A fly-wheel should be cut in one piece of metal, if it is not too weighty; in which case, the pieces of which it is composed should be melted together in the most solid manner imaginable, lest the centrifugal force of such a large mass, moving with a considerable velocity, should endanger the separation of its pieces. If by any accident the bolts connecting them become loose, or are weakened by rusting, (this failure, which has sometimes happened, is truly dreadful,) the force with which a fragment of the wheel is projected is irresistible; and if it should chance to strike the walls of the building, it would be in danger of total destruction. A method has been lately introduced of putting fly-wheels together, by dovetailing instead of screw-bolts. The arms are fastened into the ring, and the fragments of the ring fastened together by a system of dovetail, which only admit of being put together in one direction, which is contrary to that in which the centrifugal force acts. Proceed on this head will not appear trifles, when it is considered that fly-wheels of 8 and 16 tons in weight in the ring and arms are common in the machinery used for the manufacturing of iron, and their circumference moving at the rate of 300 feet per minute. We have seen one applied to a steam engine of 16 tons in weight, and moving much quicker. The ring is usually in six pieces, of about
FLY.

about a ton each, and connected only by a few wrought iron bolts as it revolves. The weight of these pieces, constantly acting in new directions, independent of the centrifugal force, is a severe strain upon the bolts and parts forming the connection.

The mode of calculating the size, weight, and velocity of a fly-wheel, proper to regulate the motion of any given piece of machinery, must be very intricate; though it is not usual for practical mechanics to employ calculation, their fly-wheels being adopted from the proportion of some other similar machine, which is found to answer its purpose. This subject has not been investigated in the elementary works on mechanics that we have seen; though, from its great practical utility, it would well repay the labour of any competent analyst, who would turn his thoughts to the subject.

The fly-wheel only acts when the velocity of the machine is variable: for having naturally a tendency to preserve an uniform velocity in itself, it will tend to move the machine connected with it in the same manner. On this account, it would be absurd to employ a fly-wheel in any machine where the power and resistance are always uniform, or bear the same proportion to each other; hence the motion of any machine, deriving assistance from a fly-wheel, cannot be perfectly regular, as it is only when a change in the velocity of the machine takes place that the fly-wheel has any action, and the power it exerts to continue the motion is greater or less, as the change in velocity of the machine is more sudden or slow.

In rolling mills, where the power which will be required is not to be estimated, and at the same time the resistance to the mill is not in action, a great proportion of the time, a large and heavy fly-wheel is necessary; in this case it acts as a collector of power. If the workman has an extraordinary, large piece of metal to be rolled, he suffers the mill to work without obstruction a few revolutions of the water-wheel, that the fly-wheel may acquire such a velocity as will overcome the resistance to be opposed to it, which is perhaps far beyond the power of the mill to accomplish without such aid.

The coming press, or fly-press, is another example of the same fort. The momentum of a fly, put in motion by a continued action of several seconds, is expended in an instantaneous stroke upon a piece of metal, acting with astonishing power. The fledge hammer may be influenced as a similar case. The power given to the hammer in a certain space of time, is exerted in an infinitely short time, and with proportional power.

In all cases where the moving force is variable, a fly-wheel must be added, unless the resistance can be adapted to vary in the same degree. A man, turning a winch by his hand, or a crank by his feet, can exert three times the power in many positions which he can in others, particularly in the latter case; a fly-wheel is, therefore, of essential service, and the rotative motion obtained from the flemm engine is wholly dependent on the assistance of the fly-wheel.

The fly may be applied to several sorts of engines, whether moved by men, horses, wind, or water; and is of great use in those parts of an engine which have a quick circular motion, and where the power or resistance acts unequally in the different parts of a revolution. In this case the fly, without adding any new force, becomes a moderator, making the motion of revolution almost every where equal and uniform; thus the engine becomes more easily and conveniently acted upon and moved by the impelling force; and this is the only advantage obtained by the fly. The best form of this appendage to machines is that of a wheel or circle, of a proper size, as this will not only be less resisted by the air, but by being continuous, and the weight every where equally distributed through the perimeter of the wheel, the motion will be more easy, uniform, and regular. In this form, the fly is most aptly applied to the perpendicular drill, which it likewise serves to keep upright by its centrifugal force; as also for wheels or common, where the motion is quick; for in pressing upwards from the lower part, a person can exercise a greater power than in thrusting forward in the upper quarter; when, of course, part of his force would be lost, if it were not accumulated and maintained in the equal motion of the fly. Hence, by this application of force, a man may work all day in drawing up a weight of 40 lbs. whereas 30 lbs. would occasion to him greater labour in a day without the fly.

The force of a fly, when joined with the screw, for flushing the image upon coins, may be calculated thus: suppose its two arms to be each fifteen inches long, measuring from the centre of the weights to the axis of the motion, and the weights to be fifty pounds each, and the diameter of the axis prefixed upon the end to be one inch; if every stroke be made in half a second, and the weights describe an half circumference, which will in this case be of four feet, the velocity will at the instant of the stroke be at the rate of eight feet in a second, and, therefore, the momentum eight hundred; but the arms of the fly being as levers, one brachium of which is fifteen inches long, whilst the other, viz. the semi-axis, is but half an inch, we must increase this force thirty times, which will give twenty-four thousand; an immense force, equal to that of a hundred pound weight falling a hundred and twenty feet, or near two seconds in time; or to that of a body of seven hundred and fifty pounds, falling 16 1⁄2 feet, or one second in time.

Some of these engines for coined crown-pieces have the arms of the flies five times as long, and the weights twice as heavy as those here mentioned; so that the effect is ten times greater. Defagustiius. Exper. Philosoph. vol. i. p. 245. 339.

Besides the utility of fly-wheels, as regulators of machinery, they have been employed for accumulating or collecting power. If motion be communicated to a fly-wheel by means of a small force, and if this force be continued till the wheel has acquired a great velocity, such a quantity of motion will be accumulated in its circumference as to overcome resistances, and produce effects, which could never have been accomplished by the original force. So great is this accumulation of power, that a force equivalent to 20 pounds, placed for the space of 37 seconds to the circumference of a cylinder, 20 feet diameter, which weighs 4713 pounds, would, at the distance of one foot from the centre, give an impulse to a much-ball equal to that which it receives from a full charge of gunpowder. In the space of six minutes ten seconds, the same effect would be produced, if the cylinder were driven by a man who constantly exerted a force of 20 pounds at a stroke one foot long. This has been demonstrated by Mr. Atwood in his "Treatise on Rotatory and Linear Motion." This accumulation of power is exemplified in the Sling: and also in the machine for casting, as already stated. Mellor, Watt and Boulton have employed a new kind of fly, called the "Conical Pendulum," for regulating the admission of steam into the cylinder of the steam-engine, which feeds.

Notwithstanding the great advantages of fly-wheels, both as regulators of machines, and collectors of power, their
utility wholly depends upon the position which is assigned them, with respect to the impelled and working points of the engine. This position depends altogether on the structure of the machinery. It may be obviated, however, in general, that where fly-wheels are employed to regulate machinery, they should be near the impelling power. And, when used to accumulate force in the working point, they should not be far distant from it. In hand-mills for grinding corn, the fly is for the most part very injudiciously fixed on the axis to which the winch is attached. It should always be fastened to the upper mill-stone, so as to revolve with the same rapidity. In the first position, indeed, it must equalize the varying efforts of the power which moves the winch, but when it is attached to the turning mill-stone, it not only does this, but contributes very effectually to the grinding of corn. Ferguson's Mechanics, by Brewster, vol. 1.

Fly-press, an instrument of most extensive use in many manufactures for flamping or cutting small articles in metal. It consists of a chisel, punch, or cutting tool, moved by a screw, which is furnished with weights acting as a fly. When these are turned rapidly round, the tool exerts an immense power on any substance subjected to its action. The press is often used without the fly, and is still called, though improperly, a fly-press.

Figs. 1, 2, 3, and 4, of Plate XXVII. (Mechanics) represent a fly-press with its minor parts, such as is in common use in Sheffield in a variety of manufactures, which we shall enumerate in their proper heads. A A A Figs. 1 and 2, is a massive frame of cast-iron, of the dimensions expressed by the drawing and scale annexed. In the upper part of this frame a female screw, or screw-box is fitted, and the screw B passes through it. The top of the screw is fixed to a curved handle a b c, furnished with a heavy weight c, which acts as a fly, when the handle is turned round by a workman sitting before a bench or table, on which the press is fastened by two bolts passing through projecting pieces, d, d, of the iron frame. At e a piece of iron is fastened, projecting from the iron frame, and supporting a socket for the square iron slider f to slide up and down through, and to avoid any shake in its motion. The socket can be at any time made to fit the slider by the four screws (seen in both figures) which draw the two halves of the socket together. The upper end of the slider f is connected with the screw B, by a joint which allows the screw to turn round independently of theslider, but obliges the latter to accompany the screw in its vertical motion, either ascending or descending. At the lower end of the slider f, the punch or tool, g, is fastened by a clamp-screw: it acts in combination with another tool, k, called the die, fixed below it in the frame by four screws l, as shown in Fig. 3, which allow of its adjustment in the true position beneath the tool. The lower tool, or die, t, is fitted into a block, which is held by the four screws, and by this means the die can be quickly changed without disturbing the press. The upper tool can be removed in the same manner by releasing the clamp-screw which holds it in the slider f.

The, as the essential parts of the fly-press and its operation, are too simple to require much explanation. The workman, being seated before the press, holds the piece of metal to be acted upon in his left-hand, and draws the handle a towards him with the other: this, by turning the screws, forces the punch down upon the metal, and the momentum of the weight c causes it to act with such force, that the resistance of punching through a thick piece of metal is fearfully perceptible upon the handle. The principal part of this power is gained by the screw as well as by the accumulated inertial force of the fly. For many purposes where the resistance is but slight, the weight c is removed; the press acts simply by the lever and screw. It still remains, though improperly, the name of the fly-press. This alteration is intended to give the workman such a command of the machine, that he can more quickly reverse the motion than will be the case when the fly is in action. This can be only done where the resistance is very slight. Nails, the teeth of saws, open-work of fenders, and similar articles, are cut with appropriate tools in this manner. Figs. 4 and 5, represent some of the tools to be used in the press; a is a punch, and b the socket, or die, for perforating a circular hole, either with the view of forming a hole in a metallic plate for riveting, &c. or to prepare the piece struck out for boat-builders rivets, washers, or collets, buttons, ornamental flamps for fenders, and a vast variety of other purposes in which small circles of metal are useful. These pieces are forced through the die, and fall through a hole made in the frame A, into a small drawer placed beneath the bench for their reception.

C, D, are another pair of tools, in which the die D is embossed to the shape intended to be impressed on the ornamental flamps cut by the former punch. These are forced into it by the flat surface of the upper tool C. In some cases this tool at the same time punches a small hole by which the flamp is to be rivetted to the article it is intended to ornament, and the die must then be perforated with a small hole to convey away the fragment of metal forced out by the punch. In many cases these flamps are intended to be fastened on by a small pin projecting from their lower surface; in this case they are forged or cast in the manner of a nail, and the point or shank of a flamp being inserted into a hole. In the lower die the upper tool is forced down upon it, and impresses its figure upon its head; it is plain that here the upper tool must be embossed instead of the lower. A concave or convex figure is given to the small circles before-mentioned, by making the end of the punch a Fig. 4, concave or convex, and the pressure it exerts to force out a piece of plate is sufficient to impose upon the fragment the figure of the punch. In Fig. 5, E, F are another small pair of dies for punching small circular holes, and G H is a similar pair of tools for square holes.

The manner of punching out the concave shells for small buttons, which are termed shell buttons, is deferring of notice. First, small circles, (one of which is seen in the section at r, Fig. 6.) are cut out from plate-brafs, by a plain round punch and die, similar to a b, Fig. 4; the dies, (Fig. 6,) are now used. The circle of brafs, being placed over the hole of the die L, is forced through it by the end of the other tool, k, which being smooth and of a spherical figure, presses the plate of metal to assume the same form, and fall into the drawer beneath the plate of s, when it is fit for use. It must be observed, that the aperture through the die, L, is as much larger than the tool K, as to admit the thickest of the metal all round it, and the upper side of the whole must not be left sharp, but rounded off, so as not to cut, but only bend the piece of metal in passing through it: also the circle of metal must be larger than the hole, that there may be a sufficiency to form the cup or hemisphere s. The size of this circle is shewn by the dotted circle r, in the plan Fig. 6, which likewise shews a piece of brafs t, in the form of a square; it is fastened upon the die, to guide and flap the circle in the point where it is concentric with the hole over which it is placed.

The open-work in fenders, and ornamental fire-grates, is clamped out by the fly-press. For this purpose the pattern
intended to be cut out is described upon the plate of calf-leather intended to form the fender, and by appropriate punches the holes are freefively cut out. In this manner the diamonds, lozenges, triangles, and other figures, we observe in these articles are removed with great facility. This operation has lately received great improvement from Mr. Proctor of Sheffield. By this new method a great number of punches, and of different figures, are moved at the same time, and the necessity of describing the pattern upon the plate is obviated; whereas in the common method the fenders must pass through the press as many times as there are figures in the pattern, and it requires some skill and judgment in placing the fender so correctly in its true position beneath the tool of the press, so to have no inaccuracies in the pattern discernible to the eye.

Fig. 7, is the press used for the purpose, though not exclusively, all heavy articles being hinged in a press of this kind. The improved apparatus is seen on the ground by the side of the press, where A A is the plate of the press, inclosed between two leaves of a frame B, similar to book-ends. The leaves are two plates of steel hardened and tempered; the figure of D (fig. 8), cut out in exactly the same pattern as the fender is intended to be. These plates are attached, by four screws in each, to an iron frame C, connected by hinges E; when shut together, as at A A, the apertures in the upper and lower leaves correspond, and the plate A is interposed between them. A number of fiddle punches of the proper figure, as T, are placed in the holes of the upper leaf, so as to fill them all up, and the whole is placed upon the lower bed H of the press, and the iron bed D being forced down upon the punches by the screw, drives them all through at once, and removes corresponding pieces from the steel plate A A. The punches fall through the plate, and are received in a small drawer, beneath the bed of the press. The screw being turned back, the tools and plate are removed to the table K before the press, the book opened, and the plate is put forwards through the leaves, so as to cut out another length. To ensure the parallelism and proper distance from the former pattern, the leaves have one more hole in them than is intended to be cut out at the operation. In fig. 8, A represents this hole, which is brought to coincide with the hole cut by A at the former operation. By this means, it is certain to be in a straight line, and to keep it so. A punch is put through the plate in this hole A before it is placed under the press a second time. The workman is seated upon the beam L, before the table K, and finds the punches, which had fallen through into the drawer, standing up in it in the true position; and he has only to transfer them to the leaves for the next stamp. At N is seen another pair of leaves; and at fig. 9, a piece of the plate cut between them: n are two of the punches; the leaves are represented as opened to admit the plate, and its position is adjusted by placing two of the punches through the holes stamped in the plate by the former stroke.

The press (fig. 7) is of large dimensions; its frame P is double to give greater strength; the lever R loaded at each end with heavy weights. It is in many feet in length, though it is seen away, and consequently foreheads serve the purpose. The frame S S L is placed beneath the surface of the ground, and a circular walk is made for the two men who run round with the end of the lever R, to give it as great a velocity as possible, that its momentum may give a great energy to the action of the screw. The workman seated upon L, is low enough to be beneath the lever as it moves over his head. The screw is pointed at the lower end, and acts in a socket on the top of the slider M; to the lever end of which the moving bed I of the press, is fastened: to balance the weight of the slider and bed, a lever X, and a heavy weight Y, are applied, which raises them up when the screw is turned back, so as to admit the work being placed beneath the press.

Fly, in Rural Economy, a disease incident to sheep, in consequence of their being flirked by a fly, which produces a sort of maggot that eats into, and remains in the flesh. The sheep that are in a poor weakly state, and in the wool of which there is a deficiency of what is denominated the yolk, are the most exposed to such attacks; as the most suitable nidus is, in such cases, afforded for the fly to deposit its grna in. After the eggs are thus deposited, they are quickly hatched by the warmth of the animal, directly eating into, and feeding upon it when not guarded against. Its attacks are the most frequent in hot funny seasons. In order to the removal of the maggots, some have recourse to the cutting or clipping away the wool about the parts affected, and afterwards to the application of tar, or a mixture of train oil and sulphur upon them. When, however, the maggots are not completely formed, the parts are only slightly dabbed with white lead in the state of fine powder. Where precautions of these kinds are neglected, the sheep are speedily destroyed by the disease. In situations where the insects are small and much surrounded with woods, it is essentially necessary to keep a constant attention to sheep, to see that they are not struck by the fly, as a few hours may often prove of the utmost consequence in the removal of the disease, and the safety of the animals.

It has been suggested that the shepherds in the midland districts of the kingdom employ a variety of applications as preventative of the fly, especially with lambs. They had train oil efficacious, but it fouls the wool, and makes the sheep unpleasant to touch. An ointment, composed of butter, and the flower of sulphur, is in the highest esteem. In preparing it, the butter is first melted over a slow fire, and then a proper quantity of sulphur is, to it, until it becomes of a pretty thick consistence, and rather firm. In applying it, a piece about the size of a small walnut is rubbed between the hands, which are then drawn along the back; or other parts of the sheep. As insects have, amidst their antipathies, it is useful and interesting to read out those of the sheep-fly. The manner of destroying the maggots just noticed is both effectual, and when referred to its time, simple and easy. In the part of the country most noted above, instead of clipping the wool from the part which is affected, and forcing out the maggots with the points of the shears, the wool is parted by theingers, and the maggots removed by the point of a knife, or dissolved in some other manner, without breaking the coat; and thus a small quantity of white lead, finely scraped from a lump, is mixed in the wool, which, by being agitated with it, is carried down in an even manner upon the part which had been affected. It is frround that a large quantity discolours the wool, while a little preserves any further harm from the maggots that may have been left among it, driving them away from the wound; a at the same time promotes its healing. It is stated that in well sheathedflocks, that are fed regularly twice in the course of the day, there is no such thing as a broken coat. But though the practice is not in full laid down may be extremely proper in many cases, it does not always prove successful. The oxides of carbon or mercury are found far more effectual in some cases of this troublesome disease.

Fly, a disease in turnips, which is supposed to be produced by a fly that eats the leaves. It has been observed by the author of the "Philosophy of Agriculture..."
and Gardening," that if this destructive insect be of the *scaecabina* or beetle kind, which arises out of the earth, it may be destroyed by rolling. He remarks, that the Chinese are said by Sir George Staunton to steep all their seed in liquid manure until they swell, and their germination begins to appear, which they believe not only hastens the growth of the plants, but also defends them against insects beneath the soil; and that to this, Sir George observes, it may be owing that the Chinese turpins escape the fly, so injurious to them in the country. An observation of Mr. Combe, in the Bath Agricultural Papers, seems, he says, also to confirm this idea. He affirms, that when turnip seed is sown during rain, or has rain immediately afterwards, the first leaves are so vigorous that the fly never attacks them; or that the rain itself is so inconvenient to the fly as to prevent its appearance. It is likewise supposed by the Rev. Mr. Stacy, in his "Observations on the Failure of Turnip Crops," that the dryness of the soil at the time the seed is put into the ground, and the great heat of the season, by not deftaining the seed to vegetate quickly, is a principal cause of the destruction that so frequently takes place in crops of this kind. It is also affected by Mr. Ester, in the Transactions of the London Society of Arts, that the flying turpins in drills deeper than by broadcast, accelerates the growth of the plant, by giving it more moisture; whereas it sooner puts forth its leaves, and escapes the depredations of the fly. He speaks highly of the use of the drill, advises the rows to be one foot distant, useth three quarters of a pound of seed to an acre, and soweth them from one inch and a half to two inches deep. As it is probable that injury may be done by fowing too deep, as well as by the contrary, in either case it will be the most proper practice to constantly choose as most a season as possible for fowing the summer crops of this sort of plants. And whenever the season is very dry, to have recourse to the sowing of the feed for a few hours, but not more than that, before it is put into the ground. It is likewise supposed by some, that by fowing radish, mustard, or some other sort of feed that this insect may prefer when in the state of young plants, at the same time with the turnip seed, the disease may be much lessened, if not wholly prevented.

But another, and probably a better mode of guarding against and preventing the disease, is that of having the land well enriched with manure before the crop is put in, as by that means the young plants are rapidly pushed forward into broad leaf, when they become secure from the ravages of the fly. The footting the rows of the young turpins just as they appear, by sprinkling the foot along them in a sort of fine rain, from a feed lip, has also been advised as a successful practice, which was long ago known to Ellis. Several other methods have been recommended at different times, but no certain mode of removing or preventing the effects of this insect on young turpin plants has hitherto been discovered. See TURPIN.

Fly, in the Sea Language, that part of the mariner's compass on which the thirty-two winds are drawn, and to which the needle is fastened underneath. See COMPASS.

Fly of an Oven, is the breadth or extent from the flaff to the extremity or edge that shutters before in the wind.

Let Fly the Sleet, at Sea, a word of command, in case of a gale of wind, left the ship should overfly, or spend her top-masts and masts, to have the sheet go-amain, and then the fall will hold no wind.

Fly the Heels, in the Manage. A horse is said to fly the heels when he obeys the spurrs. See HEELS and SPURRS.

To Fly gross, in Falconry, is said of a hawk, when the flies at the great birds; as cranes, geese, herons, &c.

Fly on Head, is when the hawk, missing her quarry, betakes herself to the next check, as crows, &c. See HAWK.

Fly-boat, or Flight, a flat-bottomed Dutch vessel, whose burthen is generally from four to six hundred tons. It is distinguished by a remarkably high stern, resembling a Gothic turret, and by very broad buttocks below.

Fly-tool, is a very light narrow wooden spade fixed with iron, which the navigators of a canal use for cutting or throwing out any lost clay, peat, or the like, and which they do so quickly and dexterously as to keep two successive pieces flying in the air together.

Fly-catcher, in Ornithology. See MUSCICAPA.

Fly-catcher of Edwards, grey and yellow. See Todus cinereus.

Fly-catcher of Latham, paradise. See Todus paradisaeus.

Fly-catcher, grey-blue, and blue-headed grey, varieties of the *Catharacta Syræa*.

Fly-catcher, yellow-throat. See *Motacilla flavigularia*.

Fly-bane, in Botany. See *Staphylea*.

Fly-honfuckle. See *Lonicera*.

Fly-horn holidays, African. See HALLERIA.

Fly-tree, in Natural History, a name given by the common people in America to a tree, whose leaves, they say, at a certain time of the year, produce ties. On examining these leaves about the middle of summer, the time at which the flies used to be produced, there are found on them all sorts of bags of a tough matter, of about the size of a half-pear, and of a dusky greenish colour; on opening one of these bags with a knife, there is usually found a single full-grown fly of the sound kind, and a number of small worms, which, in a day or two more have wings, and fly away in the form of their parent. The tree is of the mulberry kind, and its leaves are usually very largely flocced with these infect bags, and the generality of them are found to contain the infects in the worm flate; when they become vioned, they soon make their way out. The bags begin to appear when the leaves are young, and afterwards grow with them; but they never rupture the leaf, or injure its shape. They are of the kind of leaf-galls, and partake in all respects, except size, of a species we have frequent on the large maple, or, as it is called, the fycamore. Philos. Trans. N. 431. See further, Reaumur's Hist. vol. vi. p. 34. See PUCERON.

Fly-court. See SILENE.

Fly-island, in Geography, an island in the South Pacific ocean, discovered by Le Maine and Schouten in the year 1616, so called from the number of flies found there. It is covered with trees, but within overflowed at high water. Some inhabitants were seen naked. S. lat. 15°. W. long. 150°.

FLYERS, in Architecture, are the series of steps, which taken altogether constitute a flight, and any single step is called a flyer, the treads of which are of equal breadth throughout, and thus flyers differ from windsers; the treads of the latter diminish continually from the wall of the stair-case to the well-hole.

FLYING, the progressive motion of a bird, or other winged animal, in the liquid air.

Flying is either natural or artificial.

FLYING Army. See Army.

FLYING Bridge. See Bridge.

FLYING Comp. See Camp.

FLYING, natural, is not performed by an apparatus, or structure
FLYING.

Armature of parts, concerted for that end by nature herself. Such is that of most birds and insects, and of some fishes.

The parts of birds, &c., chiefly concerned in flying, are the wings and tail; by the first, the bird sustains and wafts itself along; and by the second, it is enabled to ascend and descend, to keep his body poised and upright, and to obviate the vicissitudes thereof.

It is by the largeness and strength of the pectoral muscles, that birds are so well disposed for quick, strong, and continued flying. These muscles, which, in men, are scarcely a twentieth part of the muscles of the body, in birds exceed and outweigh all the other muscles taken together; upon which Mr. Willughby makes this reflection, that if it be possible for man to fly, his wings must be contrived and adapted, that he may make use of his legs, and not his arms, in managing them.

The flying of birds is thus effected:

The bird first bends his legs, and springs with a violent leap from the ground; then opens, or expands the jointures of his wings, so as to make a right line, perpendicular to the sides of his body: thus, as the wings with the feathers therein, constitute one continued ham, being now raised a little, and vibrating the wings, with great force and velocity, perpendicularly against the air; the air, though a fluid, refits those effusions, both from its natural inactivity, and from its elasticity, which makes it restore itself after it has been compressed, and react as much as it has been acted on; by such means is the whole body of the bird protruded. The sagacity of nature is very remarkable in the opening and recovering of the wing for fresh strokes. To do it directly, and perpendicularly, it must needs have a great resistance to overcome; to avoid which, the body part, or head of the wing, into which the feathers are inserted, moves sideways with its sharp end foremost, the feathers following it like a flag.

The resistance the air makes to the withdrawing of the wings, and consequently, the progress of the bird will be so much the greater, as the weight, or force, of the fan of the wing is the longer: but as the force of the wing is continually diminished by this resistance, when the two forces are come to be in equilibrium, the bird will remain suspended in the same place; for the bird only ascends so long as the arch of air the wing describes makes a resistance equal to the excess of the specific gravity of the bird above the air; if the air, therefore, be so rare as to give way, with the same velocity as it is struck withal, there will be no resistance, and, consequently, the bird can never mount.

Mr. Ray, Willughby, &c., have supposed the tail to do the office of a rudder, in steering and turning the body this way or that; but Borelli has shown it to be unfit for any such office. The flying of a bird, in effect, is quite a different motion from the failing of a ship; birds do not vibrate their wings towards the tail as oars are struck towards the stern, but waft them downwards; nor does the tail of the bird cut the air at right angles, as the rudder does the water, but is disposed horizontally, and preserves the same situation what way soever the bird turns.

In effect, as a vessel in the water is turned about on its centre of gravity to the right, by a brisk application of the oars to the left, so a bird, in beating the air with its right wing alone, towards its tail, its force will be turned to the left; as when in swimming, by only striking out with the right arm and leg, we are driven to the left.

Add, that birds with long necks have another way of altering their course; for, by only inclining the head and neck towards this or that side, the centre of gravity of the whole being changed, the bird will proceed according to this new direction.

Birds never fly upwards in a perpendicular line, but always in a parabola, the line described by projectiles. In a direct effect, the natural and artificial tendency would oppose and destroy each other; so that the progress would be very slow. In a direct effect, they would aid one another, so that the fall would be too precipitate. Indeed the hawk will frequently find that advantage in keeping of the parabola; but ordinarily birds keep their wings expanded, and at rest, to retain their descent; and at the same time stretch out their legs.

FLYING. Artificial, is that attempted by men, by the assistance of mechanisms.

The art of flying is one of the great difficulties of mechanics; it has been attempted in divers ages; the discovery of it might prove of great service, and also of great difference to mankind.

Nobody seems to have bid so fair for that invention as our famous frater Bacon, who lived near five hundred years ago. He not only affirms the art feasible, but affirms us he himself knew how to make an engine, in which a man fitting might be able to carry himself through the air like a bird; and affirms, that there was another person who had actually tried it with success. See the article Bacon.

The secret consisted in a couple of large thin hollow copper globes, exhausted of air, which being much lighter than air, would sustain a chair, whereon a person might sit.

F. Francisco Lana, in his Prodomo, professes the same thing, as his own thought. He computes, that a round vessel of plate-brass, fourteen feet diameter, weighing three ounces the square foot, will only weigh 1543 ounces; whereas a quantity of air of the same bulk will weigh 553 ounces; so that the globe will not only be sustained in the air, but will carry with it a weight of 753 ounces; and by increasing the bulk of the globe, without increasing the thickness of the metal, he adds, a vessel might be made to carry a much greater weight.

But the falacy is obvious: a globe of the diameter he describes, Dr. Hook shews, would not hold the pressure of the air, but would be crushed towards, therefore, in whatever ratio the bulk of the globe were increased, in the same bulk the thickness of the metal be also, and consequently the weight increased: so that there would be no advantage in such augmentation.

The same author describes an engine for flying, invented by the Sénor Delincé, a man of Sable, in the county of Maine. Vide Philosph. Collect. N. 1.

The famous bishop Wilkins was so confident of successes in this art, that he seems to intimate that, in future ages, it will be as usual to hear a man call for his wings when he is going a journey, as it is now to call for his boots. See Math. Maga. b. ii. ch. 7. Discovery of a new World, prob. xiv. p. 135. Secret and Swift Messengers, ch. iv. See Alde station.

FLYING. Bretzls, in Pointed Architectede. This is one of the boldest and most striking features of the style of building in question: being a prop of masonry work, and in the air to support some elevated part of a building, when cannot be propped immediately from the ground. Flying buttresses are generally seen on the outside of ancient cathedrals, and other large magnificent churches, flying over the side aisles from the main external buttresses to the upper walls of the nave, to prevent them from spreading.
The geometrical principle on which they support the walls and the buttresses, by means of the slanting line of their upper part, and are supported by them, by means of the arches beneath, is one proof, amongst many others, of the ingenuity and scientific skill of the architects of the middle ages.

**Flying of Colours**, is used by painters to denote their want of durable paint, which they express by their *floundering*.

**Flying-fish**, in *Ichthyology*, a name given by the English writers to several species of fish, which by means of their long fins have a method of keeping itself out of water for some time. The flying-fish, most properly so called, is the exocetus of the ancient authors, and of Artech. (See *Exocetus*.) See a minute and accurate description of the *exocetus volitans*, or flying-fish, in the Phil. Trans. vol. xvi. part b. p. 791.

**Flying-fish** is also a name of a fish of the gurnard kind. See *Callyonimus Lyra*.

**Flying Pi-ha**, is a part of a clock, having a fly or fan, whereby to gather air, and so bridge the rapidity of the clock's motion, when the weights depends in the striking part. See *Clock*.

**FO**, or *Foi*, in *Mythology*, the object of religious veneration and worship in China, and also, under various other appellations, in different parts of India. *Fo* is supposed by Dr William Jones to be the Buddha of the Hindoos (see *Buddha*); and it has been generally supposed that the worship of this deity was introduced into China, together with a few of his votaries and fragments of the canonical books of the Indians, about the 6th year of the Christian era; though some have referred this event to a later period as the year 630. See under the article *China*, the account of the *Religion of the Chinese*. The native place of this pretended god is unknown; nor can his origin and the etymology of his name be satisfactorily ascertained. Some suppose that he lived about 600 years before Christ; and that he first appeared in the southern part of India, among the nations situated on the shores of the Indian ocean, and thence disseminated his philosophy, by means of his disciples, to all India. It is related by his followers, that at the age of 19 he retired to a desert accompanied by some philosophers, to whose tuition he committed himself. At the age of 30, it is said, he felt himself suddenly inspired, and that he attained to the intuitive knowledge of the first principles of all things, from which time he took the name of Fô, which signifies "something more than human." His mystical philosophy he is said to have delivered to innumerable disciples, under the veil of allegory; and the Japanese add, that in his contemplations, during which his body remained unmoved, and his senses unaffected by any external object, he received divine revelations, which he communicated to his disciples. As soon as he became a god, he thought of establishing his doctrine, and of proving his celestial mission by performing miracles. The number of his disciples was immense, and they soon spread his opinions through every part of India, and the higher extremities of Asia. His priests are generally known by Europeans under the appellation of *Bonzes*. For an account of their character and office, we refer to that article.

Buddha, Xekias, or Fôe, for by these and other names he is called, is said to have had both an exoteric and esoteric doctrine; in the former he taught the difference between good and evil; the immortality of the souls of men and brutes; different degrees of reward or punishment in a future world; and the final advancement of the wicked, after various transmigrations, to the habitations of the blest. This doctrine of the transmigration of souls has given rise to that multitude of idols, which are revereved in every place, where the worship of *Fo* is established. Quadrupeds, birds, reptiles, and the vilest animals had temples, and became objects of public veneration, because the soul of the god in his transmigrations and metamorphoses might have inhabited their bodies. His followers also say, that the god *Fo* came upon earth to save mankind; that by him their sins are expiated; and that he alone can procure for them happiness in the life to come. To the reverence of living creatures; the *Fô* forbids the killing of any living creature; the *foochal*, the taking away of the goods of another; the third forbids men to pollute themselves by uncleanness; the fourth, to lie; and the fifth, to drink wine. They, above all, recommend the practice of certain acts of mercy; such as, to treat their bonzes well, to build monasteries and temples for them, and to supply them with every thing necessary, in order that they may be able, by the affability of their prayers, and the pittance which they impose, to merit forgiveness, and the remission of all their sins. The Bonzes pretend, that when *Fo* had attained to the age of 79, he perceived that his borrowed divinity could not prevent his paying the debt of nature like other men; and, therefore, he would not leave his disciples without revealing to them the whole secret and hidden mysteries of his doctrine. Having called them together he declared that till that moment he had always thought proper to speak to them in parables, and that for 40 years he had divulged the truth under figurative and metaphorical expressions; but being about finally to leave them, he would unveil the whole mystery of his wisdom. "Learn then," said he, "that there is no other principle of all things, but a vacuum and nothing; from nothing all things have sprung; to nothing they must again return, and then all our hopes end." This is the aim of his exoteric or internal doctrine. To one of his favourite disciples he committed his most secret thoughts, and him he entrusted with the charge of propagating his doctrine. He directed him never to attempt to support his tenets by proofs and long reasoning, and commanded him to put only at the beginning of the books which he published: "Thus have I learned." In one of his works the same Fo mentioned another matter more ancient than himself, whom the Chinese name "O-mi-to," and the Japanese "Amida." The bonzes assure us, that the latter became so eminently holy, that it is at present sufficient only to invoke him, in order to obtain immediate pardon for the greatest crimes. The Chinese, therefore, on almost every occasion, have continually in their mouth these two names, "O-mi-to, Fo!"

**FO-III.,** one of the first and most celebrated legislators of China, and said to be the founder of the Chinese monarchy. (See *China*.) Little is known of the methods by which this legislator adapted for civilizing the country; and the prec-ict era of his establishment is so ancient, that it cannot be ascertained. An ancient book, called "Yekim," which is still preferred in China, is ascribed to *Fo-hi*; but it is written in hieroglyphics; and no one has been able to give a satisfactory explanation of its contents. The most probable conjecture is that of Leibnitz, that it was intended to teach the art of numeration. *Fo-hi* was succeeded by several emperors, who carried forward the work of civilization, particularly by means of moral allegories, fables, and poems.

**FOA**, in *Geography*, one of the Hapae islands, in the S. Pacific ocean, between Haano and Leleoga, to both which
FOAL, in Rural Economy, is the common name of the young of the horse kind. The male is termed a colt foal, and the female a filly foal. Foals, when they are of the valuable kind, should always be kept as well as possible while they are growing, as without attention in this respect they seldom make good horses. See HORS.

It is contended by some experienced horse breeders, that it is not by any means difficult to ascertain in the foal, what the form of it will be when grown to the full size, as it will carry the same shape at six years old that it carried during the first month, if it be not improperly managed in the keeping afterwards. And it will have the good or defective form accordingly. In judging of the height, the thin-bone should be particularly regarded; where that is large, and long from the knee to the pattern, it indicates a tall or full bred horse. And another method of judging is that of examining the space between the knee and withers, which being doubled will mostly give the height of the animal when grown. The means of ascertaining their probable goodness at this early period is more difficult, but it is commonly supposed that where they are active, stirring, not easily frightened, and anxiously striving for mastery, they will prove well metalled horses in their full grown state.

FOAL-foot, a common name applied sometimes to the troublesome weed termed colt's foot. See COLT'S-foot.

FOAL-teeth, the set which are put forth during the first year of the animal's age. See Age of the Horse, and HORS.

FOALING, a term signifying the act of parturition or bringing forth in the mare. Great attention should be paid to the animals about this period, as it not infrequently happens, that mares destroy their foals by becoming entangled in the thistles or other places, by means of their halters, &c. or by the difficulty of bringing them forth. It is the best way to look to them frequently at such times.

FOCA, in Geography, an island in the Atlantic, near the coast of Guinea, and the mouth of the Calabar, with a town of the same name, called by the Dutch Wondorp.

FOCAGE, or FUGGE, fire-money, heart-money, or chimney-money. See FUGGE.

FOCAI, in Geography, a town of Egypt; 20 miles N. of Abu-Girâé.

FOCAKO, a mountain of Naples, in Otranto; 20 miles N.E. of Tarento.

FOCAS, a town of Japan, in the island of Nippon; 145 miles N.W. of Jeda.

FOCHABERS, a market town of Scotland, in Badshire, conglom of one street, on the right hand of the Spey; 12 miles W. of Cullen and 9 L. of Elgin. Near it stands Gordon castle, a magnificent seat, in a very extensive park, founded by George, second Earl of Huntley; originally called the castle of the Dog of Cull. A little below the common ferry across the river is the ford, through which the duke of Cumberland marched his army in 1746, in the face of the rebels, who were advantageously posted on a rising ground. Thence to Elgin, the foal, for soil part, is light, montrous, and barren. At the mouth of the Spey is Carmouth harbour, where great quantities of salmon, preferred in ice, are shipped for London. From this port timber of a good quality is exported. N. lat. 57° 26'. W. long. 3° 3'.

FOCHAN, a famous village of China, lies 4 leagues from Canton, said to be the largest and most populous in the world; it is called a village, because it is not included by walls, and has not a particular governor, although it carries on a great trade, and contains more houses and inhabitants than even Canton itself. It is reckoned to be three leagues in circumference; and to contain a million of inhabitants.

FOCHEA, Fогога, or Pogogia, a sea-port of Asiatic Turkey, in Natolia, situated at the mouth of the Hermus, in the gulf of Smyrna, anciently called Phocaea; 28 miles N.W. of Smyrna. N. lat. 38° 44'. E. long. 26° 39'.

FOCHIA, a town of Bosnia; 73 miles S.S.W. of Belgrade.

FOESANI, a town of European Turkey, in Moldau, on the Milcov; 54 miles W.N.W. of Galacie. N. lat. 44° 42'. E. long. 27° 14'.

FOCUS, in Geometry, and the Conic Sections, is applied to certain points in the parabola, ellipse, and hyperbola; wherein the rays reflected from all parts of these curves do concur or meet.

The foci of an ellipse are two points in the axis, on which as centres, the figure is described; or two points in the longer axis, wherein the rays reflected from any point in the circumference, shall be together equal to the axis itself. There are also called umbilics. See Conic Sections and Ellipse.

Focus of the Hyperbola. See Conic Sections and Hyperbola.

Focus of a Parabola, is a point in its axis, wherein the semi-ordinate is equal to the semi-parameter; or, a point in the axis distant from the vertex, by a fourth part of the parameter, or latus rectum. See Conic Sections and Parabola.

Focus, in Optics, is a point wherein several rays concur, and are collected; either after having undergone refraction, or reflection.

It is thus called, because the rays being here brought together, and united, their force and effect are increased; so that they become able to burn; accordingly, it is in this point that bodies are placed to inflame the fire of burning-glasses, or mirrors.

It must be observed, that the focus is not, strictly speaking, a point: the rays are not all accurately collected into the same place: Huygens demonstrates, that the focus of a lens, convex on both sides, is 4ths of the thickness of the lens.

Focus, in Dipsis, is the point wherein refracted rays, rendered convergent by refraction, do concur or meet, and cross the axis.

The same point is also called the point of convergence, or concurrency.

Focus, Virtual, is the point from which refracted rays, when by refraction they are rendered divergent, or bent to diverge or spread from each other.

The same point is also called the point of concurrence, or point of divergence, in opposition to the real, which is called the point of contact. Suppose, 4 gr. the capacity of a gazelle to be a dot. Draw N. V. through a, and its axis a b; and draw a ray of light parallel to the axis d e, and let f be the centre of the arc d e. This ray, after it has passed the glass, at its contact at a, will not proceed directly to b, but will be refracted from the apex, parallel to d e, and become the ray d g. Draw then directly f g, so that it may cross the axis in w. The point e so found, is called by Mr. Molyneux the virtual focus, or point of divergence.

The effect of convex glasses, or lenses, is to render the rays transmitted through them, convergent, and to bring them together into a focus, which will be nearer or farther...
farther off, as the lens is a portion of a greater or less sphere.

The effect of concave lenses is to render the rays transmitted through them divergent, or to disperse them from a virtual focus.

For the place, position, distance, &c. of the foci of rays refracted through plain, concave, and convex mediums of divers densities, as air, water, glass, &c., see Refraction, Lenses, &c.

The laws of the foci of glasses, and the methods of finding the same, being those of modern and importance; we shall here subjoin a part, as directed and demonstrated by Mr. Malusius, in his "Dioptrica Nova."

1. The focus of a convex glass, i.e., the point wherein parallel rays transmitted through a convex glass, whose surface is the segment of a sphere, do unite, is distant from the pole, or vertex of the glass, almost a diameter and half of the convexity.

2. In a plano-convex glass the focus of parallel rays, or the place where they unite with the axis, is distant from the pole of the glass a diameter of the convexity, provided the segment do not exceed thirty degrees.

The rule or canon in plano-convex glasses is as 107: 193: so is the radius of the convexity : to the refracted ray taken to its concourse with the axis; which in glasses of larger spheres is almost equal to the distance of the focus taken in the axis.

3. In double convex glasses of the same sphere, the focus is distant from the pole of the glass about the radius of the convexity, if the segment be but thirty degrees.

But if the convexities be unequal, or if the two sides be segments of different spheres, then the rule is,

As the sum of the radii of both convexities : to the radius of either convexity alone :: fo is the double radius of the other convexity : to the distance of the focus.

Here observe that the rays which fall nearer the axis of any glass are not united with it so near the pole of the glass as those farther off; nor will the focal distance be so great in a plano-convex glass when the convex side is towards the object, as when the plain side is towards it.

Hence it is truly concluded, that, in viewing any object by a plano-convex glass, the convex side should always be turned outward; as also in burning by such a glass.

Focus, for the virtual, observe. That in concave glasses, when a ray falls from air parallel to the axis, the virtual focus, by its first refraction, becomes at the distance of a diameter and a half of the convexity.

2. In plano-convex glasses, when the rays fall parallel to the axis, the virtual focus is distant from the glass the diameter of the convexity.

3. In plano-convex glasses, as 107: 193:: so is the radius of the convexity : to the distance of the virtual focus.

4. In double concave glasses of the same sphere, the virtual focus of parallel rays is at the distance of the radius of the convexity.

But, whether the convexities be equal or unequal, the virtual focus, or point of divergency of the parallel rays, is determined by this rule:

As the sum of the radii of both concavities : is to the radius of either concavity :: fo is the double radius of the other concavity : to the distance of the virtual focus.

5. In concave glasses, exposed to converging rays, if the point to which the incident ray converges be distant from the glass farther than the virtual focus of parallel rays, the rule for finding the virtual focus of this ray is this:

As the difference between the distance of this point from the glass, and the distance of the virtual focus from the glass :: so is to the distance of the virtual focus :: fo is the distance of this point of convergence from the glass:

to the distance of the virtual focus of this converging ray.

6. In concave glasses, if the point to which the incident ray converges be nearer to the glass than the virtual focus of parallel rays, the rule to find where it crosses the axis is this:

As the excess of the virtual focus, more than this point of convergence :: is to the virtual focus :: so is the distance of this point of convergence from the glass:

to the distance of the point where this ray crosses the axis.

Rules for finding the focus of glasses.—To find the focus of a convex spherical glass, being of a small sphere, apply it to the end of a scale of inches, and decimal parts, and expose it before the sun; upon the scale you will have the bright interstiction of the rays measured out; or, expose it in the hole of a dark chamber; and where a white paper receives the distinct representation of distinct objects, there is the focus of the glass.

For a glass of a pretty long focus, observe some distant object through it, and recede from the glass till the eye perceives all in confusion, or the object begins to appear inverted; here the eye is in the focus.

For a plano-convex glass: make it reflect the sun against a wall; you will on the wall perceive two spots of light; one more bright within another more obscure: withdraw the glass from the wall, till the bright image is in its least dimensions; the glass is then distant from the wall about a fourth part of its focal length.

For a double convex: expose each side to the sun in like manner; and observe both the distances of the glass from the wall. The first distance is about half the radius of the convexity turned from the sun; and the second, about half the radius of the other convexity.

Thus we have the radii of the two convexities; whence the focus is found by this rule:

As the sum of the radii of both convexities :: is to the radius of either convexity :: fo is the double radius of the other convexity :: to the distance of the focus.

Focus, in Cyclopaedia, is a point wherein the rays reflected from the surface of a mirror, or speculum, and by reflection rendered convergent, do concur, or meet.

The effect of concave mirrors is to collect the rays falling on the concave surface into a focus.

The effect of convex mirrors is to disperse the rays falling on them, or render them more divergent.

For the laws of the foci of rays reflected from mirrors, or specula, see Mirrors.

The foci of concave glasses are had by reflection: for, as a concave mirror has at the distance of about half the radius of the convexity; so a concave glass, being tipped up a reflecting speculum, unitas the rays of the sun at the distance of about half the radius of the convexity.

To find the focus of all glasses geometrically.—Dr. Halley furnishes us with a general method for finding the focus of spherical glasses of all kinds, both concave and convex: exposed to any kinds of rays, either parallel,
parallel, converging, or diverging; under the following problem.

To find the focus of any parcel of rays diverging from, or converging to, a given point in the axis of a spherical lens, and incident thereon under the same angle, the ratio of the lines of refraction being given:

Suppose \( C L \) (Plate V. Optics, fig. 2.) a lens; \( P \) a point in its surface; \( V \) its pole; \( C \) the centre of the sphere where \( C \) is a segment; \( O \) the object, or point in the axis, and from which the rays do proceed; and \( O P \) a given ray; and suppose the ratio of refraction to be as \( t \) to \( s \). Then making \( C R \) to \( C O \), as \( t \) to \( s \) for the immersion of a ray; or as \( r \) to \( s \) for the emission (i.e., as the lines of the angles in the medium which the ray enters, to the corresponding lines in the medium out of which it comes), and drawing \( C R \) from \( C \) towards \( O \), the point \( R \) will be the same for all the rays of the point \( O \). Lastly, drawing the radius \( D C \), if need be, continued; with the centre \( R \), and distance \( O P \), strike a piece of an arc, intersecting \( PC \) in \( Q \). The line \( QR \), being drawn, shall be parallel to the reflected ray; and \( P \), being made parallel thereto, shall intersect the axis in the point \( F \); the focus sought.

Or, make it, as \( CQ : CP : CR : CF \); then will \( CF \) be the distance of the focus from the centre of the sphere.

This author gives a demonstration of the method; and adds various figures, exhibiting the various cases of rays either diverging or converging as they enter, or emerge out of, the surface either of a convex or concave lens.

From this principle all the rules for the foci of rays parallel to the axis, as likewise for the principal focus where the rays near the axis do unite, are deduced. As,

Hence, 1. If \( OP \) be equal to \( CR \), the points \( O \) and \( C \) coincident, and the rays \( OP \), after refraction, run on parallel to the axis. 2. If the point \( Q \) fall on the same side of the axis, as is the point \( P \); then the beams after refraction do tend to, either diverging or converging, as before; but if \( Q \) fall on the other side of the axis, the diverging rays are made to converge by a convex, or the converging to diverge by a concave glass. 3. If \( OP \) do exceed \( CR \), the focus is in all cases on the same side of the glass, as is the centre of the sphere \( C \). But contrariwise if \( OP \) be less than \( CR \), the focus falls on the other side of the glass beyond the vertex \( V \). 4. An object may be so placed, that the rays next the axis of a convex glass shall have an imaginary focus transmitting diverging rays, when the more remote parts thereof shall make them converge to a real focus. 5. If \( OV \), the distance of the object from the pole or vertex of the glass, be taken instead of \( OP \), then will \( CQ \) be the difference of \( O V \) and \( CR \); and as that difference is to \( CR \), so is the radius \( CV \) to \( CR \), the distance of the principal focus from the centre of the sphere, whereof the glass is a segment. Or else as \( CP \) is to \( CR \): \( PO \) or \( RO \) is to \( PC \), the focal distance from the pole of the glass. Whence follows a general rule for the focus of all glasses; only according to Coroll. 1. if \( OV \) do exceed \( CR \), the focus is on the same side of the glass as the centre of the sphere, but if \( CR \) be greater, the focus is on the opposite side of the glass: whence it will be determined whether the focus be real or imaginary.

What has been said of one surface of the lens, is easily applicable to the other, taking \( F \) the focus for an object.

**FODDER, in Agriculture**, a term employed to signify all such substances as hay, carry, malt, &c. which are given to cattle with the view of feeding and keeping them. These substances, when blended together, are in some districts particularly called fodder. In the giving of fodder to all sorts of animals, care should be taken that the same be not given at one time: and that it be well cut into cakes or cribbs, which should be sufficient in quantity for the quantity of cattle. Where these points are not properly attended to, there must be great loss, not only by the fodder being littered about the yard, but from many of the more work cattle not getting the quantity of food that may be necessary for their support. In respect to racks, these of the fl axing and balest kinds are best for foddering, if made strong enough, that is, to as not to be overturned; for these racks may be lifted up as the dung rises in the yard, which those fixed in the ground cannot be.

It may be observed that open wintert make hay lay the deer, if a hard frost and snow happen to come at the beginning of them: for if once cattle come to fodder they will be held to it, or they will receive great damage. In wet or wolly weather, all the hay that can be given to cattle will not make them thrive so well as in such as is dry and frosty. Hence sheds are highly useful, in order to shelter them in such cases.

At the beginning of winter, as the latter end of October and great part of November, while cattle still continue out in the field at grass, it is very necessary to fodder them early in the morning, while the hoar-frost hangs on the grass, which they will not eat kindly off till the sun has warmed it, and dissolved the hoary matter that hangs upon it.

It is a practice in many places to tie cattle up to racks to fodder. This may be done with great advantage with cows, where the fodder is good as hay, or very good straw; but with young cattle, or such as have straw fodder only, it is unseasonable. And as cattle eat their fodder when fresh threshed much better than when it has been threshed two or three days, especially if the straw be but indifferent; it is proper that this should be attended to by the careful farmer.

As it is well known in general that little dependence can be placed on feeding cattle out of the foddering yard to grass before the middle of May, the farmer ought always to be well provided with winter-fodder, for his cows and young flocks, for this and the preceding months, as he will otherwise be in great difficulty, and run much risk in his flock.

In regard to the economy of cattle-buildings, it may be observed, that to have several divisions over and above what is continually used in the foddering yards or back sheds, or other out-houses, has great conveniences in it; one of which is, that in them the farmer can dispose of and separate his two-yearling cows, or other cattle, at the time of bulking, not only to keep down the bull, but from the other heifers, that would be keeping the bull, whereby they may hurt each other, &c. especially as cows forward with calf are apt to warp by keeping bulking cows. It may therefore, in many cases, prevent much injury to such sorts of live-stock.

**FODDER, in Agriculture**, a sort of fodder formed by cutting, mixing together, and compressing, by means of proper machinery, various sorts of coarse substances, such as the hulls of peas, beans, potatoes, and various other vegetables, as well as clover, hay, straw, &c., to as to make them come into a narrow compass. The utility and advantages of this sort of fodder have been shown by Mr. Lawton.
a sudden cold is induced by a change of wind; the air then is cold, next to it the land, and last the water, which is but slowly reduced in temperature, for the reason just mentioned. But the water being comparatively warm, will, from that circumstance, be diffused to give out a quantity of steam, which rising into the cold air, is immediately condensed into fog, and wafted along the earth's surface by the stream of air. Hence arise the fogs which mariners often find in approaching land in fair weather, and which are so common in London and other places where the tide penetrates inland. The writer of this article lived some years near a river of 30 or 40 yards in breadth; on certain evenings in summer, after sunset, a dense fog was found to accompany the course of the river; it was observed that this phenomenon never occurred but when the temperature of the water was at least 10 above that of the air, and that it almost always occurred when a difference of temperature to that amount took place; but it is likely that a less difference of temperature would have been sufficient if the river had been broader. Some philosophers, particularly Sauvage, maintain that fogs and clouds consist of water in a vesicular state; or that the molecules are surronded with films of water; this opinion seems to require further confirmation. The effect of fogs in apparently magnifying distant objects is notorious; it is an optical deception: the fog diminishes the brightness of objects, and consequently suggests a greater distance; but when the visual angle remains the same, the greater the distance the greater is the magnitude; hence objects at a moderate distance appear to be magnified. See Cloud, Evaporation, &c.

Fog, or Fogg, in Rural Economy, is a term that properly signifies the fine soft grais that immediately spring mass after the hay crop has been taken from the ground; but which is sometimes used for the long grass remaining in the pastures of the winter season. See After-Grass.

FOGARAS, in Geography, a town of Transylvania, on the Alanta, the see of a Greek bishop; 18 miles W. of Kronstadt. N. lat. 46°. E. long. 24° 34'.

FOGBARRY, a town of Bengal, on the borders of Botanic.

FOGELN, a small island on the W. side of the gulf of Bothnia. N. lat. 60° 38'. E. long. 17° 44'.

FOGAGE, a term applied to coarse or rank grasses not eaten down in the summer or autumnal season by any sort of live stock. The practice of fogging grases hinders for the winter support of stock has, it is said, been found highly useful in different situations. See Grass-Land.

FOGGI, in Geography, a town on the E. coast of the island of Bouro. N. lat. 3° 28'. E. long. 126° 24'.

FOGGIA, in Geography, a town in the P. of the island of Puglia. N. lat. 41° 25'. E. long. 15° 38'.

FOGIA. See Fochia.

FOGGING, a term made use of to signify a particular practice in the management of grass-lands, which has been chiefly confined to South Wales, and some districts in its vicinity. It is said by Mr. Young to consist in keeping the whole growth of the grass, in meadows of the upland kind, free from both the sedge and live flock during the summer and autumn, and eating it off in the winter. It is added that he many years ago knew a Suffolk clergyman who was in the regular habit of this singular practice, and who spoke of it as a most profitable one. He farther states that he has himself tried it three times, and found it useful with success. It is found that it thickens the herbage greatly, and yields far more valuable winter and spring food than any person would expect who never tried it. But it is suggested that it should only be practised on dry land, or such as is in a tolerably dry state.

The advantages of this system of grass husbandry have not however been shewn by any correct statements; and it must be evident that considerable lots must be fenced in such a full body of grass remaining upon the ground for such a long time of his.

FOGGY ISLAND, in Geography, an island so called by Beering in the N. Pacific ocean, near the west coast of America, about nine leagues in compass. N. lat. 56° 10'. E. long. 202° 45'.

FOGGY, Cape, the north-west extreme point of the above-mentioned island. N. lat. 36° 31'. E. long. 202° 46'.

FOGLIANESE, a river of Urbino, which runs into the Adriatic, at Pefaro.

FOGLIANO, a town of Naples, in Principato Ultra; 7 miles W. of Benevento.

FOGLIETTA,
FOGLIETTA, Uberto, in Biography, was descended from an ancient and noble family in Genoa. He was born in the year 1516, and was brought up for the profession of the law, which, however, he did not pursue, but spent much of his early life in travelling from place to place, and at Rome, where he resided some time, he made himself known by several elegant treatises and observations. From some passages in the latter, he is supposed to have been in priest's orders, though there are no other facts that go to prove the circumstance. In 1559 he published his work, entitled "Della Repubblica di Genova," for which he was prosecuted, his property confiscated, and himself banished. The cause of these hard proceedings was the freedom which he exercised on the condottieri and great men of the country. He had, however, the good fortune not to be wholly deserted; he found a liberal patron in cardinal Hippolito d'Este, who received him into his house upon terms of intimate friendship, and he was likewise held in considerable estimation by several other persons of rank. To divert his solitary hours in exile, he employed himself in writing a general history of his own times, beginning from the war of the emperor Charles V. against the protestants. He was the author of many other pieces of a like famous nature; but the last was the history of his own country, of which he lived to finish twelve books, from the foundation of Genoa to the year 1527. He died in the year 1581 at the age of sixty-three. The history of Genoa was published by his brother Paul, who was himself a man of learning, and a good Italian poet.

FOGOLOE, or Fugloe, in Geography, the most easterly of the Faroe islands, towards the north. N. lat. 62° 3'.

FOGO, a small island near the east coast of Newfoundland. N. lat. 53° 2'. W. long. 54° 7' 40'.
the stone, to prevent the tin and quicksilver contained in the
socket from being shaken out by any violence. The lustre of
stones set in this manner will continue longer than when
they are set in the common way.

When colouring foils are wanted, those of copper, above
described, may be either tinged with smoke, or stained, or
painted with some pigment or other colouring substan-
tice. The colours used for this purpose may be tempered with
oil, gummed or fixed water, or varnish; for red, in imita-
tion of ruby, carmine, with a little lake used in thinflas
fize, or shell-lac varnish, or bright lake in oil, should be em-
ployed: for the garnet-red, dragon's blood, dissolved in
feed-lac varnish, may be used; and for the vinegar garnet,
orange lake, tempered with shell-lac varnish. For the ame-
thyll, lake, a town a little Prussian blue, used with oil for
blue: where the effect of sapphire is wanted, Prussian blue
in oil, and spread on the foil more or less thinly, according
to the lightness or deepness of the colour required; for
the eagle marine, common verdigris with a little Prussian
blue, tempered in shell-lac varnish, should be used; for a
full yellow, yellow lacquer; and for the lighter colour of
topazes, the bors礙 and oil itself will serve, without any
addition. For a deep green, the cr. del of verdigris, tem-
pered in shell-lac varnish; but for the emerald, a little yel-
low lacquer should be added. See Doublets. Handmaid
to the Arts, vol. ii. p. 333; &c.

FOIL, or Foyle, among Looking glass Grinders, a sheet
tin, with quicksilver, or the like, laid on the back-side of a
looking-glass, to make it reflect. See Foiliing. The
word is formed of the Latin folium, leaf.

FOILING, among Hunters, the footing and tread-
ing of deer, which remains on the grass, but fearfully vi-

ble.

FOISSEN, in Rural Economy, is a term sometimes used
to signify the natural juice or moisture of grasses, or other
herbage.

FOIST, a term used to signify a muddy sort of smell
among hay, straw, grain, and other farm products.

FOISTY, having a muddy disagreeable smell.

FOIX, in Geography, a small province of France, before
the revolution, including Donouzain and the valley of
Andorre, bounded on the N. and E. by Languedoc, on the
S. by Rouflon and the Pyrenees, and on the W. by Gas-
conye; lying between 42° 25' and 43° 20' N. lat. and be-
tween 1° 15' and 2° 40' E. long.; sixty miles from N. to S.,
and towards the southern boundary thirty miles from W. to
E., but more northward its breadth is from 15 to 20 miles.
This province is traversed by the river Arriege. It was
anciently governed by its own counts, and united to the
province of France in the year 1667. It is divided into Up-
ner and Lower; the former, being mountainous and barren,
produces wood and pasture; the latter, more level and
tolerably fertile, yields grains, fruits, and wine, and both
abound in mines, mineral waters, and natural curiosi-
ties, a town of France, formerly the capital of the
above described province, and now the principal place of
a district, in the department of the Arriege, is an
ancient small town, at the foot of the Pyrenees, on the left
bank of the Arriege, with a castle or a rock commanded
by two adjacent hills; 15 leagues S.S.E. of Toulouse.
The place contains 3,600, and the canton 13,322 inhabit-
ants, on a territory of 292 square kilometres, in 24 communes.
N. lat. 42° 58'; E. long. 1° 40'.

FO-KIEN, a small but flourishing province of China,
bounded on the N. by the province of Tche-kiang, on the
W. by that of Kiang-ni, on the S. by Quang-tong, and on
the E. by the Chinesc sea. It has few plains, but industri-

FOL

fertilizes even the mountains, which are disposed in the
form of amphitheatres, and arranged in terraces one above
another. The valleys are watered by rivers and springs,
which descend from the mountains, and which the Chinesc
husbandman contrives to distribute so as to favour the cul-
ture and growth of his rice; he raises the water even to
the summits of the mountains, and conveys it in different
directions by means of bamboo pipes. The mountains are
covered with trees fit for naval architecture, and the pro-
vince furnishes wood in abundance, precious stones, quick-
silver, iron, and tin. Tools of steel of various kinds, thongs
of silk, and cloths of surprising thinness and beauty are made
in this province. It is also laid to contain gold and silver
mines; which the inhabitants are prohibited to open in
their own behalf: the pain of death. In the bays, and on the coasts guarded by
fortresses, great quantities of fish are taken, which, being
dried and salted, are carried into the interior provinces of
the empire. This part of China acquires great opulence
from the trade which its inhabitants carry on with Japan,
the Philippines, Java, Camboya, Siam, and the island of
Formosa, and they also import from other countries aloes,
cinnamon, pepper, fandal-wood, amber, coral, and other
similar commodities. Fo-kien contains nine fous, or cities of
the first class, and sixty-then, or cities of the third class.
Its capital is Fou-teh-on-fou. Each city has its own pecu-
liar dialect; but the language of the Mandarins is spoken
every where; few in this province understand it; never-
theless, it produces a great number of literati. The climate
is hot, but the air is pure and salubrious. The number of
inhabitants, according to the estimate of Sir George Staunton,
is fifteen millions.

FOLARD, Charles, Chevalier de, in Biography, was
born at Avignon in 1669. He received the rudiments of clas-
ical learning, and by reading Caesar's Commentaries,
became exceedingly dextrous in entering the military
service of his country. His designs were at first thwarted
by his father, till at length, finding opposition of no avail,
he allowed him to follow the bent of his inclination. He
served during the war of 1688, and was made aide-de-camp
to the duke de Vendome in 1702. In these campaigns he
not only distinguished himself as a soldier, but acquir-
ed an exact knowledge of the country in which the
battles were fought, and drew maps and plans of every
thing which he saw, and which was calculated to be service-
able to him in his future pursuits. At the battle of Caffano
he was thrice wounded; and afterwards, at the battle of
Malplaquet, he was wounded and taken prisoner. In 1714
he went to Malta, in order to afflit in defending that islan-
d against the Turks. After this he visited Sweden, and was
entrusted by Charles XII. with negotiating a plan, with
the court of France, for a projected invasion of Scotland
for the restoration of King James II. This scheme having
failed he returned to Sweden, and followed the emperor to
Frederiehshall, where that heroic prince was killed by a
cannon shot. (See charles XII.) Folard served his last
campaign in 1719 under the duke of Berwick, and from
this period he devoted himself to the study of military
tactics. In 1727 he published his great work, entitled
"Commentaries on Polibius," in six volumes 40. which
was, in fact, a depositary of his military reflections and in-
ventions, and though it was not distinguished for the neatness
of its style, and was moreover defective in method and order,
yet it was highly esteemed as containing much useful matter.
Folard wrote a piece, entitled "New discoveries respecting
War," and some other treatises on military subjects. In
1749 he was elected a fellow of the Royal Society of
London, and in 1752 he died at Avignon at the age of
eighty-
eighty-three. He was a man of great worth and integrity, and was entrusted during the last forty years of his life with the government of Bourbourg; he would probably have risen to much higher honours and more important duties in the state, had he not been a zealous defender of the miracles of the Abbe Paris, which gave offence to cardinal Fleury. A more elaborate account has been given of this distinguished soldier in a work entitled "Memoires pour servir à l'Histoire de M. le Chevalier de Polard." Moreni.

FOLD, in Rural Economy, a small inclosed space formed for confining any fort of live flock, &c. Folds are of several different kinds, according to the objects they have in view; and are essential in many cases where a number of animals are to be kept. See Farm-yard.

Fold Garth, the old term employed to signify a farm-yard or inclosed place in which cattle are confined. See Farm-yard.

Fold-net, among Sportmen, a sort of net with which small birds are taken in the night: there are two sizes of it; the least may be managed by one man, but the largest must be carried by two, and used thus: let the net be fixed on both sides to two strong poles about twelve feet long, each man holding one of them; let a third carry lights behind them, at the distance of two yards: the net should be carried between the wind and the birds, which roost on their perches with their breasts against the wind: another person who beats the bushes on the other side of the hedge, will drive out the birds towards the light.

Fold-fence, in Law. See FALDGE.

Fold-yard, in Rural Economy, the yard where cattle of different sorts are confined and fed during the winter season. Yards of this nature should be properly fitted up with convenient sheds and racks for the animals to eat their fodder from, and have suitable divisions for containing different denominations of cattle, or other live flock. See Farm-yard.

Fold, Sheep, the yard or inclosure in which sheep are confined during the nights in the winter months. Yards of this kind are not by any means so common as their great advantages and utility would seem to demand. They are capable of being made the means of raising great quantities of excellent manure, at the same time that they contribute greatly to the health and preservation of the sheep. These folds are of two kinds, as erections of the house or shed fort constructed for the purpose adjoining to the farm-yards, or such as are moveable and formed by art by means of hurdles in the field. In the former, which is still the common practice in Flanders, &c., the floors of the sheds or houses are occasionally covered with straw, sand, or other light dry earthy matters, by which a large quantity of valuable manure is obtained; which, when applied to cold wetish foils, is highly advantageous in producing abundant crops. It is observed, however, by the author of Modern Agriculture, that, since a spirit for inclosing, planting, and improvements in general has been introduced, the original breeds of sheep have been banished to the mountainous districts in the northern parts of the island, where cultivation has hitherto been deemed impracticable. Within these few years, indeed, some valuable breeds of sheep have been brought from the southern parts of the kingdom, but they are generally kept in gentlemen's parks, and are never penned or housed; so that he thinks the quantity of sheep dung applied to tillage lands in the ancient manner is very trifling compared to what it was formerly; that practice existing in those parts of the country only which separate the lands that are generally or closely cultivated from the mountainous districts, where sheep-hut

bandry, on a large scale, and under a regular system, is established and kept up.

Moveable houses have been found in many districts extremely beneficinal in the management of sheep. See Sheep-house.

The farmers of Hertfordshire, as stated in the agricultural account of that county, find much advantage from the raising of manure in these forts of folds. At the Grove the earl of Clarendon is said to have a yard that contains good room for three hundred sheep, the number which is usually kept in it. It is surrounded by an open shed, except on one side, where a barn is the fence; the outside of the shed is formed of wattled hurdle-work, without straw or other materials, for coals, left a greater cloths should make the yard too hot. The whole is kept well littered with stubble, and yields from the above number of sheep eighty large cart-loads of manure. And the system is found to agree perfectly well with the sheep, keeping them more healthy than when they were kept in the fields in the common manner. His lordship has likewise another yard for lambing, which has also a shed connected with it. Mr. Bevan of Norfolk is stated by Mr. Young to have been attentive to this useful practice so early as the year 1792, having then a yard well fenced in for a standing fold, in sight of the shepherd's windows, calculated for littering and folding in bad weather. And that in 1822 he found him continuing the practice, and to be well perfused of the great advantage of it; he indeed considers it now as indispensable, and intends in future to have his flock in for yearning, whether the season be good or bad; having constantly fifteen or twenty loads of hay stacked up in it, for the sheep to help themselves at: he is said to find this not attended with any waste. It is difficult, however, to conceive that a number of sheep can continue pulling hay from a large flack daily, without trampling much of it under their feet, and in that way causing waste of the fodder. It is a much better method to have the hay pressed tightly into racks formed for the purpose with the slates near together, and placed upon low wheels so as to be conveniently moved.

In various other districts of the kingdom, the system of folding sheep in covered folds constructed for the purpose, has been found a highly beneficinal method by those individuals who have had recourse to it; and where it is well followed up during the months of November, December, January, February, March and April, with a sufficient supply of litter, a dung heap of at least from sixty to seventy loads of very good fluff, may be produced from not more than a hundred sheep; which will be capable of manuring two acres of land in a very perfect manner. But the same number of sheep, when folded in the field, where the grass land is even dry enough for the purpose, will not in the same time manure an equal degree much more than one acre of ground. This fully shows the great superiority of the yard method over that of the field.

The latter method, which is now the most common, is to pen or fold the sheep themselves upon the land, which on dry friable soils in particular is found to produce beneficinal effects. They are sometimes, however, folded on old pastures, but more frequently on lands in tillage, especially on fallows, as a preparation for a succeeding crop of wheat, and on light soils, by way of top dress ing after the grain is torn, or on fields of turnips. This last method is most generally adapted in the inclosed and belt improved districts of the kingdom. The hurdles or rails which form the fold are commonly about four feet six inches long, and three feet six inches high, made for the most part of either hazel or willow. About fourteen or fifteen dozen of hurdles are
sufficient to include a statute acre. They are tied to stakes fixed in the ground at regular distances, with small branches of trees twisted when green for the purpose. An acre is considered as a space sufficient for folding from twelve to thirteen hundred sheep. The sheep should never be allowed to lie above one night on the same spot of ground, and not more than twelve to fifteen upon any one patch of land. By thus connecting sheep-influently with the improvement of arable land, much may in many cases be effected, especially upon the more dry and light soils of that soil which is capable of being carried to the greatest extent, and where the quantity of grafs land either in common or otherwise is also considerable.

FOLDE and FOLK-COURSE. See FOLDAE.

FOLDEKEID, in Geography, a town of Norway, in the diocese of Drontheim; 114 miles N.B. of Drontheim.

FOLDING DOORS, in Architects, are those that are made in two parts, each part hung to each jam, and their vertical edges meet each other, lapping the rebates together when the door is shut. See article DOORS.

FOLDING SHEEP, the practice of confining them upon arable or other lands, by hurdles or other means, so as to ameliorate and improve them. This is a method that is much referred to by all open-field farmers as a preparation for wheat, and their chief dependence is upon this species of top-dressing, where the quantity of farm-yard dung is insufficient for or three hundred will trample an acre of land daily. By that connecting sheep-influently with the improvement of arable land, much may in many cases be effected, especially upon the more dry and light soils of that soil which is capable of being carried to the greatest extent, and where the quantity of grafs land either in common or otherwise is also considerable.

Methods of folding.—Mr. Young has observed on this practice, that a very great change has lately taken place in it on inclosed farms, especially with the best farmers in the county of Norfolk. They are now, he affirms, fully convinced that it is an unprofitable system of management, except where the openfields of down and common fields renders it necessary for the purpose of confined. It is contended, that the number of sheep that may be kept on a farm without folding, is much greater than that which can be supported with it. This is a most effectual point; and there is a deduction from the farmer's profit in the injury done to both crops and lambs by folding, which is liable to have been estimated by the most experienced judges, at from 2s. 6d. to 4s. per ewe; so that a farmer should consider well before he determines to follow this practice, which, as the farmers and agriculturists more and more are in favour of, is pronounced unprofitable. Mr. Bakewell considered it as lofty above. And the arguments now urged in its defence are not, it is contended, satisfactory; it is maintained, that if sheep be not folded they will draw under the hedges and other places for shelter in bad weather; so that they ought to be allowed to do it, for more would be lost in such cafs by forcing the sheep from shelter, than the value of their fold. Where this practice takes place, good sheep herds will, in case of rain, get up in the night and let their flocks out of the fold, knowing the consequence of confinement on arable land in wet weather. The instinct of these animals will, it is supposed, conduct them much better than our reason, not only where to fly for shelter, but also for choosing their own time to go to rest, and to feed in the morning. Those they vary according to seasons and weather; but folding prevents it, and forces them to a regularity never called for by the weather, nor perhaps the economy of the animals. It is added, that when he began with to entertain doubts of the propriety of folding sheep, on any farms, in which they can be kept to certain fold, in the night without that practice, he earnestly desired to try
try some experiments that might throw more light upon
the question than it was possible for reason to do; but to
effect this comparatively was very difficult, as the trial
which he has made may not be found deli-
tute of power to throw some light on this interesting
question. The writer is perfectly persuaded that it would
have been impossible for him to have kept on the same land
nearly such a flock in one parcel with folding. It is
not supposed that the fields would have carried three-fourths
managed. Four driving in a day make them trample
much food, disquiet the sheep, and transfer the choice
of their hours of feeding and rest from themselves to the shep-
and his boy. While lambs are young they are injured
by this, and the ewes are liable to be hurried and heated;
all which are objects that should weigh in the question.
When sheep are kept in numerous parcels, it is not only
driving to and from fold that affects them, but it is affected,
that they are in fact driving about in a fort of march all day
long, when the strongest have too great an advantage, and
the flock divides into the head and the tail of it, by which
means one part of the sheep must trample the food to be
eaten by the other. All this, it is conceived, points the
very reverie of their remaining perfectly quiet in small
parcels.
It is, however, supposed, that the question chiefly turns
on the benefit to be reaped by the fold; for if that be great
enough to compensate for the loss by such circumstances,
the practice may not be condemned. It is conceived that
the reason why farmers are such warm advocates for folding,
arises from the power it gives them of sacrificing the grazs
lands of a farm to the arable part of it. Their object is
corn, by which they can carry off a farm whatever improve-
ment they bring to it. Grazs improved is profit to the
landlord in future, and tenants are too apt to think that this
is done at their expense. They do not at all regard im-
poverishing a grafs field in order to improve a ploughed one;
and it need not be observed, that every fort of sheep-walk is
thus impoverished: so that ancient walks which have
been sheep-pastured perhaps for five centuries, are no better
at present than they were before; whereas most fields sheeps-
, fed, without folding from them, are in a constant state of
amelioration; this, it is said, leads him to remark the
effects he observed on several of his own fields. He care-
fully attended, during the course of a summer, many par-
tlemen over the fields, with a view to examine whether the
sheep had seemed to have relod only on spots to the too
great manuring of such, or on the contrary, to have dis-
tributed themselves more equally: and it was a pleasure to
find, that they seemed generally to have spread in every
part, if not quite equally, at least nearly so. The further
circumstance of several old leys fed in the same manner, when
examined in autumn, convinced him, as well as his bailiff,
that the ground had been unquestionably considerably
improved. Those fields had carried a very bad appearance
for some years, but they were, after sheeping, of a
rich verdure, and as full of worm-calls as if they had been
drugged. They were heavily rolled in November, but they
soon became rough again by worms, and demanded much
rolling in the spring. And they had afterwards a greener
and more fertile appearance by far than ever they were
before. It is added, that the whole of this circumstance
is the value of which he thought it quite to appreciate in the trials
of future years, belongs to this method of dividing flocks,
to the exclusion of folding. The fold is valuable, but so
is the improvement of the grafs land, and may, for what he
knows, nearly equal it when in addition however, the
greater number of sheep that can be kept is included, and
the favour done to them by letting them alone, there re-
ains in his mind no further doubt of the fact. It is re-
marked as common to hear flock-farmers in open countries
say, they have not the power to manage so. This may be
very true, it is supposed, upon the major part of the farms,
but such have often many inclosures in which this manage-
ment might be applied without difficulty. But supposing
folding to be the only form pursued, it may be remarked that
the farmers in those parts of the kingdom which under-
stand it best do not extend it so far as they might: they
give over folding in November or December, whereas it
may certainly be carried on through the whole winter with
profit; even supposing that the practice is necessary. On
those farms which have a perfectly dry gravelly pasture or
two, it is advisable to fold all winter on such dry grafs
land. It must not be attempted on most arable land, nor
on moit frag land, but on dry pastures. The safety to the
sheep is greater and the benefit to the grafs an object.
And it is stated that there is another method of gaining
all the benefit of folding quite through the winter, and on
all soils, which is that of confining the sheep in the night in
proper yards, well and regularly littered with straw, bubble;
or by which means a flock is kept warm and healthy
in bad seasons, and, at the same time, a surprising quantity
of dung raised: so great a quantity, if there be plenty of
litter, that the profit will be better than by folding on the
land. And a great improvement in this method would be
giving the sheep all their food, except their pasture, in four
yards, as hay, turnips, &c. for which purpose they may
be brought up, not only at night, but also at noon, to be
baited; but if their pasture be at a distance, they should
then, instead of baiting at noon, come to the yards earlier
in the evening, and go out later in the morning. This is
a practice which cannot be too much commended; for to
warm a lodging is a great matter to young lambs, and will
tend much to forward their growth; the sheep will also be
kept in good health; and, what is a point of confec-
tion to all farms, the quantity of dung raised will be very great,
as has been already shewn.
It has been remarked by the author of the Synopsis of
Husbandry, that the horned or well-country sheep are to be
preferred by the farmer, whose chief intention in main-
taining a flock is to improve and fertilize his arable land;
and that in this respect the sheep forms a very material part
of the husbandman's riches: for to so high a degree may
land be improved by a proper management of these animals,
that, with respect to light soils especially, it is, he con-
tends, scarcely an hyperbole to affirm, that wherever a
sheep hath set its foot, some benefit hath accrued to the
owner. The virtues of the fold are well known; besides
which, the keeping of corn close trodden in the spring, and
thereby counteracting the ill effects of the worm, is a mat-
er of such material import to the reoter of these soils, as to
be sufficient inducement to this practice. These facts are
universally known and acknowledged, that in Hereford-
shire, where every farmer is in a greater or less degree a
maintainer of sheep, it is, he affirms, an established max-
im to diee the gold or ill success of a tenant from the extent
of his fold. While the flock is kept up to its original
number, and the state of fat sheep replaced by an equal tale
of lean sheep, the owner is supposed to be in thriving and
prosperous circumstances. On the contrary, when the
flock is fold off without being renovated by a fresh supply,
the state of such a renter is anticipated by his neighbours,
and too often verifies the truth of their predictions, by a
rapid
FOLDING.

A rapid declension towards bankruptcy and ruin. Such being the state of the case, it may be no unprofitable inquiry, to trace out the several different modes of conducting this busines. There are several ways of conducting this economical plan on an arable farm: first, by the maintenance of a folding flock; and this is either of ewes or wethers. In the former instance, the lambs are reared on the farm and reared for the purpose of keeping up the flock, as the old ewes become fit for the butcher. In the latter, a proportionable number of male wethers must be yearly purchased, to make up the deficiency of those which are fattened, or sold to the feeding graziier for that purpose. But if the farm is not sufficiently extensive to admit of the practice of folding, or the local situation be such as to decide in preference of a feeding flock, the turnips and fow graffes may be appropriated towards the purpose of fattening wethers, or the raising lambs for the butcher, either in pens or in the field; the one distinguished by the name of house, and the other by that of grafs lamb. Whichever of these methods is pursued, it is obvious that a proportionable quantity of ground must be yearly allotted for turnips, tares, ryes, clover, &c.; without which it would be a vain attempt to fix about the maintaining a flock of sheep. But since it is generally in the option of the farmer, with proper management, to raise a quantity of food equal to the support of his sheep, we will suppose that these matters have been properly attended to, the lambs proceed to enhance on each of the methods above enumerated. And first, of an ewe flock kept for the purpose of folding. In order to conduct this plan of husbandry to advantage, a large tract of ground seems to be required. In farms where a due proportion of pasture is united with the arable land, and those pastures lie contiguous to the uplands, to wean lambs for the purpose of folding is a very judicious method. But where there is neither meadow nor pasture land attached to the farm, the busines of an ewe-fold cannot be so conveniently practiced. On many farms in the neighbourhood of Gravesend, in Kent, this plan is observed to be very advantageously prosecuted, from the circumstance of each of these farms having a quantity of marsh land annexed to it, at the rate of fifty acres of marsh to one hundred and fifty of the arable. The method which these farmers pursue is to buy in a number of ewes, equal to the size of their farms. If this purchase is made at the Michaelmas fairs, the ewes are then pregnant; if they be bought at the spring markets, they probably have lambs by their fides, which may go to fold with their dams; the ewes proceed to enlarge the ram in each of the methods above enumerated. In order to obtain lambs at a proper season, let the rams be turned among the flock in October, at the rate of one ram to fifty ewes. Here they are to remain for a month, by which time the greatest part of the flock will be in pregnant; and to ascertain this fact, it is a custom with many people to bemear the fore bows of the ram with tar and oche, which easily leads to a discovery. The breeding ewes may continue to go to fold every night, till towards the third month of gestation. But it is to be observed, that in folding either ewes or wethers, but more especially the former, a field of turnips should be provided near the close where they are to lodge in the winter nights, that the flock may not have too long a drift; for these animals are but forry travellers at best; and in the winter time, when the roads are become deep and miry, and the ewes begin to be heavy in lamb, a long drift would be highly prejudicial to them. Where such a turnip field does not lie handy to the fallow, it will be improper to prosecute this busines with an ewe flock, after the wheat has been down in November. When the folding is discontinued, the ewes should be driven into a pasture, where they may be quiet and undisturbed, and be often visited by the owner, to watch with a careful eye any accident that may befall them; for sheep, at all times an helpless race, are liable to a variety of misfortunes in the time of gestation, peculiar to that condition. Towards the latter end of February, the ewes will be come time their time for lambing, and should then be removed from the marshes or low pastures, and driven into the turnip field, or turned on a piece of dry upland pasture. If the farm hath produced a quantity of turnips sufficient to fatten the wethers, a portion of which will be yearly turned out of the fold, in this mode of conducting busines, the ewes, for four or five weeks previous to the time of lambing, may be lodged on that part which the fattening sheep have gone over, where they will find an ample sufficiency from the shells which were left by their predecessors; as these females do not require to fill an allowance of meat as will be necessary for them after they shall have yeaned; and too great a plenty would be very detrimental to them. But this is to be observed, that proper care should be taken to prevent the wethers from breaking into the part defined for the ewes, which at this period require the most diligent attendance from the shepherd, not only to watch the disorders and accidents which may befall them, but to maintain the fences in good repair, and to see that the hurdles are kept tight in the ground; and to prevent the wethers from drifting, both of which would be apt to seize the lambs as they fall.

Summer folding.—This should commence early in the spring season, as soon as the lambs are in a state fit for it. The lambing season generally commences about the first week in March, when the shepherd will find ample scope to exert his skill and diligence. As the weather at this season of the year is generally unsettled, and the cold often more severe than in any former part of the winter, the lambs, as well as ewes, frequently perish through the inclemency of the season. As the ewes have lambed down, it will be proper to remove them, with their lambs, into a piece of turnips, fenced off for the purpose, where they may neither be annoyed by the lambing ewes, the fatting wethers, or the flore sheep, if there are any in the same field; and which, as has before been observed, should be kept separate from the ewes. In this field, with the daily allowance of a small portion of turnips, the ewes will continue to yield abundance of milk; and, in consequence of that, the lambs will grow fat, especially if the weather shall prove warm and sunny. When the lambs become ten days or a fortnight old, the hurdles should be placed in such a manner as to leave a vacancy at bottom, in different parts of the drift, where the lambs may creep through, and take their range among the standing turnips. By this management they will enjoy a free air, and a licence to nibble on the turnip tops; but which circumstances will greatly contribute towards their future growth. When the sheep and lambs shew by their bleating and meaneats that they require a change of food, which they will pine after when the turnips have advanced far in growth, and the drifts are become fatlefs, and the bottoms void of nourishment, they should no longer be confined on the turnip field. In forward springs, the turnips will be found to be of little use for couples (sheep and lambs) after the middle of April, at which time the lambs will be fit weeks old; let them, therefore, be removed out of the turnip field, and driven on the rye, a few acres of which should, in every autumn, be turned on farms where there is maintained a large flock of sheep. Indeed the rye often affords a good bive early in the month of February, in which case the
the blade should be eaten down, and a second crop will have sprung up at the time he is now speaking of. Let this rye be parted into divisions of two or three acres each; observing the same caution, with respect to the openings at the foot of the hurdles, as was mentioned in the feeding of the turnips. In very backward springs, it frequently happens that the turnips are all eaten off, as well as the first bite of rye, before the grass has made an effort to shoot, and the farmer is under the necessity of turning his couples into the marshes by the latter end of March. In order to be provided with a remedy against this untoward event, it is a prudent measure to lay in a piece of grass in the autumn, wherein there is a large quantity of old hay, and to suffer it to be flocked during the winter; by this regulation, the young grass will shoot much earlier in the spring among this old straw, than in those marshes that have been taken off more closely by the scythe, or depasturing, and will, in all probability afford an early bite for the ewes and lambs, when the winter feed of the uplands shall be exhausted; and as a shift of wind and change of weather may shortly be expected, this will cause the rye to send forth a fresh shoot, and furnish a variety in the pasture, which, with occasional shifting into the marshes, and perhaps on a piece of forward wheat, will generally lengthen out a supply of food for the couples, and maintain them in tolerably good heart, even in those springs which are the most backward, till the winter tares become fit for their reception. In a kindly time, the grass in the marshes will have attained to a decent length, so as to afford a good bite for the sheep by the last week in April, to which time the turnips and rye will have been competent to the maintenance of the ewes and lambs. Towards the latter end of April, or beginning of May, or perhaps the middle of that month, as the season has been more or less favourable, the winter tares will have got to a sufficient height for feeding. Those who have been accustomed to this mode of husbandry will easily conceive the necessity of suffering the tares to grow to the period when they shall be nearly fit for the scythe, before they are fed off; namely, that at this time they yield the greatest and most lasting quantity of pasture. To this end, the field should be parted with hurdles according to its size, and the number of sheep to be grazed thereon: and let the ewes and lambs be brought out of the marsh when their bellies are full, and driven into the tares; observing that this be not done at a time when there is any moisture hanging on the haulm, either from dew or rain; for, as the pasture arising from their pulse is exceedingly succulent, the sheep would run great hazard in feeding on it when replete with moisture, as he has more than once experienced to his cost: this animal, like all others of the ruminating tribe, being very subject to a disorder from repletion, termed brugia, and on this account, likewise, the folding flock, when first driven on the tares, ought to go thither with full bellies, to prevent their feeding on them with too great eagerness and avidity. At this time, the lambs will have gained sufficient strength to a degree of being folded with their dams, if it should be found necessary to the farmer's occasions to pursue this method. But in this case, it is to be supposed that the field which is to have this dressing be at so great distance removed from the clow of tares; otherwise the drift will prove highly prejudicial both to the ewes and lambs. The summer fold is generally pitched on a fallow, intended to be sown with turnips in the course of the season; and this business usually commences in May. A fold for three hundred ewes and lambs may be made to include eight rods of ground; and if the turndale shall not seem to be dropt sufficiently thick from one night's drifting, the sheep may lie a second night in the same place, rather than incur the hazard of injuring the health of the couples by confining them in too narrow a compass. The time when the sheep and lambs should go to fold is about eight o'clock in the evening, and to be released at five in the morning. Such wether lambs as are intended to be fattened, or double couples, where the ewes do not give a quantity of milk equal to the demand of the lambs, or any others which may be observed to sink in flesh, may, with their dams, be taken out of the fold, and maintained in a separate pasture, where the grass has attained a sufficient head; and such of the folding ewes as appear to be weakly, or dil tempered, may, from time to time, be removed to the same pastures above mentioned, and suffered to lie in quiet, till they are judged able to return again to the fold.

It is added, that as it is likely that there will be some dry sheep in the farm, confining of the two yearling wethers and tags, these are to be kept on more ordinary pasture than the ewes and lambs; and as they have hitherto followed them in the turnips, so they must likewise succeed them on the clover and tares. The couples are to be allowed the first bite, and the dry sheep are then to be turned into the field. In the marshes likewise the same method should be taken, of referring the more forward growths for this part of the folding flock: by such management there will be two folds at work in the same instant, and the shepherd will find ample employment throughout the day.

After the tares are eaten off, the clovers and trestail will be ready to receive the flock, and here the sheep and lambs are to precede the dry flock; and the fields, if extensive, should be parted with hurdles, that the sheep may not flanue the whole piece before they have eaten half the field, which would ineffectually be the consequence if they were permitted to range over a large elose; for it is the nature of this animal, when turned at first into a field, to take a range over the whole superficies before it will settle on its feed. It follows, therefore, that a division of large pastures will lengthen out their abode in them; small inclosures do not require it, which, by the bye, shows the advantage of these contracted pieces over those of wider extent; for in such small fields the sheep lie much warmer in the winter, and a considerable expense is saved in hurdles, which in great fields are required in great abundance, besides the labour of setting them, and the necessary delay of time when the last must be taken off from other work to draw them and to. As the result, small fields, to a farmer who places much dependence on his flock, are far more commodious than large ones; but for corn the preference is to be given to those of wider domain. A good shepherd will be careful that his flock be driven late to fold in an evening, and released early in the morning from their confinement, in order that they may enjoy the coldest parts of the day on the feed. He will be cautious that they are allowed a sufficient time to graze in the uplands previous to their being driven into the fold, that they may retire to rest with their bellies full, by which the quantity of dung and manure will be considerably augmented. He will likewise be careful in reviewing the hurdles, and provide that there are fixed tight in the ground; lest by any accident they should be thrown down during the night, and the flock by these means get into catchet or internes with other sheep; he will count his sheep regularly every evening when he drives them to fold, and take a fresh count in the morning when he turns them to their feed; he will, previous to dismissing them from the fold, warn them gently round the same, in order to cause them to dung and stale plentifully, that the nature may be left in the fete, other-
wife the greatest part of the trundles will be dropt on the road, or carried on to the marth, where, lying thin, this drefling can do but little service, and where it is not wanted in any degree.

After the flock have been flour, as they are very tender for some time, it will be adviseable to keep the flock, out of the fold for a week, and, during that time, not to turn them on any pasture where there are thistles or other annoyances. If the weather should prove hot and dry at this feafon of the year, the natural graffes and clovers are generally flour, and the farmer is at a lofs for a baiting-place whereon to turn his flock previous to their going into the fold, unless he hath had the foresight to raise a piece of spring farres for this ufe. At this time, likewise, the fold, ground works like ahes, and, by the heat of the sun, a great part of the invigurating juices arising from the dung and urine of the sheep is evaporated, fo that it may be well questioned whether it be productive of any material advantage to fold the sheep at this feafon. That the sheep are greatly injured from being folded under these circumstances, especially if their drift is at any distance, with the interruption of a daily turnpike-road, for a quarter of a mile or more between the marth and the fold, as is frequently the cafe, he is fully convinced; it would, therefore, perhaps, be a great advantage to keep the flock out of the fold till the rains about Midsummer, when a day's work may be ploughed, on a lay intended to be sown with wheat in November, and the fold immediately let on that part, and so to proceed on the ploughed ground; and thus the folded surface, although the sun should still continue hot, and quicken exhale the moisure of the dung and urine, will nevertheless enjoy an exclusive benefit of being clofly prifled by the tread of the sheep, which will prove of infinite service, and which could have been of no ufe on the turnip fold, where the fold had hitherto been let. After weaning the lambs, by continuing the fold at work on the hay in the manner before noted till November, a fack of two or three hundred sheep will have drefsed a considerable breadth of new lay ground, and the wheat may then be harrowed in. But now commences a method of folding, which is of more importance than any which has preceded it. This is, to fold on the wheat when fown, the method of which is as follows: first, low a day's work on a lay that has been ploughed over fince the Midsummer rains, and when the land is fit to be fold, and let the fold fill the fold, and let the fold flow; and fo continue every night till the whole is completed, unless there should fall so heavy a glut of rain as to make it unavoidable to lodge the fold on the damp ground; otherwise there will be no fear of treading the fold too close after fowing; for on light fows, a firm furface is absolutely neceffary towards the future welfare of a wheat crop, especially when this grain is fown on hay, which, if not well trodden, is subject to be much eaten by the worm; but there need be no doubt of the corn forcing its blade through the hardened furface, although from its appearance a perfon unacquainted with this bufiness would deem it impracticable. When the fold shall have gone over this firft drift, let another day's work be ploughed, fown, and harrowed in, and the fold continue to run over the fame in like manner as before directed, and fo proceed till the wheat feafon is finished, and the corn begins to germinate, when it will be proper to difcontinue this practice as quickly as possible, as injury would be done to the crop.

Winter folding.—At this period the fold may commence their winter folding, the manner of which is thus explained. And if it is supposed that the farmer has taken care to provide a due allowance of meat for his fold on the uplands, as likewife a fufficient flock of hay or pea-feaf for them to browse on whilst in the fold, during the long brumal nights; for at this feafon they will require some influence in the night, which at the summer folding was not neceffary to be given to them. Let the fold be then pitched on a tufted, intended to be ploughed up in the spring for a fallo, and let it be made considerably larger than the summer folds. A flock of three hundred fold ought not to be limited to a fpace of ground than forty rods, which is a quarter of an acre, in which there ought to be placed a fufficient number of ranks, filled with hay or pea-feaf; and in this fold they may lie two or three nights, at the option of the owner. Whilst the weather continues mild and open, and is not attended with too considerable a proportion of moisture, the fold may run in the marths during the daytime, and be bailed in the uplands, on a piece of young clover or other succulent fowd towards the evening, previoufly to their going into the fold; but when the weather becomes cold and wet, with a few winds, they must now longer be driven into the marth, but be maintained altogether on the fold, and there fold out during the cold nights; and if it does not put the farmer to apportion any of his winter fowd for his folding fold, the bufineses must be altogether relinquished, since it would be highly improper that the fold should have so long a drift in the depth of winter. Whilst the bufineses of the fold is going forward on the tufted, in the night, as before mentioned, the fold may be employed during the day in treading the wheat, a practice of great utility both in the autumn and spring, and which in some degree answers the end of the fold, to part of the land which had not partaken of this advantage. In the winter folding the lambs ought not to share in any degree, though they are sometimes penned in the fold with the fold after weaning-time. Towards Christmas, it will be proper to difcontinue the fold fold entirely, as the ewes then get heavy in lamb, and might be greatly injured through a longer continuance of this practice. At this time, therefore, the breeding ewes should be turned into the marths, to lie quietly during the time of gelation; and if the folding be any longer continued, let it be with the young wethers and ewe tags, which are the least liable to injure it.

Thus the winter folding being finished, suppose the feeding wethers to be on turnips, and the lambs and young fold on the grattus, with occasional foldings on the shells of the turnips, left by the fattening fold, and the breeding ewes quietly lodged in the marths or low pasturage lands.

We now come to the method of conducting a folding flock of wethers, which is generally adopted by those farmers only who pollers not the advantage of breeding land, as from what has been mentioned on that head, and what remains to be said on this, it will appear, on a comparison, that the balance is much in favour of the breeder, where the situation of the farm will allow of the practice. But in order to maintain a folding fold where there is no marth land or natural graffes attached to the farm, it will be necessary that the arable land be sufficiently extensive to admit of raising annually a quantity of turnips, rye, oats, clover, and trifol, in proportion to the exigencies of the flock; and if the farm lies in a neighbourhood of an extensive common, the bufineses of folding may be carried on to a much greater advantage. The fold which are best adapted to this purpose are those of the large Wiltshire or Hampshire breeds. But these are not calculated for the purefane of the farmer who wishes to profit by his fold,
and afterwards to fatten his flock on turnips; since it is
great odds if he will be able to provide them with meat,
equal to maintaining them in the condition wherein he
bought them, and by consequence he must either discontinue
his fold, or be content to see his flock dwindled, and become
of less value the longer they are kept on the farm. But
where the purchase is made with a view of penning them
immediately on turnsips, to fatten for the butcher, such
large wethers may be very proper. Hampshire wethers are
somewhat less than those of Wiltshire, and either thefts,
or the inferior kind of Wiltshire, are best adapted for fold-
ing.

It is added that wethers are purchased by the husband-
man at different ages, according as the economy of his farm
directs his views. If lambs are preferred, these are to
be bought at the antumnal fairs, and will require to be
kept a twelvemonth before much benefit can be expected
from them, as the folding them at this early age, during
the winter, might prove highly prejudicial to their growth.
Four-tooth sheep, or two-yearlings, are likewise left in at
the autumn, and will come into work immediately. As to
the six-tooth, or three-yearlings, and full-mouthed-sheep,
there are rarely if ever bought with a view to keep as
flees; for being arrived at their full growth, the profit to
be expected from them, except for immediate fattening,
will not be considerable; and when sold off in the suc-
ceeding winter, the owner must again have recourse to the
like expedient of renewing his fold, which would occasion
a considerable drain of ready money, and not fully answer
his purpose. Whereas, by purchasing young flock, either
lambs or tags, the original price is lower, and the los of
those which die by caulsality will consequently be less
severely felt; besides that these sheep, having been insured
to the fold, will be found to go through their work with
greater facility, and the hazard of their dying will be
lessened in proportion to the time they have been resident
on the farm. For these reasons, the farmer who keeps a
wether flock should make purchase either of lambs or tags.
These tags, or two-tooths, are to be met with at the spring
fairs, and may be folded after having resided for a few nights
to recover themselves from the fatigues of the dust. A good
shepherd is equally useful to a person who keeps a wether
fold at work, as to the breeding farmer.

And now supposing the winter fold to commence at
Michaelmas, the sheep at this time are to be driven to and
from the fold, at the same hours as was directed for the
ewes, and when released in the morning should be turned
to graze on the common, where they are to continue till
two or three hours before the time of folding, when they
are to be brought home and bated on a piece of clover or
other paturage, where there is plenty of harvestage, that they
can enter the fold with full bellies. As the grass on the
common falls off, it will be proper to relinquish this
pasture, and take the flock into the meadow: here, as in the
walks, clover, &c., of which by proper management, there
will be always great buress remaining on farms of any
extent, where this mode of husbandry is pursued; and when
there is not a large tract of arable land, that sheep feed may
be yearly raised in abundance, it will be usefull to at-
tempt it. These pastures then, by favour of the antumnal
rains, we will suppose, have thrown out a tolerable bite of
grafs by the time the flock is taken off the common: and
from hence the sheep may be folded, till the state of the
weather renders it necessary to remove them on the turnsips,
of which the writer likewise presumes there is no deficiency.
From the turnip field they may be driven every night into
fold, till the further progress of the winter renders it ne-
essary to discontinue this business. In folding wethers, it
is prudent to take in a large compass of ground in the
winter time, as hath been before observed in speaking of the
ewe fold. Racks filled with hay and pea haulm should be
flaizing at this season within the fold. As there will be
annually a number of the full-mouthed sheep drafted off for
fattening, and as such forward wethers will have been
some time at turnsips before it is necessary to turn on the
tore sheep, these latter may succeed the former wethers,
and be made to eat up the hulis which they had left behind.
As to the lambs, these should be always kept to a good and
plentiful diet during the winter; by which management
they will probably gain a larger size than they could have
possibly reached if they had not been allowed a great
plenty of meat whilst they were young. The same rule
holds with colts, calves, and other young animals, which, if
fattened in alimint during their growth, will always carry
with them sufficient marks to denote this improper man-
agement throughout the remaining part of their lives. This
being the case, it is evident that some of the belter pature
and most prolific gratiens should be allowed for the lambs
till the turnsips are ready for feeding, when this young
flock ought to come in for their share of that root. By
this mode of treatment they will make large tags in the
next year, and prove a valuable addition to the fold. In buying
lambs, which are hereafter intended to compose a folding
flock, the purchaser will do well to be directed more by the
size of the young creature than by its corpulence. As the
spring advances, the fat sheep will continue to be fold off,
which will enlarge the circuit for the store wethers, so that
on land in any degree kindly for the cultivation of turnsips,
a sufficient quantity of this root may be raised for the
winter support of the folding flock. As to those sheep
which are intended to be fattened, it must never be per-
mittet for them to entrench too far on the provisions of the
fold; therefore, when the turnsips are flight, it is found
to answer better the interest of the farmer to sell the
full-mouthed wethers out of the fold at Michaelmas, than to
suffer them, on the expectation of bringing in some ready
money towards the spring, to devour the meat which
ought to have been reserved for the flock, and without
which the store sheep will sink in flesh, and the farmer in
the end will be considerably out of pocket in the prosecution
of this scheme. When the turnsips are eaten off, the flock
may be turned on the rye; or if this feed hath got to a
good bite in the month of February, which frequently
happens in mild winters, and on land that is in tolerably
good heart, the folding wethers may be occasionally shifted
from the turnsips to the rye field, and when they have
eaten down this latter, be removed back on the turnsips,
and afterwards driven again on the rye when the blade
shall have arisen to a second bite; observing that this food
should never be allowed to stand till it begins to be on
spindles, for after that time it spoils its succulence, and
becomes unfit for this use. It is therefore in the ear-
ly part of the spring, only whilst it continues in its larbaceous
state, that rye is for any use for sheep feed: as in a forward
spring it forms its spindle towards the beginning of April, it
should seem that no material benefit can be derived from it after those winters which
have been attended with a considerabe length of frost,
so as to prevent it from growing to a head for sheep
feed in the months of February and March; for it is in
these two months when rye is of the greatest advantage.
In very backward springs, however, rye may continue to
be fed much later than the period here mentioned, and be
found very useful at such times, when, from the vagu-
ness...
weather in these late springs, the rape and clover fields are
flagrant in their vegetation and growth.

The whole of the fields of rape and turnips having been
fed off, the rape grafts will by this time have formed a
shoot, and will afford a wholesome food, on which, with alternate
removals to the old lays and young clovers, the flock will find
sufficient pasturage till the time advances for turning them
on the common, when the summer freezing will commence.
The lambs which were bought in at the fall spring fairs are
now become tags or two-yearlings, and those which were
bought in tags at Michaelmas are become four-yearlings, or
two-yearlings. These will now all of them go to the fold
together, and feed in the same pasturage, that is, on the com-
mon during the day time, and in the evening, previous to
the time of folding, are to be halted on the clover, &c.
that they may go into the fold with full bellies. At the
spring fairs may be bought to supply the place of those
old sheep which were fold off, and these may conveniently
go to fold with the rest; and if at Michaelmas it should be
found necessary to increase the number, either lambs or two-
yearlings may then be purchased, at the option of the far-
mer; and by this management, if the matter be cautious
in laying out his money, and the shepherd diligent in his office,
a wether flock may be maintained to great advantage on
those farms where there is a considerable tract of land,
and an adjoining common. And thus by laying out the
most fertile part of the land and that which is at the
farthest distance from home, with rape grafts, and when worn
out to plough it up, and after having hipped one crop of corn,
to sow it again with rape grafts, and by folding on such part
of the land as will admit of being kept in tillage, with alter-
nate growths of clover, trefoil, &c., the poorest soils
may be made to answer the purposes of the husbandman.
And it is by the prosecution of this mode of agriculture
alone, that such poor, thin, and hungry ground can be cul-
tivated to any good account; for if the rector, either from
want of money, or through ignorance, should neglect to
keep a folding flock on their barren farms, and place his
whole dependence on the plough and the seed-crop, a few
years would convince him of his error, and, unless his re-
sources were very ample, bankruptcy and ruin would inevi-
tably ensue.

It has long since been remarked in the third volume of his
“Essays on Agriculture and Rural Affairs,” that much
amelioration and improvement may frequently be effected in
bringing waste land into cultivation, by the folding of sheep,
provided it be conducted with care and attention to the fa-
tion, the nature of the land, the course of crops, and the
having a sufficient number of folds, according to the ex-
tent and situation of the land.

FOLDS. in the Manufacturer. See Cloth, &c.
Folds of the Draper, in Painting. See Drapery.

FOLENGIO, or FOLENGUS, JOHN BAPTIST, in
Biography, was born at Mantua in the year 1490, and at
the age of sixteen he entered into a Benedictine monastery
in his native city, where his talents and industry obtained for
him a high reputation for proficiency in literature, and fas-
ced criticism, while the excellence of his composition ren-
tended him an object of general esteem. He was selected to
fill the most important and distinguished stations in his or-
der, and he was afterwards chosen by pope Paul IV. as vi-
lator of the Benedictine foundations in Spain. When he
had performed this task he had returned to his native coun-
try, and devoted himself almost wholly to theological studies.
His mind was liberal, and he was diligent in reforming
the church, and of uniting Catholics and Protestants in one
communion. After a life spent in the service of his fellow
creatures, he died in 1559, in his seventieth year. He left
behind him many theological works, of which the principal
were “Commentaries upon the Epistles of St. James, St.
Peter, and the first epistle of St. John,” published in 1555
in 8vo.; also a “Commentary upon the Psalms.” These
works were distinguished for erudition, piety, and liberal-
ty, and were soon prohibited by the church of which he
was an ornament. The latter was reprinted at Rome by or-
der of pope Gregory XIII. in 1582, being first revised,
and curtailed by some offensive passages. Dupin, speaking
of the labours of Folengio, says, that he “writes purely and
nobly, and Thuanus had reason to say, that no man will ever
repent the reading of his commentaries.” Moreri.

FOLENGO, THEOPHILUS, known in the poetical
world by the name of “Merlin Eoccyno,” is celebrated
for the species of poetry called macaronic. He was born
at Cipano, near the lake of Mantua, about the year 1491.
He was, in early life, initiated in the studies of polite
literature and philosophy, and at the age of sixteen entered
the order of St. Benedict, and changed his name of Jerome to
that of Theophilus; but his passions were ill adapted to the
conditions of a monastery, and he passed eleven years,
after he quitted the cloister, in a rambling kind of life,
during which he composed and published at Venice his maca-
onic verses. This mode of writing, which has not very fre-
cently been adopted with success, confuses in interweaving
Latin verse a number of words and phrases in the ver-
colour tongue, thrown in at random, and made to fit the
meter by Latin terminations. Folengo, if not the inventor
of macaronic verse, was the first who brought it into vogue.
He was, however, capable of a higher species of compo-
sition, and would probably have excelled in pure and elegan-
t poetry, had not the love of novelty led him into this extra-
vagance. The late learned Dr. Geddes, the translator of
the early books of the scriptures, wrote, about the year
1790, two or three macaronic poems, which he circulated
among his friends. Folengo returned to a religious life in
the year 1526, and published the “Chias del Tribunumo,”
which is descriptive of the various incidents of his life, end-
ing with his conversion. He then retired to a small monas-
tery, where he endeavoured to expiate the fault of his looser
writing, by composing a poem entitled “La Umanita
del Figlio Di Dio.” After this, we find him at Palermo,
where he composed a kind of drama representing the cre-
tation, the fall, &c., and some religious tragedies. He died
1533 in the monastery of S. Croce de Campe, in Pa-
dus, and was interred with great pomp. The estimation in
which he was held was exhibited in the erection of a magni-
ficent tomb, on which were inscribed several epitaphs in
various languages. Moreri.

FOLIÈKUNDA, in Geography, a town of Africa, in
the country of Koster.

FOLIA, in Botany, is used for the leaves of plants, and
also of flowers, but particularly the former; the leaves of
flowers being more properly called petala.

FOLIACEUM EXTRANSUM, in Anatomy, is that ex-
treme of the Fallopian tube next the ovary, and which is ex-
panded like the mouth of a trumpet, and insonned with a
fort of fringe.

FOLIAGE, a cluster or assemblage of leaves, branches,
leaves, &c.

Foliation is generally used for representations of such
flowers, leaves, branches, rings, &c. whether natural or
artificial; used as enrichments on capitals, friezes, pediments,
&c.

FOLIANUS, Liberius, of Modena, in Biography,
a writer on the theory of music, published a Latin treatise,
FOL.

In 1523, at Venice, folio, with the following title: "Musica Theorica, Ludovici Foliani Muticensis: docta futilis ac dilecte prætrata: in qua quaplurum de Harmoniciis interdixit, non pingat tentas, continente speculations."

The theory of music by Luigi Folgiano of Modena, in which are contained and learnedly elucidated many harmonica speculations relative to the intervals of music, never before attempted. This work is divided into three sections: in the first the author treats of musical proportions; in the second of consonances; and in the third of the division of the monochord. In the second section a foundation seems to have been laid for a musical controversy, which was afterwards agitated with great warmth; this author, contending for the doctrine of Boethius, from whom two-thirds of his book are taken, for the distinction of greater and less tone in the diatonic rectorch. The title of one of his chapters being, "De utilitate toni majoris et minoris." Harmony now began to be felt, and was improving and refining, and as there was no melody till the lyric theatre was established, and folio fongs, fine voices, and refined thinking were cultivated, it was occupied by professors and dilettanti, philosophers and mathematicians. We know not what rank Fogliano held in society if he was a professor, he adhered too exclusively perhaps to mathematics, and the science of harmonics, to be much used to practical music; and if a mere mathematician, the real beauties and refinements of the art must be unknown to him. However, to Fogliano is ascribed the first idea of introducing a temperament into modern harmony. Boethius, Guido, and Franchinus, were silent on the subject. The organ was tuned in such a manner as rendered a few keys perfect at the expense of all the rest. There was no instrument that could make occasional temperaments but the violin, and that was wholly unknown in concerts at the beginning of the 16th century. Wind instruments, and all keyed and stringed instruments, in which one note was obliged to serve different purposes, were forced to submit to false intonation, and the exclusion of all tempered keys, till temperament gained ground, and the doctrines of Didymus and Pulemy were adopted, which were in favour of major and minor tones, and semi-tones; and those who enjoy the harmony of thirds, which, without temperament are intolerable, owe their pleasure to Fogliano for recommending them, and to Zarlino for securing his endeavours. See Didymus, Pulemy, and Temperament.

FOLIATE, in the Higher Geometry, a name given to some to a curve of the second order, expressed by the equation $x^2 + y^2 = ax + by$, being one species of defective hyperbolas, with one asymptote, and consisting of two infinite legs crossing one another, and forming a forkt of leaf.

FOLIATING of Looking-glass, is the spreading a composition of something which will firmly adhere to the back of the glass, and thus reflect the image.

This composition is called the foil, and is usually made with quicksilver, mixed with tin, and some other ingredients. For the method of foliating looking-glasses, both plain and globular, see looking-glass.

FOLIATION, in Botany, &c. is used by Dr. Grew to express the assembly of the folia, or petals of a flower. The foliation is the most conspicuous part of flowers, being that collection of fragrant coloured leaves, which constitutes the compass, or body of the flower.

It is of great use in the generation and preservation of the young fruit, or seed; it filtrates a fine juice, to nourish it in the uterus or polar.

In some species, as apricots, cherries, &c. it likewise serves to guard the young tender fruit from the violence of wind, weather, &c. For this being of a very tender and pulpy body, and coming forth in the colder times of the spring, would be often injured by the extremities of weather, if it were not thus protected, and lodged within the flowers. Before the flowers open, the foliation is curiously and artfully folded up in the calyx or petalium.

Dr. Grew enumerates several varieties of these foldings, viz. the close folded, as in roses; the semi-closed, as in the Blattariae; the fleshy, as in pea-blossoms; the fold and flat, as in marigolds; and the oval, as in the ladies bower.

FOLIES, Fr. Folhia, It. a Spanish dance, formerly in high favour. It is composed on a ground with variations, and danced by a single performer a pas seul. Corelli's twelfth folio, consisting of 24 variations on a tune called "Tarnell's ground," which is laid to have been composed at Hanover on purpose for Corelli to exercise his fancy upon, by a German musician of the name of Tarnell; but unluckily, Corelli never was at Hanover, and this ground, on which he worked, was an old Spanish dance, long before Corelli was born.

FOLIGNO, or Folinio, in Geography, a town of Italy, in the province of Umbria, the seat of a bishop; built on the ruins of the ancient Forum Flaminii. According to its old constitution, it was governed by seven magistrates, called "Septemviri," who are changed every two months. It contains eight churches, and many convents, and though it has some good streets, it has neither squares nor town-houses: its chief business is confectionery, paper making, and manufacture of silk. In 1756 it was taken by the French; 10 miles N. N.W. of Spoleto. Lat. 42° 55'. E. long. 12° 15'.

FOLINGRE, a town of Sweden, in Jamland; 30 miles N. of Otterlund.

FOLIO, or rather Folium, in books of account, signifies page.

Thus folio 7, written abridgedly F 7, denotes the seventh page, &c.

Folio recto, or F R', expresses the first side or page of a leaf.

Folio verso, or F V', the second or back-side of the leaf.

The word is Italian, and literally signifies leaf.

Folio, among Book-keepers, a book in folio, or simply a folio, is that where the sheet is only folded in two, each leaf making half a sheet.

Beneath the folio are the quarto, octavo, duodecimo, sexten, twenty-fours, &c.

FOLIS, or Follii, anciently signified a little bag or purse; whence it came to be used for a sum of money, and very different sums were called by that name: thus the scholiast, on the Bibles, mentions a follis of silver, which was worth the twenty-fourth part of the minas: the glosse noun, quoted by Gronovius and others, one of a hundred and twenty-five minas, and another of 253 denarii, which was the ancient sextarius; and these different sums of eight, four, and two pounds of gold, were each called follis. According to the account of the scholiast, the ounce of silver, which contained two hundred of fifty in the pound, was worth a hundred and twenty follis of copper. The glossographer, describing a follis of two hundred and fifty denarii, sa it was equal to three hundred and twelve pounds of ounces of copper; and as the denarius of that age was the eighth part of an ounce, an ounce of silver must have been worth a hundred and twenty ounces of copper; and, therefore, the scholiast's follis was an ounce.
ounce of copper, and equal to the glossographer's nummus. But as Constantine's copper money weighed a quarter of a Roman ounce, the schollak's folios and the glossographer's nummus contained four of them, as the ancient nummus contained four ares. See Phil. Trans. vol. 18. p. ii. p. 515. &c.

FOLIUM, in Botany and Vegetable Physiology. See Leaf.

Folium Branchiæ, the leaf of the gills, a term used by some of the ichthiologists, to express that part of the gills which looks red and fringed. The gills of fish are composed of certain bony circles, which are formed on the convex side with a great number of laminae; these serve to receive the ramifications of the arteries, and are called the folium or leaf of the gills. The aorta or great artery reaches no farther than this part of the gills. It has no descendent trunk, but every part of the body is supplied by a large venal trunk, formed by the joining of the several smaller trunk of the several circles of the gills.

Folium Indicum, or Indicum, called also tamaralapatra, and malabathrum; a leaf brought from the Indies, growing chiefly about Cambay, produced by a tree not unlike the lemon-tree; used in the composition of Venetian red.

FOLKES, Martin, in Biography, an eminent philosopher and antiquary, was born in Wethamstede in the year 1695. He was educated under Mr. Cappel, formerly Hebrew professor at Sæomur, but at the age of 17 he was sent to Clare-hall, Cambridge, where he pursued the studies peculiar to that university with so much affability and success, that he was elected member of the Royal Society before he had completed his twenty-third year. His communications to this learned body were so much esteemed, and his understanding so highly appreciated, that he was frequently chosen into its council. He was in habits of friendship with the illustrious Newton, at that period president of the society, and by his influence Mr. Folkes was elected one of the vice-presidents in 1733; and at the death of that great man in 1727, he was candidate for the vacant chair, but the superior interest of Sir Hans Sloane rendered his application unavailing. The contest was probably carried on without that bitterness and animosity which occur too frequently on occasions of this fort, for we find Mr. Folkes still in the council, and vice-president till the year 1733. During this and the two following years he resided for the most part in Italy, improving himself in the knowledge of classical antiquities. Here he laid the foundation of his works on ancient and modern coins, having by his situation ample opportunities of ascertaining their weight and value; the result of which he laid before the Royal Society on his return from the continent. He likewise read before the same body memoirs upon the measurements of Trajan's and Antonine's pillars, together with other remains of antiquity. A table of all the English gold coins, drawn up by Mr. Folkes, was afterwards printed at the request of the Royal Society, before whose he laid his "Remarks on the Standard Measure preferred in the Capitol of Rome," and a model of an ancient sphere preferred in the Pantheon. A representation of this sphere was published in Dr. Bentley's edition of Manilius. Mr. Folkes visited Paris in 1739, where he was received with great respect, and was introduced to the company, and obtained the friendship of the most eminent literary characters in that metropolis. On the abdication of Sir Hans Sloane in 1741, he was elected to the honourable office of president of the Royal Society, and in a very short time he was nominated to succeed Dr. Halley as one of the eight foreign members of the Royal Academy of Sciences at Paris. In 1745 he published a thin quarto volume, printed at the expense of the society of antiquaries, his very valuable "Table of English silver coins, from the Norman conquest to the present time, with their weights, intrinsic values, and some remarks on the several pieces." In an appendix to this work we have an account of the "Coins minted in Scotland since the Union of the two Crowns:" and "A table of English gold coins from the eighteenth year of King Edward III., when gold was first coined in England, to the present time." He intended to have illustrated the folium by plates, which he had prepared; but he did not live long enough to publish. They were, however, purchased by the Antiquarian Society, and published some years after his death. Mr. Folkes, in addition to his many other honours, had conferred on him the title of doctor of laws by both universities, and he was also chosen president of the Antiquarian Society. He died in the year 1754. Dr. Birch collected materials for a life, which are preferred in the anecdotes of Bowyer. He was a man of very extensive and accurate knowledge, and he was distinguished in private life for politeness, generosity, and friendship. Biog. Brit.

FOLKINGHAM, in Geography, though a market town in the hundred of Aveland and division of Kesteven, in the county of Lincoln, distant from London 107 miles, is but a small place, situated on the side of a hill, abounding in springs, containing 99 houses, and a population of 531. The church is a well built structure, having at the west end a handsome lofty tower surmounted by eight elegant light crocketed pinnacles. The feoffes-house has lately been built, and the houses in general have a commanding view over the extensive adjacent flats. It possesses little trade, and the small market is held weekly on Thursdays. Folkingham was included in the one hundred and thirty-one manors in the county of Lincoln only, which formed part of the immense possessions belonging to Gilbert de Gaunt, who accompanied the conqueror from Normandy, and afterwards it was granted, in the reign of Edward I. to Henry de Bellamonte, or Beaumont, who it is supposed erected the castle, which having been defended for King Charles I. was destroyed by Cromwell. In this vicinity are the remains of the monastery of Sempringham, remarkable for having been the first double house in England, for the singular and ridiculous order of rebuilding that comprised both monks and nuns under the same roof, called, from their founder, Gilbertines. Gough's Camden's Britannia, and Beauties of England and Wales.

FOLK-LAND, a term which in the ancient Saxon columns signified "cyphæbold lands." And in opposition to these, charter lands were denominated "book or bot lands." FOLKMOTE, FOLCMOTE, or FOLKSMOTE, among our Saxon ancestors, signified any popular or public meeting of all the folk or people of a place, district, or the like; e.g. of all the tenants at a court-leet, or court-baron; or of all the freemen of the county; or of all the barons of a kingdom.

The word, says Stowe, is still in use among the Londoners, and signifies "celebrum ex omni civitate conventum," an assembly of all the citizens. Manwood says, it is the court held in London, wherein all the folk and people of the city did complain of the mayor and Aldermen for any misgovernment. Somner, in his Saxon dictionary, makes folkcomte to denote a general assembly of the people, for doing fealty to the king, and considering and ordering matters of the common-wealth; whence some date the origin of parliaments.

"Oxime

When such assembly is made in a city it may be called a largsmot; when in the country, a largsmote.

"Cum aliquid vero inopinatum & malum contra regnum vel contra coronam regniemerit, ilium debent, pulfratis campanis, quod Anglice vocatur molothel, convocare omnes et univerfós, quod Anglice vocant folkomote, &c." Leg. Alfred.

FOLKSTONE, in Geography, a town of England, in the county of Kent, situated in the English channel, and a member of the Cinque port of Dover, irregularly built along the cliff, nearly opposite to Boulogne. It was formerly a large town, containing five parish churches (now only one); but the greater part of it has been carried off by the sea. There was an ancient flation on Cape-hill, which is a small oval of about two acres, double-ditched on the east, and triple on the north and west. Some vestiges of walls remain, and Roman bricks have been found.

This town is a corporation, governed by a mayor, 12 jurats, and 24 commoners. It is populous, and contained, in 1801, 3257 inhabitants, who chiefly subsist by fishing, and employ a great number of smacks in this trade. Before the town there is good anchorage in 8 or 10 fathoms water. Two holes fail alternately every other week to London, when wind and weather permit. It is distant seven miles S.W. from Dover, and 72 E.S.E. from London, N.lat. 51° 5' E.long. 1° 10'. "To the westward of the town is a bracken-cake, built by Henry VIII.

FOLLICULUS, in Botany, a kind of percarp or food-veil, consisting of one valve and one cell, budding longitudinally, and bearing the seeds on or near its edges, or on a receptacle parallel therewith. Its subitanea is usually conicous and tough, in some instances approaching to woody. Examples of this sort of fruit are found in the Peony, Periwinkle, Sterculia, and some others. Linnæus esteemed the follicle distinct from a capsule, but Gertner, more properly perhaps, comprehends it under his idea of the latter. (See Capsule.) The capsules of Helichorum, Diphinium, Aconitum, &c. come very near the idea of a follicle, except that they appear to be formed of two valves, but this is rather in appearance than reality, and if true, would, on the other hand, bring them to the definition of a ligure; but the latter is always folitary, which the said capsules are not, except in the anomalous instances of some species of Diphinium, in which their true nature is nevertheless evident from analogy.

FOLLICULUS, in Anatomy, a name sometimes given to small glandular bodies; it means a little bag. The parts described under this name have an opening in their centre, through which the secreted fluid is discharged. They are frequently termed mucous follicles, as they generally produce a mucous secretion.

FOLLINUS, HERMAN, in Biography, was born at Friou, and during several years was physicman to the chief magistrate of Bois-le-Duc, until he was elected professor of medicine at Cologne, where he was equally distinguished as a public teacher and as a practical physician. He died of the plague near the middle of the seventeenth century, and left some works of repute. The titles of these are, 1. "De Lucae pelliferie flag. deque remedios ejusdem, libri duo, &c." Antwerpse, 1618, 8vo. 2. "Orationes duæ; de natura et curatione Febris peticularis; de studis chymicis conjunctis cum Hippocratis," Cobuz, 1622, 8vo. His son John, born at Bois-le-Duc, was also distinguished by his practice and his writings.

FOLLIVUS, CAELIVUS, was born at Modena in 1615, after the death of his father, and was educated at Venice, under the care of his uncle, who held a distinguished station among the physicians of the council of health. His medical education was completed at Padua, where he received the degree of doctor in physic. He returned to Venice, where his talents were rewarded by the senate with the honour of knighthood, and an appointment to the fellowship of anatomy, which he long held. He published the following works. 1. "Sanguinis a dextro in sinistram cordis ventriculum definentis, facultas reperta via," Venetis, 1639, 4to. He erroneously supposed that a communication between the cavities of the heart fulfilled through life, by means of little collateral apertures which supplied the place of the foramen ovale, as soon as it was closed after birth. 2. "De generatione et usu della pinguëdine," Venetit, 1644. 4to. 3. "Novo auris internæ delineatio," Venetis, 1645. 1647. 4to. This little work of six pages is esteemed on account of the accuracy of the figures.

Another author, Francis Follis, published a work at Florence in 1665, under the title of "Recreatio Physica, in qua de sanguinis et omnium viventium analogia circulatione difficilior,", 8vo.

FOLLIVERS, in Rural Economy, is a term employed to signify such bees or hive cattle and sheep as follow the fattening bullocks or other live fock in the pastures or other grass lands. It is only in this way that such lands can be fed down in the most effectual manner, and with the greatest profit to the grazing farmer.

FOLLOWFIELD, in Geography, a township of America, in Washington county, Pennsylvania; containing 1639 inhabitants.—Arch. E. and W. Followfield, are two townships in Chester county, Pennsylvania, the former having 1622, and the latter 839 inhabitants.

FOLLY, according to Mr. Locke, consists in the drawing of false conclusions from just principles; by which it is distinguished from madness, which draws just conclusions from false principles.

But this seems too confused a definition; folly, in its most general acceptance, denoting a weakness of intellect or apprehension, or some partial absurdity in sentiment or conduct.

FOLPAGO, in Geography, a town of Italy, in the Trevisan; six miles N.W. of Trionvigio.

FOLSIGE, a town of Africa, in the country of Barea; 18 miles S. E. of Derna.

FOMAHANT, or FOMAHUT, in Astronomy, a star of the first magnitude, in the constellation Aquarius.

FOMANO, in Geography, a river of Naples, which runs into the Adriatic, N.lat. 42° 40'; E.long. 14° 5'.

FOMATION, a liquid medicament, applied to any diseased part, to relieve, diffuse, soften, affage, fortify, or console the same.

Fomations are either simple or compound.

Fomations, Compound, are decoctions of roots, leaves, flowers, and seeds, made in common water, or other proper liquor, to which are sometimes added salts, astringent, oils, &c.

To use, or apply them, they dip a hot linen cloth, or flannel, in the liquor, and spread it on the part affected. These are also fomations made another way, viz., by boiling...
boiling certain drugs in linen bags, and then applying them, bags and all, on the part.

There is also a sort of dry fomentations, being bags filled with medicines, but not boiled, only sometimes sprinkled with a little wine or brandy.

Fomentations, Simple, are those made with Luke-warm water, milk, oil, oxycerate, or the like liquors.

Fomentations are also called local barks, or partial batbings; because, being applied on a diseased part, they have much the same effect as a bath, or half-bath, has on the whole body.

Fomentations have different names, according to the preparations of which they consist, and the uses to which they are applied. Thus, the medicime, fomentation, used for relieving acute pain, is composed of white poppy-heads, with cinchona flowers; half an ounce; which are boiled in three parts of wine to one part of water; or until one part is evaporated, and then the liquor is strained out: the aromatic fomentation is prepared by boiling half an ounce of Jamaica pepper, in a pint of red wine for a little while, and straining out the liquor: this is used both for external and internal complaints. Culcis and disorders of the bowels are often abated by fomenting the abdomen and region of the flank with this warm liquor. The common fomentation is made by slightly boiling the dried tops of wormwood and camomile flowers, of each two ounces, in two quarts of water, and pouring off the liquor; to which may be added such quantities of brandy or spirit of wine as the particular case may require. The emollient fomentation consists of one ounce of camomile flowers; elder flowers, and sweet-fennel seeds, of each half an ounce; boiled for a little while in two quarts of water, and strained, with the addition of spirit of wine, &c.

The strengthening fomentation is prepared of oak bark, one ounce; granite-pellet, half an ounce; alum, two drams; and smith's forge-water, three pints; the water and half tan ounce is boiled; and then the half tallow third is confumed, and in the remaining decotion, Braided, the alum is to be dissolved. This astringent liquor may be applied to foment weak parts, and also used internally.

Fomentations, in Veterinary Science, are commonly made by boiling wormwood, foonerherm, camomile flowers, and bay-leaves in water, so as to make a strong decoction, which, being strained off, are to be applied as hot as possible, without giving pain to the animal, by means of large flannel cloths. The efficacy of fomentations depends in great measure on their use; being continued for a considerable time, and their being frequently repeated.

FOM- HOAM-TOUKA, in Geography, a town of Chiinc; Tartary, near a mountain of the same name; seven miles N. W. of Tab-fan.

FOMHIO, a town of Italy, in the department of the Ada; 15 miles S. E. of Lodhi.

FOM-UL-SICH, a town of the Arabian Irak, on the Tigris; 20 miles N. of Vait.

FON-AMI, a town of Japan, in the island of Xinto; eight miles S. of Taifero.

FONCEAU, in the Marage, is the bottom or end of a cannon-bltt mouth; that is, the part of the bitthat joins it to the banquet. See BITE and CHAPRON.

FONQUEVILLERS, in Geography, a town of France, in the department of the Brains of Calais; 12 miles W. of Bapaume.

FOND DE L'ISLES DE VACH, a town of the island of Hispaniola; 80 miles W. of Jaquemel.

FOND DES NERES a town on the S. coast of Hispaniola; 40 miles W. of Jaquemel.
nicht begin to find that Gluck, Piccini, and Sacchini, could produce good music without the assistance of his basso fondamentale; his system has as pretent but few effectors.

Such is the history of this famous system of the fundamental base.

See Bass Fondamentale, in which article we have explained a curious discovery of natural philosophy, and the life that has been made of it in practical harmony. Though M. Rameau's system will not alone enable a student to compose good music, it will help to facilitate his studies, give him the etymology of chords, and of innumerable passages in melody, and regulate his harmony on a sure foundation. And though it would be dull music indeed that had no other base than the fundamental, as the harmony and modulation of no music is so simple as to be wholly confined to common chords; the fundamental base will therefore teach their warrantable succession, perhaps suggest a melody, or at least guide its progress.

Nothing more seems necessary to be said on this subject; but in looking into the Encyclopædia Methodica, we find that it has furnished matter for an article of such enormous length, as to occupy 3740 pages, 26 of which have been scientifically filled by M. d'Alembert himself, with an elaborate attempt at confuting all that has been said by previous writers on the subject. We have heretofore frankly confessed, that after frequent perusals and confutations of Rameau's theoretical works, and a long acquaintance with the writings of his learned commentator, d'Alembert, and panegyrists the Abbé Rouffier, M. de la Borde, &c., if any one were to ask us to point out what was the discovery or invention upon which his system was founded, we should find it a difficult task.

The base to a common chord has been known ever since the first attempts at counterpoint; and it only seems as if Rameau had given new names to old and well-known combinations, when he calls the key-note, with a, generateur, basso-fondamentale. But the Italians, ever since the time of Zarlino, have distinguished this lowest found by calling it the first base, i.e., basso, and the other parts of the chord, when made the base, basso ricodato, or sib. basso. But Broadwood in his Musical Dictionary, published 1792, in defining Trias harmonica, or the three sounds of a common chord in its first state, calls the under-note basso, or fundamentale; and afterwards remarks that among the three founds that compose the Triade harmonique, the gravell is called basso, or fondamentialis. And what has Rameau told us more, except that the harmoniques produced by a string or pipe, which he does not pretend to have first discovered, are precisely the third and fifth in question. This is the practical principle of the fundamental base; the theoretic was surely known, of harmonical, arithmetical, and geometrical proportion and ratios of sound, with which so many books have been sententiously filled ever since the time of Boethius.

The Abbé Rouffier, his most learned apologist and able champion, candidly confessed in his last work, that the system of a fundamental base ought not to be regarded as one of those principles which precedes the consequences to be deduced from it. "Le mérite de cette découverte consisterait à avoir réduit en un système simple, commode, et facile à faire, toutes les opérations des grands maîtres de l'harmonie. " Traite des Accords, 1764.

Rameau's system, as composed and arranged by d'Alembert, is perhaps the shortest, clearest, and best digested, that is extant; and yet, from the geometric precision with which it has been drawn up by that able mathematician, many explanatory notes and examples are wanting to render Rameau's doctrine intelligible to musical students, in the first stages of their application; and even after that, the work, to be rendered a complete theory, would require many additions of late discoveries and improvements, both in the theory and practice of harmony.

About the year 1760, the System of a Fundamental Base, by Rameau, gave occasion to much discussion in Germany. For some it was adopted there as well as in Italy, by others disputed. It seems, however, as if this system, ingenious as it is, was somewhat over-rated by French theorists, who would persuade the world that all music not computed on Rameau's principles should be thrown into the flames—"Jufqu'à un fondamenta:," says Rameau himself; and M. de la Borde says, that "Music, since the revival of arts, was abandoned to the ear, caprice, and conjecture of composers, and was equally in want of unerring rules in theory and practice—Rameau appeared, and chaos was no more. He was at once Descartes and Newton, having been of as much use to music as both those great men to philosophy." But were Corelli, Geminius, Handel, Bach, the Scarlattis, Leo, Caldara, Durante, and others, etc., such incorrect harmonists as to merit annihilation, because they never heard of Rameau or his system? Indeed, it may be further asked, what good music has been composed, even in France, in consequence of Rameau giving a new name to the base of a common chord, or chord of the seventh? The Italians still call the lowest found of music in parts the basso, whether fundamental or derivative; but do the French imagine that the great composers above-mentioned, and the little composers who need not be mentioned, were ignorant whence every supposed base was derived? The great harmonists of the sixteenth century seldom used any other than fundamental bases. And the fundamental base to the hexachords has always been the key-note, and the fifth above and fifth below, just as Rameau has given it in his theoretic tracts.

The rules, however, which Rameau has given, with d'Alembert's commentary, were tolerably clear for composing according to his system; but are now "explained till all men doubt them!" and the editor of the long article, or rather treatise on the subject, seems only to have puzzled the cause. The definitions and nice distinctions in this article appear to us more ingenious and futile than useful, at least in practice. The nature of our harmony, like the nature of man, is so imperfect, that all the calculation and reasoning which enable us to discover their imperfections, can never supply us with the means of cure.

If by labor and labour we can somewhat diminish these imperfections, and approximate that perfection at which we aspire, it is all that our nature and the nature of things will allow. We can only counterfeit perfection, as a painter or sculptor can counterfeit a man. On our keyed instruments we have but one key or mode perfectly in tune; and on wind instruments not even that. Temperament and deviation from the laws of nature, which our modulation and mixture of keys require, give our musical organ pleasures, as it accommodates itself to the sight heuristics and
imperfections in our intervals and scales. Many think the
character and beauty of keys depend on these false in-
tervals in the C8 temperament. We shall not here give our readers all the prob-ems to
solve, or metaphysics to study, on the fundamental base,
with which the New Encyclopaedia abound; but where it is
said, p. 150, that the fundamental base produces the dia-
tonic genus only as long as it confines its movements to the
octaves, 5ths, and 4ths; when it moves by 3ds it gives the
chromatic genus; and the enharmonic genus when it moves
diatonically to the two first affirmations we can readily
subscribe, but deny the last. A fundamental base, moving
diatonically, would only produce major 15ths to all the
founds; that is, the notes in the flop of the organ called the
ricer, moving in the key of E major, while the base moves
in C. See Plate VI. Music, N. II.

It is very perplexing to young contrapuntists to find
theory and practice so frequently at strife; they are told that
though the fundamental base may ride diatonically, that is,
two bases, carrying common chords by contrary motion,
it never must defend. The student, however, if he has
read nothing until recollect that in Corelli's XIIth folio called "La Pollica," on Parnell's ground, or bet-
ter known by the first line of a song written to the melody,
"All joy to great Cesar," bar the 4th, the modulation
is from D minor to C major; and the effect, which at first
surprizes, from being so uncommon, is pleasing. In the
second bar of Pergolesli's "Stabat Mater," the fundamental
base moves diatonically, from F to E. How is a tiro
to reconcile these contradictions? Nature gives harmonics to
every found, which are never heard but from very low and
very flow notes, and are we never to have a moving base,
or an elegant passage in melody, because every found has
latent harmonics, which, though we cannot hear, (any more
than with the naked eye we can see the satellites of Jupiter),
who but the utterly ignorant doubt of their existence! Let
us never forget that practical music is wholly a work of
art. We are very proud to find that there subsists in nature
any thing on which to build our theory. It is true that with
great difficulty we can discover from the resonance of a
single string, or single bell, the founds of a common
rife in the following fives and octaves; the principal found, 5th to the 8th, and major 3d to the 15th or double octave,
as trebles to the fundamental found. But there are mere
indications, of which none but cultivated, curious, and
nice ears, can ever be convinced. The system built on these
phenomena is very defective; it extends our ideas of nature,
but contracts those of art. Whatever melody or harmony
has been found, or may be found, that is grateful and pleasing
to the ear, may surely be admitted in practice, though
not consonant to mathematical demonstration, or the spec-
ulations of mere theorists. The philosopher, Euler, says
that time, in music, is a silent arithmetic; and we may add,
that harmonic intervals are an auricular geometry; but mea-
ured by a strong hand and good ear.

M. l'Abbe Feytou, who has furnished so many scientific
articles in music to the Encyclopaedia Methodique, thinks
so differently from all other writers on musical articles
which he treats, that his readers have every thing to learn,
which they knew toklomely well before. He neither gives
the students nor their masters credit for knowledge of
any kind. And when in the new edition of the Encyclo-
pedia, he takes up an article after the editors who have
preceded him, it is not to explain more clearly what they
have advanced, but totally to overthrow their reasoning,
and neutralize their precepts and opinions. He seeks to speak
like the first inventor of every thing pertaining to the
musical science. Of practical music he knows but little,
and seems to feel less.

He seeks, in speaking of the fundamental base of Ras-
mean, and the third found of Tartini (see Tertia Suana),
by saying, that "noir inventors were ignorant of the na-
ture, the product, and movements of the founding bodies
or fundamental founds; they did not know the law of pre-
paring, resolving, synthesisions, &c.; nor the principle of
measure, nor that of the pause at an harmonic phrase, nor
the character of a mode or key in general, nor the dif-
tinction of different keys, nor the origin of chords, nor
the formation of different parts, nor the difference between a
continued and fundamental base; and that they have sub-
fitted, without necessity, numbrels' abstrack relations to
those experiments which the vibrations of the founding
body offered to their investigation." And yet these were
the greatest composers of their time in France and Italy :
the one for the organ, and the other for the violin.

The Abbe F. gives some amusing experiments in har-
monies in confirmation of Galileo's discovery, who is, how-
ever, never mentioned in a French book on the subject of
music, except by Merfennius. The experiments given by
the Abbe are ingenious and curious illustrations of Nature's
propensity to give a perfect chord to every single found, but
in composing music for imperfect instruments, till bet-
ter are invented, we must content ourselves with such an
approximation to perfect harmony as we can acquire by
tuning and perfect execution; the rest, we fear, is imprac-
ticable.

The Abbe shows the imperfection of our intervals and keys,
when every fixed found in the course of modulation
must necessarily serve for two or three purposes. This
had been very clearly and ingenuously done in our own country
twenty years ago, in a tract called "An Effay on Tune."
The diacafe has been long discovered; but where, with our
present instruments, is the cure? See Harmonics.

Still disputing the principles of Ramcan and Tartini,
M. Feytou clearly shows what had been long known by
speculative musicians before, that we have no true base to
the scale or octave of C: but this accounts for the Italians
fingering in their solfeggio only the hexachords of each key.
(See Solfeggio and Hexachord.) Of the two
tetrahords in C, whether we suppose the frift in F, as the
Abbe has done, or in C, as in practice, there must be
two fundamental bases riding diatonically, as

C D E F | G A B C | or C D E F | G A B C
F D G C | C D G C | or C D G C | C A F C | C F G C

But as there is no necessity for these fundamental bases
in practice, which can be avoided by innumerable expe-
dients, why regard them as such evils? In fact, the octave,
as the Abbe observes of the key of C, has three genera-
tors, or fundamental bases, F C G, or C F G. It is
only the violin and its kindred that can give every found
its true intonation in all keys; as D B and C B, D G and E B,
&c.

We are obliged to mitigate these wants by temperament,
which makes all keys imperfect to a certain degree; though
the suffering is not great, when the music and execution
are perfect. And, till new instruments are invented, what
can we do? Must we burn the old, drive music from the
company of the fine arts, nor longer allow her to rank in
the circle of the sciences till perfectibility in all instrumen-
ts is attained? which will probably be when that perfectibility
of man is acquired that shall exempt him from all the infini-
ties which flesh is heir to, and enable him, "unless he chuse it,
to escape death itself.

M. l'Abbe
M. l'Abbe deduces every thing of importance in practical music from the fundamental base. Not only the most perfect chord in harmony, the most pleasing notes in melody, but choirs, measures, genera, progression and modulation of discords, keys, and modulation. The only thing in which he allows Rameau to be right in explaining his own system, is the terming the fundamental base the magnet, compass, sovereign guide of the ear.

The making the F. B. the regulatrix of time in music is new and fanciful; but, we fear, visionary and impracticable in the unbridled range of modern music, which is to defultory, wild, and often capricious, comic, and whimsical, as well as solemn and pathetic, that if regulated in its measures and phrasing by any new restraint, there would be an outcry against the invasion of a musician's rights, and "la liberté de la musique," a subject which M. d'Alembert has treated with great gravity. See d'Alembert.

Besides the experiments in harmonics, we have musical problems, which manifest much ingenuity and meditation. In speaking of the genera, the learned Abbé was naturally led to the subject of Greek music. He regards the notes of the hypaton, or lowest tetrachord, C D E, as the original four strings of the Mercurian lyre; and gives Ptolemy's ratios of those sounds. He has nothing new on this subject, except that it is not a subject of disputes. He therefore gives the ratios of the three genera from the Greek writers in Mesobions, which others have often done before. But that the fundamental base may have a share in the honour of Greek inventions, he informs us that the scale of the conjoint tetrachord in the diatonic genus is derived from the F. B. of two keys, C and F, and the modern octave scale from three. (See Tetrachords and Scale.) But we have long observed, that there is no ascending more than three notes gradually without a change of key. Notwithstanding the extreme length and labour of this article in the Encyclopaedia, M. the Abbé F. has left many of its constituent parts where he found them, with respect to practice: such as the scale, cadences, measure, modulation, eu- or harmonic, &c. (which see under their several heads.) He neither allows Rameau nor Tartini to know the gamut; he disputes with them the intervals of the f c k, and the base to those intervals. Indeed nothing has ever been advanced by a musical writer, that has fallen in his way, of which he does not set fire to the refutation. To have a new gamut to learn, new techniques, and to accustom the ear to new sounds, is a talk to which great musicians will not submit, and the little ones will follow them, not the advice of speculative theorists, which indeed they are not likely to read.

We cannot help supposing that the ears of modern musicians are as well organized by nature, and as highly polished by art, as those of the ancients; and that the present gamut, and laws of harmony, are as perfect and refined as the present construction of our instruments will allow: and if ever better should be invented, that they will soon be universally adopted, piano forte being preferred now to harpsichords, as harpsichords were to spinets, and spinets to virginals. But till the improvement and refinements in our scales, intervals, and confonances are rendered practicable by new instruments or corrections of the old, music will not be bettered by these speculations, though they may point out ineradicable evils to the ignorant, and make them more unwilling to be pleased than before they were told of them; and which they never could have found out or suspected. And after the bold assertions concerning the ignorance of two men of such great professional abilities as Rameau and Tartini, we had a right to expect the abbé Feyton's rules to be illustrated by examples of composition on his own principles, or at least rendered to evident, that all musicians, and the artistic ear would be benefited by them; but alas! latterly shaking the student's faith in the rules which long guided him to the means of delighting the musical world by what were then thought admirable productions: it appears according to the learned Abbé, that we are all in the wrong, to be pleased; for all the music hitherto composed has proceeded from false principles: neither the form, melody, nor harmony, with which we have been delighted, was genuine and pure; concords nor discords properly treated, accents rightly placed, nor measure correct. The true distinctions, refinements, and scientific paradox, with which they are laid down, give them an imposing appearance; but when examined, and we consider what has been done, and is still being done without them, and that nothing has yet been achieved with them; that many are unintelligible, and others impracticable; it seems as if we had better cease to try in explaining, the old established rules upon which Corelli, Handel, Vinc, Perotto, Jomelli, Piccioli, Sacchini, the Bachs, Hayes, and Mozart, have been formed; nor are we sure of the effect, can we conscientiously recommend young subjects to be inculcated by matter taken from this learned and elaborated article.

Fondamentalis, Souris, Lat. is the principal foundation of the harmonic triad. Walther.

Fondaments, Ital.; Fondament, French; Fondamentum, Lat. is the lowest and most important note in the harmony of the common chord, the ground or foundation upon which the chords in thorough base are built. Walther. See Basse Fondamentale.

Fonde, Isles de, in Geography, three small islands in the Southern Indian ocean, near the S. coast of Kerguelen's land. S. lat. 29° 31'. E. long. 16° 39'.

Fonderoy, a town of Annapolis, in Virginia, situated on the Rappahanock river, ten miles S.E. of Leeds. N. lat. 38° 2'. W. long. 76° 34'.

Fondu, a town of Naples, in Lavora, near a lake to which it gives name; the site of a bishopric of Cagnone. This was anciently a municipal town, and afterwards a prefecture; which stood on the Appian way. At the extremity of the town is a castle, of no great strength. It was erected by Ferdinand, king of Naples, into a dukedom, in favour of Prosper Colonna. In 1534, Barbarossa, the famous corsair, wishing to seize the beautiful Julia of Gonzaga, widow of the fon of Colonna, for the purpose of carrying her off, and presenting her to the Grand Signor, but disapponted by her escape, took vengeance on the town, which, as well as the inhabitants, he treated with the utmost barbarity. The story of the havoc, which he committed, is painted in the church of the Annunciation. Fondo is situated on a plain, surrounded on one side with hills, having the appearance of an amphitheatre; most of these hills are covered with olive-trees, and the whole plain is interpenetrated with orange, lemon, and other fruit-trees; the verdure of which forms a perpetual spring; 56 miles E. of Rome. N. lat. 41° 25'. E. long. 13° 50'.

Fondo, or Sceneto Fondo, a small island in the gulf of Venice, near the coast of Iliria. N. lat. 45° 14'. E. long. 13° 44'.

Fong, the name of several towns of China; one in Quang-tong; another in Hon-quang; and a third in Kwang-nan.

Fong-chan, a town in the island of Formosa; 25 miles S. of Tay-souan.
FONG-CHANG, a town of Corea; 11 miles S. of Hoang-tehcoou.

FONG-HOA, a town of China, in the province of Tchao-kiang; 11 miles S.S.W. of Ning-po.

FONG-HOA-TCHING, a large and commercial town of Chinde Tartary, in the province of Chen-yang, on the borders of Corea; the chief manufacture is paper of cotton, which is white and transparent, and used for windows instead of glass. N. lat. 40° 31'. E. long. 123° 42'.

The adjacent country contains many mountains, some of which abound with metals and wood fit for building; the land is in general fertile, and produces wheat, milt, leguminous plants, and cotton. Immense herds of oxen, and flocks of sheep feed in the valleys. The inhabitants grow little rice; but fruit-trees of almost every kind are found here.

FONG-KIEOU, a town of China, of the third rank, in Honan.

FONG-SIN, a town of China, of the third rank, in Kiang-nan.

FONG-TCHING, a town of Corea; 117 miles W.S.W. of Hoang-tehcoou.—Also, a town of China, of the third rank, in Quang-tong.

FONG-TEN, a town of Corea; 24 miles N.N.W. of King-kistao.

FONG-TSIANG, a city of China, of the first rank, in Chuan-fu. N. lat. 34° 36'. E. long. 107'.

FONG-YANG, a city of China, of the first rank, in the province of Kiang-nan; situated on a mountain, which hangs over the Yellow river, and inclining within its walls several fertile little hills. Its jurisdiction is extensive; comprehending 18 cities. This was the birth-place of the emperor Hong-vou, who formed a design of rendering it a famous and magnificent city, as the seat of empire. After having expelled the Western Tartars, who had taken possession of China, he transferred his court hither, and named the city Fong-yang, i.e. the place of the eagle's splendour. But several objections occurring in the further view of the situation, he abandoned his design, and established his court at Nan-king. Of his design three monuments were executed, which, now remaining, sufficiently show how magnificent the city would have been, if the emperor's plan had been completed. The first of these monuments is the tomb of the father of Hong-vou, called "Hoang-lin," or the Royal tomb. The second is a tower built in the middle of the city, of an oblong form, 100 feet high, and said to be the most lofty in China. The third is a magnificent temple erected to the god Fo. This was at first a pagoda, to which Hong-vou entered when he had left his parents, and where he found an asylum in his distress; but after he had been elevated to the throne, in consequence of a succession of vicissitudes, he caused this temple to be constructed, in testimony of his gratitude to the Bonzes; assigning them a revenue sufficient for 300 persons, under a chief of their own sect, whom he constituted a mandarin. At present here are only about 20 priests, who being neglected are almost reduced to beggary.

FONGA, a town of Japan, on the island of Niphon; 55 miles S.E. of Meaco.

FONIA, a kingdom of Africa, on the borders of the river Gambia, near the sea.

FON JUN, a town of China, of the third rank, in Pesceli.

FONS PULSATILIS, in Anatomy, a name given to the ventricle, in consequence of the pulsation felt there, which arises from the influx of blood into the arteries of the brain.

FON, in Geography, a town of France, in the department of the Lot; 12 miles S. of St. Cere. N. lat. 44° 40'. E. long. 2° 20'.

FON, Cape, a cape on the S. coast of Minorca. N. lat. 39° 30'. E. long. 4° 10'.

FONSECA DAY. See AMAPALLA.

FONSECA, Peter de, in Biography, a learned Jesuit, was born about the year 1528. He entered the society at the age of twenty, and became distinguished by his talents, learning, and address. He was the first who was appointed professor of philosophy in the university of Coimbra; afterwards he undertook the professorship of theology in the university of Evora, where he was admitted to the degree of doctor, in the year 1570. From this period he filled, with high reputation, several very considerable posts belonging to his order. He was also in high favour with Philip II. king of Spain and Portugal, and with pope Gregory XIII.; by both of whom he was employed in different important negotiations. He died at Lisbon, in the year 1599, at the age of 71. He was author of many publications, chiefly philosophical, which have been printed in three volumes, folio. Moretti.

FONSECA, Gabriel de, was born at Lamengo, in Portugal, and became a public teacher of philosophy at Pisa, and of medicine at Rome, where he was appointed physician to Inoence X. He survived that pope, and died in 1668, under the pontificate of Clement IX. He left some writings under the titles of "Economia Medici;" "Consultationes;" "Convivix Medicinalia." It is believed that he was the author of some of the works, which bibliographers have attributed to his cousin Roderic.

FONSECA, Roderic de, was a native of Lisbon, and the reputation which he had obtained in that city, by the practice of his profession, induced the university of Pisa to invite him to the chair of professor of medicine. He accepted the invitation, and filled the office with considerable distinction for a number of years; but at length relinquished it, in 1615, in order to become the principal of the faculty of Padua; an office which he adorned by his talents until the period of his death, in 1622. The following are the titles of the numerous works which are attributed to him:

FON SOMME, in Geography, a town of France, in the department of the Aisne, near the source of the Somme; 5 miles N.E. of St. Quentin.

FON SSAY, a town of France, in the department of the Vendée; 6 miles N.E. of Fontenay-le Comte.

FON, in Ecclesiastical History, is now applied to designate
F O N T.

The term font was early adopted among the fathers of the primitive church. It was originally applied to the lake, river, or stream, where persons, in the dawn of Christianity, received initiation into the congregation of Christ, by the ceremony of immersion. At the period it was a matter of doubt, and of difficult determination, whether a person was baptized in the sea, or a lake, in fluctuant or running water; and the validity of the ordinance was alike acknowledged in those who had received it at the hands of St. Peter in the Tiber, and in Jordan by St. John. As the gospel was extended, and the number of converts increased, this practice, from local circumstances, must in a variety of influences cease; and an artificial fountain, or basin of water, was adopted in place of the natural stream. During the first period of the church, and while Christians laboured under the disadvantages of persecution, the font-van could be performed in no fixed place; but when once established, and places of public worship erected and sanctioned by law, it is reasonable to suppose that some proper place would be chosen, and an appropriate structure built for the performance of the baptismal rites. This was a principal building among those that were termed the public buildings of the early churches. Enaeus, describing the church of Paulinus at Tyre, says, that when that curious artific had imitated his famous structure, and completed the internal decorations, he then commenced the exedra, or buildings annexed to the church, and which, he observed, were chiefly for the use of such persons as needed purgation by ablation of water, and the Holy Ghost, viz., the baptistery. Hence it is evident, contrary to the opinion of Dr. Beveridge, and other learned writers, this building was a distinct place from the church; and that the font, or lavatory, was not originally placed in the narthex, or western part of the church, as at present; but in a place peculiarly appropriated for its reception. This opinion is supported by positive evidence. Paulinus, bishop of Nola, displaying the great munificence of his friend Severus, observes, that he erected two churches, and a baptistery between them. And Cyril, bishop of Jerusalem, in describing one, represents it as a separate building, which had first its sepulchrum, or porch or ante-room, where the catechumens or novitiates delivered their renunciation of Satan, and confession of faith; and its atrium, or inner apartment, where the sacrament of baptism was performed. Sidonius Apollinaris also speaks of it as a separate building; and St. Augustin intimates that there were distinct apartments for the accommodation of male and female converts. Thefe baptisteries were anciently very capacious, because, as Dr. Cave justly observes, the slanted times of baptism but seldom occurring, immense multitudes usually attended at the appointed season; and the manner of baptizing by immersion, and many of the subjects adults, rendered it requisite to have a very large re-voir or font for water. Accordingly Venantius Fortunatus fyles the baptistery "sua baptismatis," the grand hall of baptism. So capacious indeed were some of them, that it is reported councils have held their fittings in such structures; as Du Prene clearly evinces from the acts of the council which sat at Chalcedon. Suicerius also mentions, that in the acts of the council of Carthage, a recapitulation is made of tractsions which occurred in one, held in the baptistery of Constantinople. Thence answered the purposes of schools also, where the catechumens received instruction previous to their being baptized; and from this circumstance, and the consequent illumination derived from the sacrament, the baptistery also obtained the appellation of ostium, or place of divine illumination. The distinction, then, between the baptistery and the font is now apparent: the one comprehending the whole building, dressing rooms, and other apartments; and the other, the receptacle for the water used in the solemn rite. The latter, in Greek writers, is usually denominated ὑποδοχή τοῦ ἔριος, in the Latin piscina, and is frequently distinguished from the baptistery, and spoken of as a separate place. For Socrates expressly styles font the baptismal pool. The Greek name, Dr. Beveridge supposes, was given to the font in allusion to the fishful reservoir of Bethel; and Opstius furnishes a more mythical reason for the Latin appellation. He observes it was called piscina, in allusion to our Saviour's name, more technically, Πισιν, an acrostyle composed of the initial letters of his several titles, Jesus Chrifti, the Son of God, our Saviour. But these are remarks unworthy of criticism, and derogatory to the dignity of antiquarian research. Both terms are common names for fountains, pools, or baths, in Greek and Latin authors. And the font appears to have been originally, in these baptisteries, a kind of bath in a separate room from that where the vestments were deposited, while the ceremony was performed; for Cyril describes the catechumens as being unclothed in an inner apartment, and thence conducted to the larger of regeneration, where, after having made a profession of their faith, they were immerged three times in the water, in allusion to the doctrine of the trinity.

Respecting the form of the ancient baptisteries, little can be collected from early writers. Leo III. who, according to Du Pin, was elected pope A.D. 795, is stated to have erected one, probably agreeable to the ancient model, which is thus described: "Iadem precatum fundamentis ipsum baptisterial in rotundum, ampla largitate continuas in meliorum statum, atque facrum fontem in medio largiori spatio fundavit." What was the form of the font, or of what materials constructed, little satisfaction can be obtained. In a canon of the council at Lerida it is observed, the font should be lapillus, made of stone. What Damasus relates, in the pontifical, of a font made of porphyry marble, richly ornamented with gold and silver imagery, and other elegant decorations, in which the emperor Constantius was baptized, and by him presented to the church of St. Sophia at Constantinople, is a mere fabulous legend, unworthy of the smallest credit.

Thus did the use of baptisteries, as structures distinct from the church, continue till about the sixth century; though Mofheim observes, "baptismal fonts were now, (in the fourth century,) erected in the porch of each church, for the more commodious administration of that initial sacrament." But in this observation he is only borne out by the brief hint of Du Pin, in his remarks on the life and writings of Athanasius. "As to what concerns discipline in his time, one may observe in his works that there were fonts in churches, and that oil, wine, and bread for offerings were kept for the use of the font. Stately, in his History of Churches, observes the first fonts were set up in private houses, and after those professing Christianity had received from perfection, they were placed in more conspicuous situations at a small distance from the church; afterwards they were removed into the church porch; and subsequently into that part of the nave where they usually stand at present. The learned are generally agreed that anciently there was but one baptistery in a city, and that at or near the bishop's church; which usage Durandus informs us was continued down to his time at Pisa, Bologna, Orvieto, Parma, and Florence, in Italy. And the church of St. Jean le Rond at Paris was the place for the general baptistery of that city. In his, which
Font.

were called baptismal churches, baptism was administered during the vigils of Easter and Whitsun-tide, with lighted tapers burning, by the bishop, and the prebendaries by him commissioned for that purpose; and it was only in cases of extreme urgency that a faculty could be obtained for the administration of this sacrament. But at these two solemn fealtions of its administration. In after ages, however, the inconveniences were found so great from this restriction, that baptistries were allowed to be set up in many parochial churches. For in the council of Ancyere, baptizing in villages, by allowance from the ordinary, is formally recognized. This privilege, however, was not granted to every place, but only to those the bishop appointed; and where the necessity of the case seemed to require such extension, whereas the churches at such places obtained the distinction of mother-churches, because the real dependence upon them for receiving the ceremony of regeneration, as they had previously done on the episcopal church. After the establishment of Christianity in Italy, subjects following the example of their sovereigns, almost universally became professing Christians; and as they would early desire the participation of the same faith, adult baptism would seldom be found necessary. For notwithstanding the unsupported allusion of Mr. Robinson in his history, that infant baptism did not become an established custom till the fourteenth century; yet Bingham and Wall have incontrovertibly proved that it was a practice generally prevalent in the latter end of the thirteenth, or beginning of the fourteenth centuries. Indeed the existence of fonts only calculated for the immersion of infants, made so early as the Saxon period of our own annals, would be sufficient to refute the allegation.

On increasing the number of baptismal churches, the general adoption of infant baptism, and the necessity of a capacious bath for the immersion of adults no longer existing; a large basin of stone was substituted for the spacious bath, and the baptistery exchanged for the Lapidian font; which afterwards retained the original appellation.

Respecting fonts in England, they are mentioned by Bede in his Ecclesiastical History, under the name of Lavata: for he mentions King Edward having received the "lavacrum sanctae regenerationis" and other fonts in imitation of those in the year 689, "Rex Cadwalla venit Romam ut ad hinc beatorum apollorum fonte baptismali abluereetur." Though the privilege was early extended to certain parochial churches, yet the erection and use of fonts, in conventual churches, occasioned as strong contentions as the setting up conventional minds under the feudal system. An author in the Gentleman's Magazine, (Mr. Donne) is of opinion, that few cathedrals were ornamented with fixed fonts, at a much earlier period than the date of one set up in the cathedral at Canterbury, in the year 1236; unless in indulges where they had also parochial altars for the use of the lay-people of some contiguous districts; which was the case at Salisbury, and probably also at Winchester and Lincoln. Yet Edmund, archbishop of Canterbury, in the constitutions promulgated by him in the year 1236, directs that a stone font should be provided in every baptismal church; which, according to Lywood, was a church having the city connected with it. "In quibus ecclesiis baptismali, tabulae in tabernis, sine altari, sine pulpitum, sine cathedra, sine confessionales, sunt." In the history of Sherborne monastery, a contention is noticed between the monks and the parishes, in which disfension the former complained, that though there had been from the foundation of the monastery a font in the nave of the conventual church, where the children of the parish had usually been baptized; yet the inhabitants had set up another in that part of the church in which they were accustomed to hear divine service.

Fonts were generally formed of stone, yet some instances occur of their being made of lead; and Staley mentions a small magnificent one of solid brass, that was placed at St. Albans. This, in which the children of the kings of Scotland used to be baptized, had on it an inscription, indicating that it was Richard, Lan, knight, master of the pioneers, took and brought it home among the spoils, and presented it to this church. The general adoption of fonts for the composition of fonts, say Darell, and other Roman ritualists, was, because, as water sufficed out of the rock, as a type of baptism, fo Christ, who is the fountain of living water, is also a rock, and the chief corner stone of the spiritual church.

A description and detail of the architecture, sculpture, and doings, displayed in all the fonts subsisting in this kingdom, would be an interesting work. To attempt to clas them under sylvis at first sight appears impossible. The suite ensemble puts on such a Roman shape, and affumes such a confounding variety, as seemingly to defy all attempt at arrangement. Upon a closer survey, however, they appear to separate, and fall within certain epochs; and though some anomalous cases may occur, and some fanciful inferences may be produced; yet when properly ranged they will be reducible perhaps to three periods, viz. Saxon, Anglo-Norman, and English: no monument of this kind appearing to be distinctly British, as to be referable to that period.

After the conversion of the Saxons to Christianity by the missionary, St. Aulfin, they appear to have had a close connection and intercourse with Rome. And in their ecclesiastical buildings and ornaments they would naturally imitate the practices of the church, from whence they had imbibed their faith; and indeed it is recorded that for a considerable period their architects and other artists were brought from Italy. These would of course imitate such ornaments as they had been accustomed to admire in the magnificent temples, and other structures in that country. Thus some of the most ancient fonts are in their forms evidently taken from vats, urns, votive altars, &c. Some, for instance, are hollowed out of a solid granite, placed upon plain pedestals, and covered with one, two, or more steps; others altar shaped, and ornamented with pilasters.

Under this early, or first, period, may be classed the font at Wimpole in Cambridge-shire, consisting of a simple stone of an hexagonal shape, having a circular cavity in the centre, and placed on a flat square base. The one at Studeley Bucks is a vase, in the shape of a truncated hollow cone, inerently fixed upon two circular steps. Another of dark grey marble, in which, as Camden was informed, princes had been baptized, of a similar shape, is at Preute in Wilts; the columns of which church are clearly approachable to a Saxon era. Rotherfield-Graves, Oxonshire, is of an oblong form, with a circular hollow, and has a pilaster at each angle, and the base and upper part surrounded with ogee moldings. The font in the upper church of Lewes in Sussex is harel-shaped, the convex part ornamented with fretwork, and round the top and bottom runs a frieze, composed of rings and quatrefoils. Nefwick in Yorkshire is a cylinder, ornamented with numerous slender pilasters, surmounted with interlacing arches; and a similar one may be seen at Ancaster, in the county of Lincoln.

Next to these, in point of antiquity, appear to be those of a quadrangular or circular form, placed upon a single central shaft, encompassed with pillars; or having a small column at each
Each angle of the font, which they apparently support as an entablature. Of the first kind is the font at Berkley in Gloucestershire, which has four mullioned round columns with simple capitals, flanking on a plain pedestal, and a scroll moulding round the lower edge of the font. Under this division range the fonts at Buxborough, Herts; Sudbury, Suff.; Roydon, Essex; Hendon, Middlesex; and Albury and Sandridge, Herts. One at Berkley, Oxfordshire, has the columns devoid of base and capital, and ornamented with divers fanciful circulations. Of the second, or circular kind, are those of Hornhead and Oxleworth in Gloucestershire. Other instances occur, where the central shaft is wanting. The one at Bowes, in Yorkshire, is a circular bafin, supported by three columns; one at Wiceldon, Bucks, by two; and the one at Ely, in Yorkshire, is round, and rests on a shaft, formed by a circular arcade. In point of time it is difficult to decide which of these two kinds justly claims precedence. But, The next in antiquity seem to be those decorated with historical or emblematical bas reliefs. At Everingham, in Yorkshire, is a very antique font, ornamented with Saxon carving; and one at Alphinton, in the county of Devon, is charged with interlaced arches and a falcia, comprising the figures of birds, beasts, sportmen, &c. emblematic of hunting. One at Sharnebourn, Norfolk, is still more formal and rude in the designs; and a similar one is in the church of Daven, Kent. The font of Burnham Depeleda, in Norfolk, is deserving of particular notice. The sculpture is so mean, and the figures so rude, as clearly to evidence it to be a work of remote antiquity; and notwithstanding Mr. Pegge has assigned some reasons in the Archæologia for referring both the church and font to a later than the Saxon or Danish periods, yet they are very far from being satisfactory. The pecular, far more antiticated that the body of the church, is one of those round towers supposed to have been erected by the Danes, which give almost an exclusive peculiarity of features to the ecclesiastical structures in the counties of Norfolk and Suffolk. The rudeness of the figures, and the nature of the subject they were meant to represent, militate also against Mr. Pegge's conjecture. The font is of a quadrangular shape, supported by four clustered columns, each composed of three pillars. Of the square form resting upon four pillars, devoid of the central column, the one in Sharnebourn church, in the county of Norfolk, prefers a curious insalience. The body of the font rests upon four mullioned clustered columns, the capitals ornamented with grotesque heads, and a fanciful border extends round the edge of the font. This, though rude, is a rich piece of sculpture. The whole is placed against one of the pillars of the nave, for which position it was originally designed, one of the sides having been left blank. The three others are ornamented with figures in baso relief, representative of agricultural subjects. The compartments are twelve, and the emblems were designed to depict the labours of husbandry through the different months of the year. January represented by a figure seated on a mangel horn in his hand; February, by a figure fitting in a quicke pasturage, emblematical of the inactivity of that month; March, by a husbandman in the act of digging; April, by a man with a pruning-hook in one hand, and a branch in the other; May, by a female figure with growing hair, displaying a basket; June, by an uncouth figure holding a wedding implement; July, by a man mowing; August, by a person gathering and binding corn; September, by a man threshing; October, by a person carrying liquor; November, by a man carrying wood; December, by a group feasting. A font decorated with rude and emblematic sculpture in Fincham church, Norfolk, which was misunderstood by the historian of that county, is by some supposed of equal antiquity. Such were, probably, many of the first fonts in the early days of Christianity among the Saxons, while heathenism was strongly mixed with Christian rites; but as the genius of the gospel was better understood, it would be natural to decorate their temples, and ornament their sacred shrines, with Christian emblems. Such appear the fonts of Lincoln, Winchester and Earl Mean, in Hants. The latter two, which are very similar, are probably as ancient as the time of Battius, the first bishop of Winchester; and the emblems by which they are enriched are supposed allusive to the conversion of the West Saxons from idolatry. An engraving of the former has been given in that splendid work, the "Vetustia Monumenta." The latter is a square block of black marble, having a central excavation, and resting on a shaft, formed of three single stones, with a circular column at each angle of the font, devoid of bases, and capitals composed of foliage. At two of the angles are two doves, represented as putting their beaks into bottles, surmounted by a crofs. Two faces of the square are ornamented with arches, supported by alternate double and single pillars, and the incumbent frieze is charged with various birds and beasts. Of the alternate two are represented, in the rudolf style of relief, on one the creation of man, the conformation of Adam, and Eve taken from his side, and the temptation by the serpent; on the other, their expulsion from paradise by an angel driving them, with an uplifted sword, through the portal of a palace; and the other scene represents Adam with a spade, Eve with a distaff, and an infant placed flanding between them.

The next, in respect of time, are probably such as are ornamented with figures of the apostles, as the one at Kiddington, in Oxfordshire, removed from Ilth, in the same county. This is said to have been the identical font in which Edward the Confessor was baptised. The font at St. Peter's, Oxford, which was charged with figures of the twelve apostles, Hearne erroneously supposed to have been one of the fonts decorated with religious emblems and ornamental bearings. This fashion was probably introduced from Normandy soon after the conquest. The fonts at Eton, Kirkby Belers, and Market Bosworth, in Leicestershire, are of an hexagonal shape, and the bases charged with flaxes of arms. Of a like description Burgh, Great Shephey, and Utford, in Suffolk; St. Olyth, Essex; Maltavers and Winterbourne, Devon; and numerous others in various parts of the kingdom. About the time of Henry III. this mode of introducing heraldic devices, to emblazon the deeds of munificent or pious performed by great families, became extremely prevalent; and was not only made a subject for sculpture, but also of painting, when what was at first in relief and in miniature on fonts or monuments, was transferred on an extended scale to the windows of churches, and gave rise and encouragement to the elegant art of framing glass. To this period are assignable such as are ornamented with armorial bearings, and those also having borders of quatre-fills, initials, &c. supported in divers instances with figures of animalis conchans, rampant, and in other attitudes. To a succeeding period may probably be referred those bearing the symbols of the evangelists, ornaments of the passion, with the shafts supported by figures of the apostles, and other fonts. Of this kind are Filton, in Suffolk; St. Clement's, at Hatfield; and Sittingbourne, in Kent. The font at Lutter, in
in Bedfordshire, is of an octagonal shape, raised upon a flight of octagonal steps. Over it is a canopy supported by eight columns, about twenty-five feet in height, forming a kind of piazza, under which might stand eight people. This may be considered a baptistry on a small scale, and is the only thing of the sort in the kingdom. In the centre of the roof is a lion O., and a griffin V., rampant.

The *post period* comprehends a portion of our history for about two centuries anterior to the reformation; and is the more remarkable, because the change which occurred in the mode of ornamenting fonts is connected with that event, it having been one of the jetic hicks made use of by the freuch abettors of the Romish tenets to support their tottering faith against the tremendous blows it was then receiving from the formidable attacks of Lol-lardin. The controverted doctrine respecting the seven sacraments, powerfully opposed as antiscriptural, must be defended, and every art was had recourse to likely to accom-
plish the desirable measure. Not only were they embodied, but so represented in painting and sculpture. They were depicted on glass in the windows of churches, delineated in stone on the baptismal fonts; and the emblems of actual events and real personages of scripture were superseded by figures representative of the fuperilitions and errors in the Romish

church. No people better understood the mode of working upon the minds of men, and bringing adventitious objects to assist the powers of persuasion, than the priests in general of that communion. The effects produced upon the mind by objects represented strongly to the sight by the fascinating arts of sculpture and painting, they had well studied for centuries, and now had recourse to them for mortifying the doctrine, and fixing the vacillating minds of the multitude on the occasion. Appeals were made to Rome for arts, uages, &c., and no expense was spared to combine elegance of design with exquisiteness of execution. The octagonal form was adopted, not only because it exhibited sufficient sides for the requisite exhibitions, but because it was sanctioned by a custom of high antiquity. It is thus recommended in lines, written by St. Ambrose, placed over the font of St. Tecla, at Milan, in Italy, prior to its having been adorned with modern magnificence.

"Oc[estwororum fanetos templum surrexit in usus, O[cagonus fons oft munere dignus co, Hoc numero decuit facii baptismatis aulam Surgere, quo populis vere falus reddit Luce refurgenti Christi, qui clautra revolvit Mortis a timulis sapient comites."

During the period in question, some most costly structures were erected. The florid Gothic, as it has been termed in architecture, was carried to its height; and the mode of enriching fonts with elegant sculpture, as well as decorating various parts of the building, seemed to keep pace with each other. Numerous fonts erected at that time are objects of laudable curiosity, and worthy of peculiar investigation, as serving to mark the progress and advancement in the art of sculpture, and how much it appears to have derived improvement from the cultivation of the finer art. To point out all, or to describe even a few of those worthy of notice, which fall under this division, would ex-
tend this article too far. A description of one will in high preservation at Waltham abbey church, in the county of Norfolk, unnoticed by writers on this subject, may be ac-
ceptable; as it is, perhaps without exception, the finest and most perfect specimen in the kingdom. The base is an octagon, decorated with rosettes and quatre-foils; the plinth, of the same shape, has in it four steps, the fronts and sides of which are enriched with divers ornaments. The oce-
gonal shaft is decorated with various tabernacle-work, and the pilasters concentrating from niches with crocheted pin-
acles, in which are placed statues of the apostles. The lower border of the font also is decorated with emblematic heads and devices; and the eight sides have the seven fa-
cient forms, and the crucifixion, executed in bold relief. Among other fine specimens of this kind may be briefly enumerated Earl Dereham, Norfolk; Melton, Suffolk; and Grantham, in Lincolnshire. The covers seem generally to have been made to correspond with the work ex-
hibited in the font: the simpler fonts having plainier covers, and vice versa. These generally consisting of wood were of a pyramidal shape, crowned with a crosset pate russe; and in some instances over it was placed the figure of a dove. In some cases the covers were curiously carved, and deco-
rated in the pointed style with rich tabernacle-work. Such is the one at Sudbury in Suffolk, made of oak, variously carved in the pointed style, the sides adorned with the figures of four lambs, as atgni de, over which are the symbols of the evangelists; and between these, angels present-
ing shields charged with different family arms. This is conjectured to be coeval with the time of Richard I. Mr. Vertue distinctly mentions his having seen several fonts in Nor-
folk, which had alludes to the "high pinnacled wooden spires," richly ornamented with elaborate carving.

It may at first seem paradoxical that fonts should have gradually come into disuse, so far as respects the original purpose of them, as vesels for containing the consecrated water, from the time of the Reformation; especially when, among the canons promulgated in 1571, one particularly directs the providing a *font*, and prohibits the substitution of a *bassin*. But the reason will be found in the variety of superfluous connected with the use of fonts previous to the time in question; the effects of which remained long after, and are not even at the present day eradicated from the minds of the common people. In the ancient fonts there was a hole in the bottom of each, provided with a hoppole, for letting out the water, after the ceremony was over; which was conveyed away under ground by means of a pipe, included in the shaft. This was done to prevent a super-
fluous use being made of such consecrated water: poffons frequently taking it to the houses of those afflicted with divers diseases, in order to perform miraculous cures. Two others also are alluded to in one of the before-mentioned canons: "whether any use be had of the font on Easter even? and, whether the water in the font be changed every month?" Upon the abolishing of the liturgy, and the sub-
stituting the directory in its stead, an order was issued by the parliament for the removal of all fonts out of the churches, and to adopt the use of basins in their stead. Many were then sold, turned into horse-troughs, and de-
cremented to other ordinary uses; and though, at the Restora-

tion, many were repurchased, and again set up in the respective churches, yet numbers never were replaced. From the coldness of our climate operating on that timidity of parents, arizing from luxury, which obtained the op-
tional privilege of asperion instead of immersion, and grad-
ually introduced the use of sprinkling altogether in the baptismal ceremony, large fonts became unnecessary, and basins were found much more commodious: so that now, in most of our modern churches and chapels, the vesel for this purpose consists simply of a small marble bowl, placed upon a broader column or flange of the same material; so that, in no distant period, fonts will become, not only reflecting their age, and as specimens of art, but also as to their de-
ignation and use, a subject of curious inquiry and anti-
quanian
acquainted with him, he was highly esteemed. In his character he exhibited the simplicity of a child: he was mild, gentle, timid, credulous, sincere, and void of envy and ambition. He was singularly retent in the concerns of life, and readily submitted himself to the guidance of others. He obtained the appellation of "le bon-homme." In company he was usually silent, and seldom sought in society, unless with a few intimate friends. La Fontaine was not in favour with Lewis XIV., and was almost the only considerate writer who did not partake of that prince's bounty. The king even solicited to confirm his election to a seat in the French academy, and would probably never have given his consent, but to compromise the matter in respect to Boileau, who was elected to please the sovereign, though much against the wishes of the majority of the academy.

After the death of Mme. de la Sablière, with whom he had lived 20 years, La Fontaine was invited to take up his abode in England; but the difficulty which he found in the attempt at acquiring the language made him abandon the design. In the year 1692 he was taken seriously ill: a priest was introduced to him for the purpose of ascertaining his faith. The sick man began the conversation: "I have," says he, "lately taken to read the New Testament. I assure you, it is a very good book; but there is one article to which I could not accede: it is that of the eternity of future punishments. I cannot comprehend how this eternity is compatible with the goodness of God." The priest, it is said, explained the doctrine to the entire satisfaction of the poet, who, probably to free himself from the controversy, acknowledged that he was perfectly satisfied. As an effect of his conversion, he threw into the fire a theatrical piece which he had begun, confessed his forswear for his offences against morality and decorum, and gave up the profits of a new edition of his tales, then printing in Holland. The fact being related to the young duke of Burgundy, he was very generously ordered, that it was unreasonable that he should become poor for having done his duty, and sent him a purse containing 5,000 d'or. La Fontaine survived this illness, and passed about two years in the house of M. d'Hervart, who supplied the place of his former friend. He now undertook to translate some pious hymns, but did not succeed in this new species of composition. He died at Paris, in the year 1695, at the age of 73; and when he was moulded for interment, a fine cloth was found next to his fain. The best albums of his "Tales" are those of Amsterdam, 1675, and Paris, 1702. His "Tabl's" have passed through a vast number of impressions. Splendid editions of them with engravings, in 4 vols. folio, were published in 1755 and 1759. La Fontaine was author of many other works, as, "Les Amours de Pylée," a romance; "L'Florentin," a comedy; "L'Euvre," another comedy; "Astérophantes," "Lettres," and "Bons." D'Alembert has given his literary character in the following words: "If among the celebrated writers of the age of Lewis XIV. La Fontaine is not the greatest, he is at least the most irregularly original, the most an object of delight to imitators, and the writer whom it would cost the most pains to reproduce." His works, though uneven, have the charms of nature, which none of his contemporaries could acquire. They appear to flow from his pen spontaneously, and abound in grace and facility. His manner of narration is diversified with all the little touches which render description animated and interesting; and his reflections are just, natural, and appropriate. His memory was so highly respected by his country, that when his widow was insolvent for the payment of taxes that bore
hard upon her, an order was given that the family of La Fontaine should be for ever exempted from all public bur- thens; a privilege which has been granted to them ever since.

Fontaine, N. Cholat, a considerable French writer, the son of a taverner, was born at Paris, in the year 1625. He lost his father when he was twelve years of age, and was entrusted to the care of a relation, who was desirous of bringing him into public life by placing him under the patronage of cardinal Richelieu. The youth did not relish the proposal; he felt a stronger inclination for retirement and study, than for mixing in the muffle of the world; and resolved, if possible, to enter into the society of the Jesuits. At the age of 20 he accomplished his plan, and by a fe- dalous attention to the studies which were preferred to him, and by the excellence of his character and urbanity of his manners, he acquired the esteem, friendship, and con- fidence of the most respectable members of the society. He was, in a short time, appointed one of the tutors to the young persons sent to the Seminary, of which he was a member, for education. His leisure hours, and all that he could redeem from sleep, he devoted to theological studies. When M. Arnauld was expelled from the Sorbonne, and withdrew into privacy, M. Fontaine, already attached to him by the closest ties of friendship, readily followed his fortunes, and those of M. Nicole, for whom he acted as their secretary. He was also the friend and companion of M. Sacy, the disciple and nephew of Arnauld, and accom- panied him into places of concealment, where he took ref- uge from the persecutions of the Jesuits. In one of these they were discovered, and committed prisoners to the Bailli, where they were confined two years. After their liberation in 1668 or 9, their intimacy became stronger than ever, and continued unbroken till the death of M. Sacy in 1684. From this time Fontaine was obliged frequently to change his place of retirement, until he removed to Me- lun, where he died in 1709, when he had completed the eighty-fourth year of his age. He was the author of nu- merous works, published chiefly without his name, and sometimes with fictitious titles. The most important that are considered as belonging unquestionably to him are, "Illustrations of the New Testament," first published in 2 vols. Svo., and afterwards in 2 vols. 4to. "An Abridgment of St. Chrysostom on the Old and New Testament;" "The Lives of the Patriarchs, Prophets, and Saints," in several octavos. M. Fontaine was distinguished for great integrity, for the simplicity and innocence of his manners, and for unaffected modesty, humility, and piety. Morier.

Fontaine, in Geography, a town of France, in the department of the Upper Rhine, and chief place of a can- ton, in the district of Belfort. The place contains 261, and the canton 7,124 inhabitants, on a territory of 140 kilomètres, in 29 communes.—Allo, a town of France, in the department of the Vendée; 6 miles N.E. of Fontenay-le-Comte.—Allo, a town of Canada, on the S.E. bank of the lake St. Pierre. N. lat. 46°. W. long. 75° 40'.

Fontaine-le-Bourg, a town of France, in the depart- ment of the Lower Seine; 9 miles N. of Rouen.

Fontaine-le-Dun, a town of France, in the department of the Lower Seine, and chief place of a canton, in the dis- trict of Yvetot; 12 miles S.W. of Dieppe. The place contains 823, and the canton 10,448 inhabitants, on a ter- ritory of 165 kilometres, in 22 communes.

Fontaine-l'Eveque, a town of France, in the department of Jemappes, and chief place of a canton, in the district of Clauray; 3 miles W. of Clauray. The place con- tains 2,468, and the canton 11,245 inhabitants, on a terri- tory of 100 kilometres, in 12 communes.

Fontaine-Française, a town of France, in the depart- ment of the Côte-d'Or, and chief place of a canton, in the district of Dijon; 10 miles E. of la Turque. The place contains 1,920, and the canton 5,460 inhabitants, on a terri- tory of 157 kilometres, in 14 communes.

Fontaine-Guerin, a town of France, in the department of the Maye and Loire; 13 miles E. of Angers.

Fontaine-les-Joye, a town of France, in the depart- ment of the Eure; 60 miles N.E. of Evreux.

Fontaine-sur-Somme, a town of France, in the depart- ment of the Somme; 4 miles S.E. of Abbeville.

Fontaine de Vaucoulx, a town of France, in the depart- ment of the Vaucluse, from the residence of Petrarch and Laura; 15 miles E. of Avignon.

Fontaines, Peter Francis des, in Biography, a cele- brated French critic, was born at Rouen in the year 1685, where his father was a councillor of parliament. He re- ceived his education under the Jesuits, and obtained ad- mission into that order; but at the age of thirty, distilling the restraint attached to a clerical character, he quitted the society, and at the same time a cure he possessed in Normandy. Having excited some attention by his critical writings at Paris, the Abbé Bignon, in 1724, committed to him the conducting a distinguished periodical publication, entitled "La Journal des Scavans." While peacefully enjoying the fame and emolument of his literary labours, his numerous enemies, whom he had excited by the severe strictures on their works contained in that publication, determined on revenge; and they cruelly retaliated by accusing him of having been guilty of an unnatural crime; which expatriation on his character occasioned his imprisonment. He however- procured his liberty after fifteen days, and a justification of his conduct, in a letter from the magistrate, addressed to the Abbé Bignon, which tended to re-establish him in his former credit. The Journal having been suppressed by au- thority, he obtained permission to publish, in 1731, a similar work, under the new title of "La Nouvelle du Pamphlet, ou Réflexions sur les ouvrages nouveaux." But this only proceed- ed to two volumes, when the imprimator was also withdrawn, on account of the numerous and loud complaints of the various authors, lampooned, and held up to ridicule by the severity of its criticism. In 1735 he again entered the theatre of literary diffusion, and by assurances of more candour, and les personality, he procured a licence for an- other periodical publication, entitled, "Observations sur les écrits modernes;" which, after running to the protracted length of thirty-three volumes, was by order of government- silenced. But terrified by menaces, and intimidated by difficulties, in 1744 the critic appeared again in the path of science, and published his remarks in a weekly paper, called "Jugemens sur les ouvrages nouveaux," which proceeded to the eleventh volume under his direction; and the last two, thirteen, and fourteen, of that work were performed by fome other hand; he having been attacked with a disorder in his ched, that occasioned his death in 1745; on which occasion his enemy, Piron, wrote this satirical epitaph,

"Sous ce tombeau gît un auteur
Dont en deux mots, voici l'histoire
Il eut ignorant comme un predicateur,
Et malin comme un auditoire."

Besides his avocations in the voluminous periodical publi- cations, he found leisure to execute a variety of other works,
of which his biographer enumerates seventeen; some critical, some historical, and some transliterations. He published a prose translation of Virgil with plates by Chiscio in four volumes, 8vo., in which some critics have decided Virgil is either translated or murdered in every line. In 1754 a translation of Horace's odes appeared from his pen, and at different times from the same prolific source, sacred poetry, in imitation of the Psalms; Dictionnaire Neologique; a new Gulliver, in two volumes, a translation of Swift's Gulliver's travels; and portions from his other works, and those of Pope, Fielding, &c.

Vergil, who has drawn up his character, observes, that he was born a sentimental person, a philologist in conduct, as well as principle; except from ambition, and of a free and noble spirit, which would not bloom for titles or pretexts. In common conversation he appeared only a common man; but when any thing out of the ordinary way occurred, he discovered great discernment, force of imagination, depth of humour, and brilliancy of wit. The Abbé de la Porte published in 1757, "L'Esprit de l'Abbé des Fontaines," with a life annexed; and a catalogue of his writings, and those who wrote against him, in four volumes, 8vo., which see, and Nouveau Dictionnaire Historique.

FONTANA, Prospero. A painter of history, born at Bologna in 1512. Vasi mentions him as having been employed in 1556 to finish works left incomplete by Innocenza da Imola at Bologna, and he appears more as the fervent and attendant to others, than as the inventor of great works. He is introduced here principally, as having had the honour of offering into the world of art those two brilliant luminaries Amilare and Ludovico Carracci. It is not known when he died.

FONTANA, Latania, daughter of Prospero, practised portrait painting with very considerable success, under the patronage of Pope Gregory XIII. She died in 1602, at the age of 50.

FONTANA, Dominico, an eminent architect, was born in 1543 at a village on the lake of Como. Having acquired the elements of geometry, he went to Rome, where his elder brother John was a student in architecture. Here he applied himself most diligently in studying the works of antiquity, and at length was employed by cardinal Montalto, afterwards pope Sixtus V. Montalto had already begun to display the magnificence of his character, by undertaking the construction of the grand chapel of the manger in the church of St. Maria Maggiore. The pope, Gregory XIII, jealous of the munificence of his cardinal, took from him the means of his designs, and thus put a stop to the works. Fontana, with a spirit worthy of a great man, went up with the building at his own expense, which he projected to the cardinal, that when he was raised to the popedom, he created Fontana his architect. The chapel and palace were finished in a splendid style, but this was a small part of the vast designs projected by Sixtus. Besides completing the dome of St. Peter's, he relished to contribute to its grandeur by conveying in front of its piazza the obelisk of a single piece of Egyptian granite, which had formerly decorated the circus of Nero. This design had been contemplated by some of the predecessors of Sixtus, but none had actually attempted it. Sixtus summoned the architects and engineers from all parts, to consult on the best means of effecting the business. Fontana's plan obtained the preference, and he was able to perform in practice what he had in four or five years. This was regarded as the most splendid exploit of the age, and rewards and honours the most magnificent were bestowed upon Fontana and his heirs. He was afterwards employed in the elevation of other obelisks, and in the embellishment of the principal streets of Rome. He built the Vatican Library, and began considerable additions to that palace, which were interrupted by the death of Sixtus.

One of Fontana's great works, was the conducting water to Rome from the distance of fifteen miles, in a channel supported upon arches. The successor of Sixtus, Clement VIII, was prejudiced against the papal architect, and dismissed him from his office, but his reputation caused him to be engaged by the viceroys of Naples as architect to the king. He accordingly removed to Naples in 1552. Here he undertook and executed many works of consequence. His last efforts were directed to a new harbour for Naples, which he did not live to finish. He died at Naples in 1627 in his sixty-fourth year, Gen. Log.
The town is built in the form of an amphitheatre, upon a hill which faces the sea, and in the fourth angle of the gulf of Gaflony. It has a governor, a king's lieutenant, or major, an aide-major, and a garrison, more or less numerous at different times. N. lat. 43° 23'. W. long. 1° 55'.

FONTELLO, a town of Portugal, in the province of Beira; 4 miles N.E. of Lamego.

FONTEHAY, Peter Claude, in Biography, a French Jefuit, was born at Paris in 1689, and entered on his novitiate in the order when he was fifteen years of age. Having completed his initiatory studies, he was employed some time to furnish extracts and remarks on books relating to religion and ecclesiastical history in the "Journal de Travaux." He was engaged for some years in collecting materials for writing a history of the popes, in which however he made but small progress. His attention to ecclesiastical history did not prevent him from pursuing the lighter studies of polite literature, in which he excelled, and as the result of those pursuits, he published various small poems in the collections of the day. His studies and learning pointed him out as a fit person for rector of the Jefuits'college at Orleans, where he continued till the year 1715, when he was recalled to Paris, and appointed to continue, Longueval's "History of the Gallican church." Eight volumes of this work had been already published, and Father Fontenay proceeded with it till the twelfth, when he was incapacitated for further progress in the undertaking by a paralytic stroke. He survived the stroke but twelve months, and died at the college La Flèche, in the year 1744, in the fifty-sixth year of his age. Moret.

Fontenay, in Geography, a town of France, is in the department of the Two Seines, and chief place of a canton in the district of Nioit. The place contains 1,235, and the canton 6,183 inhabitants, on a territory of 14.246 square, or 10 communes.

Fontenay-le-Comte, a town of France, and chief place of a district, and capital of the department of Vendée, situated in a fertile valley on the Verdée. The place contains 6,660, and the canton 15,283 inhabitants, on a territory of 147.6 square, or 15 communes. The chief articles of commerce of the inhabitants are cloth, woollen stuffs, and cattle, of which they sell a great number at the three annual fairs. N. lat. 46° 50'. W. long. 0° 24'.

Fontenelle, Bernard le Bovier de, in Biography, a man of letters, was born at Rouen in 1657. He was educated among the Jefuits, and became, at a very early age, distinguished for the progress which he made in polite literature. He studied the law as a profession, but leaving his right hand in the courts, he renounced the bar, and devoted himself entirely to literature and philosophy. In 1674 he visited Paris, and became known as a poet; and in 1683 he published "Dialogues of the Dead," in two volumes. These were well received, and proved a happy specimen of his talent of combining morality and literature with the graces of elegant and ingenious writing. Three years afterwards he published his most popular work, entitled, "Entretiens de la Pluralité des Mondes." In this little piece, which has been translated into all languages, science and philosophy are united with vivacity, gallantry, and delicate humour. The next production of Fontenelle was "The History of Onæus," which appeared in 1674, and which exposed the author to the suspicion of infidelity, because he opposed certain dogmas held by the clergy as sacred. He published, in the year 1688, "Pastoral Poems, with a Difcourse on the Elocution," and in 1692 and the following year the opera of "Thetis and Pienus," and "Aneas and Lavinia," which met with a considerable share of
in popularity. In 1690 he was admitted into the French academy; and in 1699 he was elected secretary of the academy, a post which he occupied forty-two years. In this situation he wrote a history of that body, of which he published a volume annually, containing extracts and analyses of memoirs, and eulogies of deceased members. Fontenelle was author of many other pieces, of which the principal are, "L'Histoire du theatre Francois jusqu'à Corneille," "Réflexions sur la Poësie du theatre, et du theatre Tragique;" "Elements de Geometrie de l'Infinit;" a tragedy, and some comedies. His constitution was originally and naturally delicate, yet he reached the great age of four score years and ten, with no other infirmity than that of deafness. After this his fight began to fail him; but he lived till he had nearly completed a century. A short time before he expired, he was asked by his physician if he felt any pain; "I only feel," he replied, "a difficulty of existing." He died January 9, 1757. Fontenelle, says his biographer, "as a poet, did not rise beyond elegance and ingenuity; as a man of science, he excelled more in elucidating the inventions of others, than in discovering new truths. In the commerce of life he was truly a philosopher; florid of his own happiness, yet without sacrificing the duties of a man of honour and virtue. In his conversation he was guarded; in his actions firm and decided. He often gave an honest vote in a minority at the academy, and was the only one who had the courage to vote against the exclusion of the abbe St. Pierre from its meetings, when he had been declared guilty of treating the memory of Louis XIV. with disrespect. He had many friends; and, in the latter part of his life, fearlessly an enemy."

The works of Fontenelle, with the exception of those on geometry and physics, have been collected in eleven volumes, 12mo, under the title of "Œuvres Diverses." Moretti.

Fontenelle, the most pleased and allowing writer on subjects of history, criticism, and philosophy, was so totally inoffensive to music, that, like our Pope, he wondered how its votaries could be so delighted with it. Pope ascribed all the pleasure expressed by the admirers of the art to affectation; while Fontenelle, ignorant of its objects, concerning which his ears afforded him no information, cried out, "Savate, que vant tu?" and this humble question has passed for a bon mot among scoffers ever since. The forna personified might have answered, "I would have you listen with attention to the sweetness of the harmony, the grace, spirit or pathos of the melody, and the ingenuity of the composition." But it is wonderful that so intelligent an author should write dramas for music, without knowing what music meant: yet, when no more than twenty years of age, he produced Plièche, and Bellerophon, two famous operas for the lyric theatre, and which were set by Luili in 1681; Pélus and Thésis, another famous opera; for what he could not understand; in 1689, Jennes and Latavina; and in 1731, Endymion; and all these dramas were to be translated into melody, a language of which he knew not the alphabet. He used to say that the ancient music of the Greeks could never be recovered, or similar effects produced by the moderns, unless the poet and musician were united in one and the same person, for, he had read that Sophoehles and Euripides set their own dramas to music. Metattalio was more modelled and more reasonable; for, upon being asked if he had ever met any of his own dramas to music, he answered in the negative, alluding as a reproof, that music was now become so difficult and complicated a study, that a man of letters had not leisure sufficient for its cultivation; as it is necessary now not only for an opera composer to be possessed of genius, taste, invention, and knowledge of counterpoint, but he should know the peculiar art and power of different voices, the scale and genius of different instruments, and sing in good taste, though without a voice. Pope, whose aural organs were too obtuse to vibrate in unison with musical tones, wrote a beautiful ode for music on St. Cecilia's Day, and Addison not only wrote an ode, but an opera for music, both as ignorant of its meaning as Fontenelle. These admirable writers, who, on subjects within their competence, from beings of a superior order, only degrade themselves to a level with the common maze of mankind, in condemning what they neither feel nor understand. No one is ashamed to own that he is near-fighted: none will allow that their apathy and contempt for music arise from an imperfect organization. There is an ear for music, an eye for painting, and a voice for song, with which those who hear, see, and talk well enough for the common purposes of life, are not gifted. Dr. Johnson, who had no ear for music, and tried to have some pleasure in humbling those whom he thought vain of their musical talents, seeming to hang over the harpsichord as if he were listening to the sounds, being told by the performer that he hoped he would grow fond of music at last, the great philologist said, "Sir, I shall be glad to have a new feline given me!" which was candidly affording his contempt for music to its true caufe. Fontenelle, whose style in his prose writings was the most ingenious, elegant, playful, and correct, of any author who contributed to embellish the splendid and literary reign of Louis XIV., was nephew to the great Corneille.

FONTENAY, in Geography, a village of France, in the department of Jemappes, famous for a title which was fought near it between the French and the Allies, in May 1745; the allies and English were commanded by the duke of Cumberland, and the French by maréchal Saxe. The allied army left 12,000 on the field of battle, and the loss of the French was not much less; 4 miles S.E. of Tournay. — Also, a town of France, in the department of the Meuse; 8 miles N.E. of Toul. — Also, a town of France, in the department of the Aisne, on the Aisne; 5 miles W. of Soissons.

FONTES, a town of France, in the department of the Herault; 13 miles N. E. of Beziers.

FONTEVRAUD, a town of France, in the department of the Mayenne; famous for an abbey, in the church of which several kings and queens of England were buried; 6 miles E. of Saumur.

FONTEVRAULT, in Ecclesiastical History, an hermit priory of order of monks and nuns, 13 which, contrary to others of a similar complexion, the weaker sex has allowed the pre-eminence. It was founded four years after the celebration of the council at Reims in the year 1190, by Robert d'Arbrissel; who was archbishop of Reims, and then received a particular visita, from pope Urban II., to become an itinerant preacher, for the better instruction of profiting Christians. Having been very successful, and persuaded numbers, both men and women, to devote themselves to a monastic life, he erected for their accommodation cells in the woods of Fontevraud, three leagues from Saumur, on the confines of Poitiers, in France. After lodging the women in separate apartments, and subjected the men to the control of the abbess, in honour of that portion of sacred history written by St. John in the 19th chapter of his gospel; he placed the whole order under the rules of St. Benedict, only adding some particular constitutions; and appointed this house to prelude over the whole. Pope Paul
on the latter from fire." Hence he has given it the name of *antipyretica* and hence some have supposed it incombinable, for which there is no foundation, except perhaps when it is thinly encrusted all over with earth. Its use can be accounted for sufficiently, by its being a bad conductor of heat, and excluding the passage of air.

3. *F. capillacea*. Brittly Water-moss.—Leaves linear-bristle-shaped. Spreading. Scales and fruitstalks elongated, thread-shaped; the scales acute, reaching beyond the capsule.—Duck. Crypt. falc. 2. 1. Sm. Fl. Brit. 1572. With. 789. Hull. 275. (F. capillacea, calycibus fityliformibus capitatis; Dill. Mufc. 260. t. 33. f. 5.)—Native of the alpine rivulets of Scotland, where it was discovered by Mr. Dickson. The celebrated John Bartram sent it to Dillenia from Pennsylvania. This is of a dull olive green, scarcely shining, and is known by its long leaves with capillary points, which spread nearly equally in all directions. The long fruitstalks, invetted with the close flender sheaths, are also remarkable, and readily distinguish it from the foregoing.

4. *F. falicata*. Sickle-leaved Water-moss.—Leaves ovate, lanceolate, taper-pointed, in three rows, curved to one side. Fruitstalks elongated, half naked.—Hedd. Sp. Mufc. 299. Crypt. v. 3. 57. t. 24. Swartz. Mufc. Succ. 72. (F. capillacea; Linn. Fl. Suec. 379. Ebrh. Crypt. 257.)—Found in mountainous rivulets in Sweden. Einhart gathered it near Upfal. Much less slender than the last, from which it is essentially distinguished by the sickle-shaped leaves, curved all one way, and the nakedness of the upper part of the fruitstalk, whose sheaths seldom reach further than their middle. Linnaeus noticed this for the plant of Dilennis, quoted under our last species, on which, without seeing a specimen, he had previously founded his own *F. squamosa*. He tells us in the Flora Suecica, ed. 2, he had not the plant at hand when he wrote that book, but adopted it from Olaus Celsius.

The *F. pennata* of Linnaeus is *Nekera pennata*, Hedd. Crypt. v. 3. 47. t. 19, a most elegant moss, erroneously supposed to have been found in England.

Concerning *F. minor*, Linn. Sp. Pl. 1571, there has been much doubt and controversy. The plant of Dilennis and of British writers, from which the Linnaean specific character, of the terminal fructification, was taken, is *Tricleftum foniculaculatwm* of Hedw., and of Fl. Brit. 1248. This is what grows at Oxford and in the Thames, and is figured in Engl. Bot. t. 357. But the herbarium of Linnaeus contains a specimen, gathered at Upfal, marked by him *minor*, which is certainly different, though probably only a variety of *F. antipyretica*. This is what he described in the second edition of *Species Plantarum*, "leaves folded so as to form a keel, two together on the thicker branches." There are no capsules on the specimen, but some appearance of axillary male flowers. As the acute and active cryptogamists of Sweden have not since detected this plant
at Upsal, we must conclude it to be an evanescent variety of
the first species. The Swifs botanists have been no less
puzzled than Linnaeus about F. minor. What Favrod and
others have taken for such, and which they contend is Hal-
ler's Hypnum, n. 1795, appears to us not different from
Hypnum rufifolium, Fl. Brit. 1292. Possibly, from his
quotation of Dillenius, Haller might mean our Trichefomum
fontinalidet; but on this little dependance can be placed,
as under his very next species, n. 1796, which is An：han-
gium aquaticum of Hedwig, Hypnum aquaticum Jacq. Austr.
t. 290, (as the late Mr. Davall first suspected), Haller
quotes the synonym which belongs to Fontinalis squamosa, a
widely different moss. The synonyms of this eminent writ-
er indeed require much correction, even in his Nomenclator,
where he is supposed to give only the most obvious and indu-
bitable. S.

FONTINELLE, in Geography, a town of Walachia,
on the Danube; 18 miles E. of Nicopoli.

FONTIVEROS, or Hortiveros, a town of Spain, in
Old Castile; 10 miles N.N.W. of Avila.

FOOD. For the substances capable of affording nutriment
to man, see Digestion; and for information relative to the
quality and quantity of those substances to be taken with a
view to the prevention and cure of diseases, see Diet.
