1819.
Starch.

Starch, a substance which is extracted from wheaten flour, by washing it in water. All farinaceous seeds, and the roots of most vegetables, afford this substance in a greater or less degree; but it is most easily obtained from the flour of wheat, by moistening any quantity thereof with a little water, and kneading it with the hand into a tough pâte: this being washed with water, by letting fall upon it a very slender stream, the water will be rendered turbid as it runs off, in consequence of the fecula or starch which it extracts from the flour, and which will subside when the water is allowed to stand at rest. The residuum of the flour, which remains after the water has extracted all the fecula, and runs off colourless, will be found to be gluten which fee.

The starch so obtained, when dried in the sun, or by a flove, is usually concreted into small masses of a long figure and columnar shape, which have a fine white colour, scarcely any smell, and very little taste. If kept dry, starch in this state continues a long time uninjured, although exposed to the air. It is not soluble in cold water; but forms a thick pâte with boiling-hot water, and when this pâte is allowed to cool, it becomes semitransparent and gelatinous, and being dried, becomes brittle, and somewhat resembles gum.

Starch, although found in all nutritive grains, is only perfect when they have attained maturity, for before this it is in a state approaching to mucilage, and so mixed with saccharine matter and entellial sile, that it cannot be extracted in sufficient purity to concret into masses.

Wheat, or such parts of it as are not used for human food, are usually employed for manufacturing starch, such as the refuse wheat and bran; but when the Sicil starch is required, good grain must be used. This, being well cleansed, and sometimes coarsely bruised, is put into woodenaffs full of water to ferment: to affit the fermentation, the vessels are exposed to the greatest heat of the sun, and the water is changed twice a day, during eight or twelve days, according to the season.

When the grain bursts easily under the finger, and gives out a milky white liquor when squeezed, it is judged to be sufficiently softened and fermented. In this state, the grains are taken out of the water by a sieve, and put into a canvas fack, and the halves are separated and rubbed off, by beating and rubbing the fack upon a plank: the fack is then put into a tub filled with cold water, and trodden or beaten till the water becomes milky and turbid, from the starch which it take up from the grain. A scum sometimes swims upon the surface of the water, which must be carefully removed; the water is then run off through a fine sieve into a settling-veil, and fresh water is poured upon the grains, two or three times, till it will not extract any more starch, or become coloured by the grain. The water in the settling-veil, being left at rest, precipitates the starch which it held suspended; and to get rid of the saccharine matter, which was also dissolved by the water, the veils are exposed to the sun, which soon produces the acoust fermenta- tion, and takes up fuch matter as renders the starch more pure and white. During this process, the starch for fale in the shops receives its colour, which confits of smallt mixed with water and a small quantity of alum, and is thoroughly incorporated with the starch; but this starch is unfit for medicinal purposes. When the water becomes completely clear, it is poured gently off from the starch, which is washed several times afterwards with clean water, and at last is placed to drain upon linen cloths supported by hurdles, and the water drips through, leaving the starch upon the cloths, in which it is pressed or wrung, to extract as much as possible of the water; and the remainder is evaporated, by cutting the starch into pieces, which are laid up in airy places, upon a floor of plaster or of slightly burnt bricks, until it becomes completely dried from all moisture, partly by the access of warm air, in and about the building, and partly by the change of the seasons, which renders the air too cold to admit of its being taken up again.
warm air; and by the floor immibing the moisture. In winter the heat of a stove must be employed to effect this quickly. Lastly, the pieces of dried flour are scraped, to the outside crust, which makes inferior flour, and the pieces are broken into smaller pieces for sale.

The grain we remain in the stack after the flour is extracted, consists chiefly of the husks and the glutinous part of the wheat, which are very nutritious food for cattle.

The French manufacturers, according to Les Arts et Metiers, pursue more economical methods, as they are enabled, by employing an acid water for the fermentation in the first instance, to make the malt inferior, and the bran or husks of the grain are saved for food. This water they prepare, by putting a sufficient quantity of water into a tub, and adding two pounds of leaven, as some bakers use to make their dough rise or ferment. The water stands two days, and is then stirred up, and a pain of warm water added to it; then being left to settle till it is clear, it is poured off for use. To use this water in the fermentation of the materials, a quantity of it is poured into a tub, and about one third of the materials, a quantity of it is poured into a tub, and about as much water is poured upon it as will fill the tub half full; the remainder of the tub is then filled up with the materials, which are one of refuse wheat, and the other half bran. In this tub continues to steep and ferment during ten days, or less, according to the strength of the leaven-water, and according to the disposition of the weather for fermentation. When the materials have been sufficient steeped, or fermented, an amass matter, which is: oil of the grain, will be, swimming on the surface, having been thrown up by the fermentation. This must be skimmed off, and the fermented grain, being taken out of the tub, is put into a fine sieve, placed over a filter-tub, when fair water is poured upon it, and washed through the sieve into the tub; by which means the flour is cleared through the sieve with the waste of which about five times the quantity of the grain are used.

The water stands in the filter-tub for a day, and becomes clear at top; when it is carefully laded out of the tub, leaving at the bottom a white sediment, which is the flour. The water which is taken off is ar, and is called pure water: this is the proper leaven for flour steeping & the materials. The flour now obtained must be rendered marketable; for which purpose, as much water is poured upon it as will enable it to be pounded and broken up with a shovel, and then the tub is filled up with fair water. Two days after this, the water is laded out from the tub, and the flour appears in the bottom, but covered over with a dark-coloured and inferior kind of starch, which is taken off, and employed for fattening hogs. The remainder of the sediment, which is good flour, is washed several times, to remove all the inferior flour; and in this manner, a quantity of four inches of thick flour household found at the bottom of each tub; but the quantity varies, according to the goodness of the meal or bran which has been used. It is evident that the refuse wheat, when employed for making flour, ought to afford more, the whole bag used, than the bran or husks; but the flour so extracted is always of an inferior quality to that which is extracted on the bran of good wheat, particularly in the whiteness its colour. The flour in the different tubs is brought together into one, and there worked up with as much water as will dissolve it into a thin paste, which is put into a filter-tub, drained through with fresh water. This water is settled in the tub, and afterwards poured off, but before it is so completely settled as to lose all its white colour: this renders the flour which is deposited in the filter-tine and whiter, and the flour which deposited by the water so poured off is of a more common quality.

Flour thus purified is taken out of the bottom of these tubs, and put into wicker baskets, about 18 inches long and deep, rounded at the corners, and lined with linen cloth, which are not fastened to the baskets. The water from the flour through the cloths for a day, and the baskets are then carried up to apartments at the top of the house where the flour is male of very clean white plasters; when the windows are open, to admit a current of air, here the baskets are turned downwards upon the floor, and the linen cloths, not being fastened to the basket, follow the flour, and, when taken off, leave or cakes of flour, which are left to dry a little, and then broken into smaller pieces, and left on the flour-tub; till very dry. If the weather is at all umit the flour is removed from the platter-floor, and preserved upon shelves, in an apartment which is warmed by a fire, and there it remains till perfectly dry. The piece of afterwards removed, to remove the outside crust which skims common flour and the scraped pieces being thrown into the basket, the flour is carried to the above, and spread to a depth of three inches, on hurdles covered with cloths. The flour must be turned over every morning and evening, to prevent it from turning to a greenish colour, which would otherwise do.

These manufacturers, who are not provided with a stove, make use of the top of a beer's oven to spread the flour upon; as after being thoroughly dried here, it is ready for sale.

Starch may be made free potatoes, by soaking them about an hour in water, and taking off their roots and fibres, then rubbing them quite dry by a strong brush; after this they are reduced to a powder, by grating them in water. This pulp to be collected in a tub, and mixed up with a large quantity of clear water: at the same time, another clean tub will be provided, and a sieve, not too fine, must be inserted over it by two wooden rails extended across the tub. The pulp-water are thrown into the sieve, and the flour or starch is carried through with the water; the flour is then thrown out, till it runs through quite clear. The subsolp which remains in the sieve, being wicked in water, makes an excellent food for animals; in the quantity this pulp is near seven-eighths of all the potatoes employ

The liquor which has passed through the sieve is turbid, and of a dark colour, is an extractive matter which is distilled in it. When it is subjected to ret for five or six hours, all the matter depts or settles to the bottom, and the liquor which remains to be poured off as sublees; and a large quantity of fresh water is thrown upon the flour, and stirred up: it is then left for a day, and the water being poured off, the flour will found to have again settled in a white slaty. But to improve it, another quantity of water is poured on, and mixed with it; in which state it is pulled through a fine sieve, to arrest any small quantity of the pulp which may have escaped the first tine. The whole must afterwa be suffered to stand quiet, till the flour is entirely set, and the water above become perfectly clear; but if water has any sensible colour or tans, the flour must be washed again with fresh water, for it is absolutely necessary none of the extractive matter be suffered to remain in it. The flour, when thus obtained pure, and drained from the water, may be taken out of the tub with a wooden shovel, and placed upon wicker-frames covered with paper, to be dried in some situation properly defended from the weather.

When the mass of flour from potatoes is attempted in a large waster kind of mill must be used to reduce
reduce them to a pulp, as the grating of them by hand is too tedious an operation. Anmill invented by M. Damien is very complete for this purpose. In its general structure it resembles a large coffeemill; the grater consists of a cone of iron-plate, about seven inches in diameter, and eight inches in height, the exterior surface of which is made toothed, like a rasp, by piercing holes through the plate from the inside. This cone is fixed upon a vertical axle, with a handle at the top to turn it by; and is mounted on the pivots of the axle, within a hollow cylinder of plate-iron, toothed with parallel like the outside of the cone; the smallest end of the interior cone being uppermost, and the larger or larger end being as large as the interior diameter of the hollow cylinder. A conical hopper is fixed to the hollow cylinder, round the top of it, into which the potatoes are thrown; and falling down into the space between the outside of the cone and the inside of the hollow cylinder, they are ground, and reduced to a pulp, when the interior cone is turned round by its handle; and as the lower part of the cone is fitted close to the interior diameter of the cylinder, the potatoes must be ground to a fine pulp before they can pass through between the two. The machine, when it works, is placed in a tub filled with water; and as fast as the grinding proceeds, the pulp mixes regularly with the water, ready for the process before described.

Mr. Whatley of Cork has also proposed a mill for the same purpose, on a different plan. The grater is a cylinder, with its axis horizontal, and turned by a handle at one end, with a fly-wheel to regulate the motion. A hopper is placed over the cylinder, into which the potatoes are thrown, and are grated by rolling upon the cylinder, as it revolves round. There is also an horizontal box opposite to the cylinder, into which the potatoes are received from the hopper, through a sliding-door; and a moveable end, which is fitted to the box, is prefixed forwards towards the cylinder by a lever and weight, so as to force the potatoes contained in the box against the cylinder, which, being kept in constant motion, grates away the potatoes into a pulp with great rapidity, and it falls into a box beneath.

In the year 1796, lord William Murray obtained a patent for manufacturing flarch from horse-chestnuts. The method was to take the horse-chestnuts out of the outward green prickly husk, and either by hand, with a knife or tool, or else with a mill adapted for the purpose, the brown skin was carefully removed, leaving the chestnuts perfectly white, and without the smallest speck. In this state the nuts were rasped or ground to a pulp with water, and the pulp washed with water through a coarse horse-hair sieve, and twice afterwards through finer sieves, with a coagulant addition of clear cold water, till all the flarch was washed clean from the pulp which remained in the sieve; and the water being settled, deposited the flarch, which was afterwards repeatedly washed, purified, and dried, in the same manner as the potatoe-flarch before described. We are not informed if this manufacture has been carried into effect.

The four, nauseous, milky liquor obtained in the process of flarch-making, appears, upon analysis, to contain acetic acid, ammonia, alcohol, gluten, and phospate of lime. The office of the acid is to dissolve the gluten and phospate of lime, and thus to separate them from the flarch.

Flarch is used along with salt, or flour-blue, to stiffen and clear linen. The powder of it is also used to whiten and preserve the hair.

It is also used by the dyers, to dispose their fluffs to take colours the better.

Flarch is sometimes used instead of sugar-candy for mixing with the colours that are used instrong gum-water, to make them work more freely, and to prevent their cracking. It is also used medicinally for the same intentions with the vioceous insubance which the flour of wheat forms with milk, in fluxes and catarrhs, under various forms of powders, mixtures, &c. A draught of flarch, with three or four spoonfuls of any agreeable simple water, and a little sugar, compose an elegant jelly, of which a spoonful may be taken every hour or two. These gelatinous mixtures are likewise an useful injection in some diarrhoeas, particularly where the lower intestines have their natural mucus abraded by the flux, or are constantly irritated by the action of the matter. Starch is the common vehicle for the exhibition of opium per anum.

By 43 Geo. III. c. 68. sched. (A), upon every hundred weight of flarch imported a duty is imposed; and by 49 Geo. III. c. 58. sched. (A), a further duty upon every hundred weight is imposed.

No person shall be a maker of flarch within the limits of the head-office of excise in London, unless he occupies a tenement of 10l. a year, or upwards, for which he shall be assessed in his own name, and also pay to the poor-rates; nor elsewhere, unless he pay to the church and poor; or if there are no such rates, to the rate on houses and windows, under the same penalty as for making flarch without entry. (19 Geo. III. c. 40. f. 5. 26 Geo. III. c. 51. f. 20.)

By 43 Geo. III. c. 69. sched. (A), every flarch-maker shall take out a licence, for which he shall pay 5l., and renew the same annually within ten days before the end of the year, on pay of 20l. 24 Geo. III. c. 41. f. 2.

Places of making flarch are to be entered, under penalty of 200l. (24 Geo. III. c. 48. f. 2.) All rooms and places, vessels and utensils, shall be marked and numbered, on the penalty of 50l. (19 Geo. III. c. 40. f. 12.) Flour, and other materials, found in any private place, and all private utensils and vessels for making or keeping flarch, unentered, shall be forfeited, or their value. (10 Ann. c. 26. f. 22.)

Every flarch-maker shall cause his name to be painted over his door, or on some conspicuous part of the front of his house, with the addition of flarch-maker, on penalty of 100l. (24 Geo. III. c. 48. f. 2.)

Officers may at all times enter and search, and make return to the commissioners, leaving a true copy of the quantity, if demanded, under his hand, with the maker; and if he leave not such copy, after it has been demanded in writing (12 Geo. I. c. 28.), he shall forfeit 40l. (10 Ann. c. 26. f. 14.) Notice of emptying the vats, and of taking the waters out of the tubs, shall be given, on pain of forfeiting 100l. (19 Geo. III. c. 40.) The maker shall use regular, square, or oblong boxes only, for boxing and draining his green flarch, before it is dried in the flore, on pain of 10l.; and give notice of boxing, and an account of drying, &c. Nor shall he remove any flarch after it is dried, before it be weighed, &c. by the officers, on pain of 200l. (14 Geo. III. c. 14. 19 Geo. III. c. 40.) All flarch, before it be put into any flore or place to dry (except for cruffing), shall be put in papers, tied up with string, pasted over with a piece of paper of a different colour, and stamped by the officer, under penalty of 100l. (26 Geo. III. c. 51.) Foraging or using forged stamps incurs a forfeiture of 500l. (26 Geo. III. c. 51.)

The maker shall have just scales and weights, on pain of 10l.; and if he shall use insufficient scales or weights, he shall forfeit 100l. (10 Geo. III. c. 44.) Removing flarch before due notice is prohibited by 10 Ann. c. 26. f. 19. And if it be removed before it is weighed by the officers, he shall be liable to an additional fine forfeit 200l. (19 Geo. III. c. 45.) And if any dealer in flarch shall receive more than 28 lbs. not duly marked, he shall forfeit 200l. 24 Geo. III. c. 48. 10 Ann. c. 26. f. 16.

Clandestine manufacture, or concealing of flarch, exposes the party concerned, unless he can make it appear that the duty
duty has been paid, to a forfeit of 50l.: and obstructing the officer in entering, seizing, &c. the same, incurs a forfeit of 100l. (4 Geo. II. c. 14. 23 Geo. II. c. 21.) And by 19 Geo. III. c. 40. if the maker shall conceal any tartrach, with intent to defraud his majesty of the duties, he shall forfeit 100l. Weekly entry shall be made, on pain of 50l. and the duties shall be cleared within one week after entry, on pain of double duty. No tartrach shall be imported, except in packages containing at least 224 lbs., on pain of forfeiture, and of 5ol. from the master of the vessel. (42 Geo. III. c. 93.) Tartrach that hath paid the duties may be exported with a drawback of the duties. (10 Ann. c. 26. 27 Geo. III. c. 13.) The officers of excise or customs may seize any flour or hair-powder, with the horn and package, fullpanted on good reason to have been privily made, or imported without payment of duty, or relashed after drawback; and if the party doth not make it appear that the duty hath been paid, they shall all be forfeited, with an additional forfeiture of 5l. for every hundred weight. (42 Geo. III. c. 93.) If any person shall knowingly harbour or conceal any flour unlawfully imported, or relashed after shipping for exportation upon debarment, he shall, whether he claim any property in it or not, forfeit 50l. for every hundred weight, together with the goods and package. (23 Geo. II. c. 21.) No perfumer, &c. shall make use of, or offer to sale, any hair-powder made of or mixed with alabaster, tale, platter of Paris, whiting, lime, &c. (sweet scent only excepted), on pain of forfeiting the same, and 50l. (12 Ann. Mat. 2. c. 9.) And if any maker of hair-powder shall mix any powder of alabaster, &c. (rice first made into tartrach, and sweet scent only excepted), he shall forfeit the same, and 50l. (12 Ann. Mat. 2. c. 9.) Or if any one make or fell any trade with such materials, he shall forfeit the same, and 50l. (4 Geo. II. c. 14.) Or if he shall have in his possession, for making, mixing, or counterfeiting hair-powder, any materials besides flour, or powder of flour, or rice made into tartrach, he shall forfeit the same, and 10l. Places for making hair-powder are to be entered, and officers may enter and feruey them, under a penalty of 20l. 4 Geo. II. c. 14.

Every maker of blue for sale shall make entry of his name, place of abode, place of manufacture and keeping, and materials, in pain of 50l. (4 Geo. II. c. 51.) Officers may enter and survey without obstruction, under penalty of 50l.: nor shall any flour, meal, or other ingredients (other than for colouring the same), be used, except tartrach for which the duties have been paid, on pain of forfeiting the same and 100l.

Nor shall any maker of blue for sale receive into his possession any tartrach in papers not stamped, under pain of forfeiting 10s. a pound, together with the same: and if any maker shall keep above 28 lbs. of tartrach or hair-powder in any unentered place, the same shall be forfeited and mitigated, as by the laws of excise, or in the courts at Westminster; and be distributed, half to the king and half to the prosecutor.

STARCHY Matter of Roots, Plants, and Seeds, in Rural Economy, is a material which forms a principal part of a great number of excellent articles of different kinds, upon which their nutrient properties and qualities probably in a great measure depend when used as the food of man, or employed in the feeding and fattening of several different kinds of domestic animals. See STARCH.
for his: five hundred and one par of firth, twenty-two of saccharine matter, thirty-five of albuminous matter, and sixteen parts of extract, which became insoluble during the evaporation of the saccharine fluid.

From three thousand eight hundred and forty parts of marrow beans, (Vicia faba,) the latter writer is flatted to have obtained one thousand three hundred and twelve of flarch, thirty-one of albumen, and onethousand two hundred and four of other matters which may be conceived to be nutritious; such as gummy, flarchy, fibrous matter, analogous to animal matter.

The fame quantity of kidney-beans (Phaseolus vulgaris) is said to have afforded him, one thousand eight hundred and five parts of matter analogous to flarch, eight hundred and fifty-one of albumen and matter, approaching to animal matter in its nature, and seven hundred and ninety-nine of mucilage.

From the fame number of parts of lentils he is also stated to have obtained one thousand two hundred and sixty-five parts of flarch, and one thousand four hundred and thirty-three of a matter analogous to animal matter, which is described as a glutinous substance insoluble in water; but soluble in alcohol when dry, having the appearance of glue; probably, it is supposed, a peculiar modification of gluten.

Different tuberous, bulbous, and common roots contain a large portion of flarchy matters; but it probably abounds most in the potato. It is said that these roots in general afford from one-fifth to one-seventh of their weight of dry flarch. And that from one hundred parts of the common kidney potato Dr. Pearson obtained from twenty to twenty-three of flarch and mucilage: the same number of parts of the apple potatoe afforded by Humphrey Davy in various trials, from eighteen to twenty parts of pure flarch. From five pounds of several other different varieties, in the trials of another experimenter, from twelve to eighteen ounces and a quarter of flarch have been obtained. It is added, that from the analysis of Einhoff, it appears that seven thousand fix hundred and eighty parts of potatoe afford one thousand one hundred and fifty-three of flarch, five hundred and forty of fibrous matter analogous to flarch, one hundred and seven of albumen, three hundred and twelve of mucilage in the state of a saturated solution: in the whole, two thousand one hundred and twelve parts. So that a fourth part of the weight of the potato at least may, it is said, be considered nutritive matter. Hence its very great utility as an article of food for man, and its great application in the feeding and fattening of animals.

The propriety of encouraging the production of flarch from useless roots, plants, and products, has been some time since suggested by Mr. Pitt in his Account of the Agriculture of Staffordshire, and which is said to equally apply to the preparation of this substance from any other vegetable which may not be a leading article of food, as well as to the production of hair-power, pale, and other articles generally made from wheat.

STARCENBERG, in Geography, a town of the county of Tyrol; 13 miles N.E. of Landeck.

STAREIN, a town of Austria; 4 miles S. of Hardegg.

STARENBERG, a town of Upper Bavaria, on the Wurmei; 14 miles N.E. of Weillam.

STARGARD, or Stargaard, a town of Puffian Pomperia, situated on the Pers; now belonging to Prussia; 20 miles S. of Dantzig. N. lat. 53° 57'. E. long. 16° 20'.

STARGARD, or Old Stargaard, a town of Germany, which gives name to a circle in the duchy of Mecklenburg; 55 miles S.E. of Gultro. N. lat. 53° 32'. E. long. 13° 17'.

STARGARD, or New Stargaard, a town of Germany, in the circle of Upper Saxony, capital of a duchy, and like-wise of the whole Hinder Pomerania. Its vicinity produces corn and excellent vegetables in great plenty. As it lies on the Ina, it has a free communication with the town of Eichstädt, a large and well-built towne, containing two churches, with one in the suburb, and a conventual church, where Lutherans, Germans, and French Calvinists, perform their public worship. Near the town is a noble college, founded in 1621, by burger-maister Peter Groning, and improved with regard to its constitution in 1704. Here are likewise a free-school, with divers good manufactures and a considerable trade; 74 miles N.E. of Berlin. N. lat. 53° 28'. E. long. 15° 20'.
very different it was from the *A. Lyechnis*. In this case the habit, supported by the character of the hairy, not chaffy or fealy, receptacle, surely authorizes a separation. The *lens* is herbaceous, erect, from two to three feet high, somewhat angular, clothed with dense white cottony down, intermixed with brown hairs; leafy in the lower part; forked at the summit, the central branch longest. Leaves opposite, flat-tack, ovate, acute, fleshy and sharply serrated; tapering at the base; green and smooth, though covered when young with deciduous cottony down, on the upper side; always very white, soft, and densely wolly, beneath; somewhat triple-ribbed, with many branching veins. Flower-flats several, at the top of each branch, fimple, hairy and downy, an inch or two long, forming a sort of umbel, with a few lanceolate bracteas at its base. Calyx half an inch long, somewhat cottony. The flowers are yellow, an inch in diameter. Browne says the taste of the herb is aromatic, leaving a sweetness upon the palate, not common in this class. He supposes it must be a fine vulnary. Its cottony texture, no doubt, would contribute to flame the blood of a fresh wound.

**STARKENBACH**, in Geography, a town of Bohemia, in the circle of Koniginrath; 11 miles N.E. of Gotttch. **STARKENBERG**, a town of Prussia, in the province of Natangen; 17 miles E.S.E. of Konigberg.—**Alto,** a town of France, in the department of the Sarre; 1 mile N. of Traarbach.

**STARKS**, a township of America, in the district of Maine and county of Somerfet, on the W. side of Kennebeck river, containing 828 inhabitants; 35 miles N.W. of Augusta.

**STARKSBOROUGH**, a town of the flat of Vermont, in Addison county, containing 726 inhabitants; 12 miles E. of Ferrisburg.

**STARKSTADT**, a town of Bohemia, in the circle of Koniginrath; 8 miles W. of Branau.

**STARKLEACKEN**, a town of Prussia, in the province of Bartenland; 9 miles S. of Bartenlein.

**STARLING**, or **Stare**, in Ornithology. See **STERNUS**. The common starling is about the size of the common black-bird; the weight of the male being about three ounces, and that of the female somewhat less; the bill, in old birds, is yellow; the whole plumage black, very repulent, with changeable blue, purple, and copper; each feather being marked with a pale yellow spot; the inner coverings are edged with yellow, and slightly glossed with green; the quill-feather and tail are dusky; the former edged with yellow on the exterior side, the latter with dirty white; the legs are of a reddish-brown. These birds breed in hollow trees, eaves of houses, towers, cliffs, and high rocks over the sea; they lay four or five eggs of a pale greenish-ash colour; they feed on worms and insects, and, it is said, will get into pigeon-holes, anduck the eggs; in winter they assemble in large flocks: their flight is fo boisterous r as to be scarcely eterable: they are very docile, and may be taught to speak. Pennant.

Mr. Ray mentions a beautiful species, described by Bonnus under the name of the Indian starling, or *farrus indicus*. This is of the size and shape of our common starling, but is variegated with a deep blue, a lead-colour, and a pale grey, and has on its head a very beautiful yellow crest. It learns to imitate the human voice, and talks much better than the parrot, but is troublesome in being over noisy.

**STARLING Colour, a particular colour of a horse. See Colour.**

**STARO, in Commemr**, a corn measure in Italy. At Mantua, a faro of corn weighs 80 lbs.; and 86 such measures are = 25 English bushels nearly, or 80.94 faro = 10 Eng.-quarters, and each faro = 2125 cubic inches. At Ferr_, 93.22 faro = 10 English quarters, and each faro = 5 cubic inches. At Florence, 118.70 faro = 10 Eng.-quarters, and each faro = 1440 cubic inches. See in Dry Measure.

**STARDUB**, in Geography, a town of Russia, in the province of Novgorod; 11 miles N. of Nov. Siererelio. N. lat. 52° 35'. E. long. 33° 44'.

**STARSOLO**, a town of Russia, in the government of Pskov; 20 miles N.W. of Rogatchev.

**AROSIT, in Geography**, a name given in Potosi to the governors of mines and cajenas. They are appointed by the king to supervise their revenues, and to administer justice in his name. The district subject to the jurisdiction of each is called *stare*. However, there are fortresses who have no jurisdiction.

**AROSCH, in Geography**, a town of Moravia, in the circle of Znaym; 15 miles N. of Budweis.

**STAY BAY, a bay of the English Channel, on the coast Devonshire, between Dartmouth and Start Point.**

**SALT POINT, a cape on England, on the S.E. coast of the city of Devon; 9 miles S. of Dartmouth.** N. lat. 50° W. long. 3° 3'.

**SARTING, amon Drinkers, the putting of new beer; ale, to that which is decayed, to revive it again.**

**STING, in the Marge.** A horse is said to be stabling, thriving, or timorous, that takes every object he sees to be surplus to what it is: upon which he flrops, flies out, and is suddenly to be seen, insomuch, that the rider cannot make him com near the place where the object is. It is more common to geldings than foamer-horses. Such horses as have bad ears are most subject to it, as well as those that have been kept a long time in a stable without airing out their ears are easily cured of it. When they have a Hittis horse, never beat him in his confomnatic but make him advance gently, and with soft means, till the scarecrow that alarms him, till he recovers it, and gains assurance.

**STAZITZ, in Geography**, a town of Moravia, in the circle of Znaym; 15 miles N. of Znaym.

**STAZHOVA, bay or gulf of the Frozen ocean, on the coast of Russia; 16° 38'. E. long.: 16° 38'.**

**STAREGUT, a bay on the S.W. coast of Jamaica, of Star gut Point.**

**STARVY Point, cape on the S.W. coast of Jamaica.** N. lat. 17° 58'. W. long. 7° 45'.

**STARTING to cat**, a kind of punishment used by the people of Arag one ages ago; and it is reported by Tavore, that chief ladies in the kingdom of Tonquin are at this day served to death for adultery.

**STAVITZ, in Geography**, a town of Silefia, in the principality of Groth; 3 miles N. of Pafchikau.

**STARZEL, a part of Wurtemberg, which runs into the Neckar; milesove Rotenburg.**

**STASITZ, a town of European Turkey, in Bosnia; 22 miles Sf Banjulika.**

**STASFELITZ, own of Webuahia, in the duchy of Magdeburg; 40 miles S. of Magdeburg.** N. lat. 51° 55'. E. long. 11° 45'.

**STASIDA, a hill island in the Mediterranean; 8 miles N.W. of Scarpun; N. lat. 35° 53'. E. long. 26° 44'.**

**STASIS, in Ant Geography, a town of Alia, in the Pericle; built upon large rock.**

**STASIS, a word used by physicians to express a flagitation of the humours.**

**STASNAS, Geography, a town of Sweden, in Warmland; 12 25 W. of Carlsbad,**
STATE, or Estate, an empire, kingdom, province, or extent of country under the same government. See Estate.

A state or nation, for in this place we consider the terms as synonymous, is a body politic, or a society of men united together to promote their mutual safety and advantage by their union. From the very design that induces a number of men to form a society that has its common interests, and ought to act in concert, it is necessary that there shall be established a public authority, to order and direct what ought to be done by each in relation to the end of the association. This political authority is the sovereignty; and he, or they, who are invested with it, are the sovereign.

It is evident, therefore, from the very act of the civil or political association, that each citizen subjects himself to the authority of the entire body, in every thing that relates to the common welfare. The authority of all over each member mull, therefore, essentially belong to the body politic, or to the state; but the exercise of that authority may be placed in different hands, according as the society shall ordain. If the body of the nation keeps in its own hands the empire, or the right of command, it is a popular government, or "democracy;" if it refers it to a number of citizens, or to a senate, it establishes a "republic," an "oligarchy," or an "aristocracy;" or if it confines the government to a single person, it is a "monarchy;" and this monarch may be limited or absolute. See Society, Sovereign, and Sovereignty.

Every nation that governs itself, whatever may be the forms of that government, without any dependence on a foreign power, in a "sovereign state." Its rights are the same as that of any other state: and if it be sovereign and independent, it must govern itself by its own authority and laws. Indeed, these are synonymous expressions. Those states may be reckoned in this class, which have nevertheless bound themselves to another more powerful by an unequal alliance: and these unequal alliances may be infinitely varied. But whatever they are, provided the inferior ally refers to itself the sovereignty, or the right of governing its own body, it ought to be considered as an independent state, that keeps up correspondence with others, under the authority of the law of nations. Thus, a weak state seeks protection from one that is more powerful, and from gratitude enters into engagements to perform levant offices equivalent to that protection, referring to itself the right of government and sovereignty. Thus also, though a weak state may pay tribute to a foreign power, and by so doing in some degree diminish its dignity, yet still its sovereignty may subsist entire. In some cases, sovereignties have been given in lieu, and sovereignties have voluntarily rendered themselves feudatories to others; yet if the homage leaves indepedency and sovereignty authority in the administration of the state, and only means certain duties to the lord of the fief, or even a mere honor aritnowledgment, it does not prevent the state, of the feudatory prince, from being strictly sovereign. Two sovereign states may also be subject to the same prince, without any dependence on each other, and each may retain all its national rights, free and independent. In short, several sovereign and independent states may unite themselves together by a perpetual confederacy, without each in particular ceasing to be a perfect state. They will form together a federal republic; the deliberations in common will offer no violence to the sovereignty of each member, though they may, in certain respects, put some constraint on the exercise of it, in virtue of voluntary engagements. But a people that has pilled under the dominion of another, can no longer form a state, and in a direct manner make use of the law of nations. Such were the people and kingdoms which the Romans rendered subject to their empire; most, even of those whom they honoured with the name of friends and allies, no longer formed states. Within themselves they were governed by their own laws and magistrates; but without, they were obliged in every thing to follow the orders of Rome; they dared not of themselves make either war or an alliance, and could not treat with nations.

The preservation of a nation confits in the direction of the political associations of which it is formed; and the perfection of a nation is found in what renders it capable of obtaining the end of civil society, and a nation is in a perfect state, when nothing necessary is wanting to arrive at that end. The end of civil society is procuring for the citizens whatever their necessities require, the conveniences and accommodations of life, and, in general, whatever constitutes happiness; with the peaceful possession of property, a method of obtaining justice with security, and, in short, a mutual defence against all violence from without. In order to form a just idea of the perfection of a state or nation, every thing must conform to promote these ends.

The fundamental regulation that determines the manner in which the public authority is to be executed for the attainment of these ends, is what forms the "constitution of the state." The constitution is, in fact, nothing more than the establishment of the order in which a nation proposes to labour in common for obtaining those advantages with a view to which the political society was established. The laws are regulations established by public authority, to be observed in society. All these, in order to relate to the welfare of the state and of the citizens. The laws made directly with a view to the public welfare are the "political laws;" and in this class, those that concern the body itself, and the being of society, the form of government, the manner in which the public authority is to be executed; and those, in a word, which together form the constitution of the state, are the "fundamental laws." The "civil laws" are those that regulate the conduct and behaviour of the citizens among themselves. The constitution and its laws are the basis of the public tranquillity, the firm support of the public authority, and pledge of the liberty of the citizens. But this constitution is a vain phantom, and the laws are idle, if they are not sufficiently observed. The nation ought then to watch very attentively, in order to render them equally respected by those who govern, and by the people destined to obey. To attack the constitution of the state, and to violate its laws, is a capital crime against society; and if those guilty of it are invested with authority, they add to this crime a pernicious abuse of the power with which they are entrusted. From the principles here stated, we may infer, that a nation has a right to form, maintain, and perfect its constitution, and to regulate at pleasure every thing relating to the government, while no person has a right to hinder it. Government is established only for the sake of the nation, with a view to its safety and happiness. If any nation is dissatisfied with the public administration, it may reduce it to order, and reform the government. The nation may do this, but not any discontented and querulous malcontents. The body of a nation has a right to call to account those at the helm, who abuse their power; but if the nation be silent, it is not the business of a small number of citizens to put the state in danger under the pretence of reforming it. If the nation be uneasy under its constitution, it has a right to change it.

If it be asked, what ought to be done if the people are divided?
According to the common method of states, the opinion of the majority must pass, without dispute, for that of the whole nation; otherwise it would be impossible for the society ever to take any resolution. It appears then, for the same reason, that a nation may change the constitution of the state by a majority of votes, and whenever there is nothing in this change that can be considered as contrary to the act of the civil association, or to the intention of those united under it, all are bound to conform to the resolution of the majority. But if the question be to quit a form of government, to which alone it appeared that the people were willing to submit, on their entering into the bonds of society; if the greatest part of a free people, after the example of the Jews in the time of Samuel, are weary of liberty, and resolved to submit to the authority of an absolute prince, the citizens more jealous of that privilege, so invaluable to those who have tilled it, though obliged to infer the majority to do as they please, are under no obligation at all to submit to the new government: they may leave a society, that seems to have dissolved itself, in order to be united under another form; and have a right to retire elsewhere, to fill their lands, and take with them all their effects.

After all it may be observed, that great changes in a state, being delicate and very dangerous affairs, and that frequent changes being in their own nature prejudicial, a people ought to be very circumspect in doing it, and never be inclined to make innovations without the most serious reasons, or an absolute necessity. The spirit of inconstancy which prevailed among the Athenians, was always contrary to the happiness of that republic, and was at length fatal to that liberty of which they were so jealous, without knowing how to enjoy it. Vattel's Law of Nations, b. i. State, Civil. See Civil.

State, Free. See Free.

State is also used for the policy or form of government of a nation. Hence, ministers of state, reasons of state, &c. See Government.

State, Council of, in Modern History, was projected by the states of Holland, Zeeland, and Utrecht, in conjunction with William I. prince of Orange, and erected, in 1584, with ample authority. All affairs of state, the army, and revenue, were entrusted to the care of this council; but the states, growing jealous of this extraordinary power, reduced it gradually, and by a new instruction, in 1651, the disposition of military affairs, and the command of the army, were in part transferred to the states-general, with the advice of the council. In this council, the provinces were represented by such a number of deputies as bore some proportion to the quota of money which each contributed for the support of the whole, Groningen excepted. Guelderland had one, Holland three, Zeeland two, Utrecht one, Friesland two, Overyssel one, and Groningen two. These were all changed every three years, except the deputy from the nobility of Holland, and the two from Zeeland, who enjoyed their posts for life. Here every member had a decisive voice, and presided for a week in his turn, without regard to the rank of the provinces. The governors or stadtholders of the provinces had a seat, but no decisive vote in this council, in which affairs were determined by a majority of voices. See Stadtholder.

State of a Dipylos, the same with acro. See acro.

STATED WIND. See Wind.

STATELY, in the Manage. A horse is said to be fleetly, that goes with a proud, frutting gait.

STATEN ISLAND, in Geography, an island belonging to the United States of America, and forming the county of Richmond, in the state of New York. It is situated below the bay of New York, and is the southern extremity of the state. It is of ancient date, having been represented by two members in the colonial legislature in 1661. The centre of Staten Island is about 12 miles S.W. of New York; it is about 14 miles long, and its greatest breadth is about 12 miles; the area is about 77 square miles, or 49,280 acres. It is bounded on the N. and W. by Newark bay and Bruntwick river; E. and S. by Hudson river and the Atlantic ocean. Its southern extremity is in N. lat. 40° 29', and the western extremity 16°: W. long, from New York.

The towns are, Castletown, containing 1350 inhabitants; Northfield, including 1595; Southfield 1007, and Westfield 1444 inhabitants; the whole population being 5347, and the number of electors 599. The county of Richmond is hilly and broken, including some extensive tracts of good arable land. Its infarur situation, and the benefic it affords to mariners, have given it celebrity, and several privileges to its inhabitants. The surrounding waters abound with a variety of fish. The quarantine ground for ships entering the port of New York lies in this county. It sends one member to the house of assembly.

STATER, an island at the extremity of South America, separated from Terra del Fuego by the strait of Le Maire. In the appearance of Staten Land, when Cook visited it in January 1769, he did not discover the wilderfe and horror ascribed to it in the account of lord Anfon's voyage. On the N. side, Hawkeworth fays, in his detail of this voyage (vol. ii. p. 64.), are the appearances of bays or harbours; and the land was deftitute neither of wood nor verdure, nor was it covered with snow. The island seemed to be about 12 leagues in length, and 5 broad. On occasion of another voyage he visited it in January 1775, and gives the following account of it. (Second Voyage, vol. ii. p. 200.) Staten Land lies nearly E. by N. and W. by S., and is ten leagues long in that direction and no where above three or four leagues broad. The coast is rocky, much indented, and seemed to form several bays or inlets. It fiews a surface of craggy hills which fpare up to a vail height, especially near the west end. Except the craggy summits of the hills, the greatest part was covered with trees and shrubs, or some fome of herbage, and there was little or no snow on it. The currents between Cape Defeada and Cape Horn fent from W. to E., that is, in the fame direction as the coast; but they are by no means confiderable. To the E. of the cape their direfection is towards Staten Land. They are rapid in Strait Le Maire, and along the S. coast of Staten Land, and fent like a torrent round Cape St. John, where they take a N.W. direktion, and continue to run very frong both within and without New Year's Ifles. S. lat. 54° 40'. W. long. 65°.

STATER, an ancient silver coin, weighing four Attic drachms, and worth about three shillings or three fhillings and a penny sterling. See Drachm.

There was also a gold coin under this name: that of Cyzicus was much valued, having on one fide the figure of a woman's head, and on the other that of the head of a lion; in weight it was equal to two drachms, and in value to twenty-eight silver drachms of Athens. The gold fater of Athens was equal in value to twenty drachms, and a drachm of gold was equal to about ten of fiver.

The χρυσος, gold piece, gold fater, or "Philipus," as it was called in compliment to Philip of Macedon, was a dirachm; and there is reafon to believe, that it paffed for twenty silver drachms on its firft aparence; but in later times for twenty-five Greek drachmas, or Roman denarii. That the gold coins of Philip, called "Philippi," were dirachms,
drachms, we know from ancient authors, and from the great number of them that still remain; and that the χρυσῶν or chief gold coin of Greece, which of the same weight, is also evident from ancient authors. Being of twenty silver drachms, it was annually worth 1 s. 2 d. but valuing gold now at a medial price of 4 l. per ounce, it is intrinsically worth 1 l. at present. But we have larger gold coins than the χρυσῆ or didrachm. The δρακάριον of Alexander and of Lycurgus weighs its double, or about two hundred and sixty-six grains, and passed for forty silver drachms, or l. 10s.; now worth 3 l. Of Lycurgus, Antiochus III., and of some of the Egyptian monarchs, we have even the τιμίακαριον or quadruple χρυσῆ, weighing about five hundred and thirty grains, and current for eighty drachmas of silver, 3 l., now worth 4 l. flersling. We have also smaller coins, such as the διδρακάριον, or half the χρυσῆ, of Hero I. of Syracuse, and of Pyrrhus, which weighed three drachms, and passed for ten silver drachms, or 7 l. 6d.; now worth 10 l.;—also, the τριεκτάριον, or quarter of the Philippus, of Philip, Alexander, and Lycurgus, weighing thirty-three grains, and passing for five drachmas of silver, 3 l. 6d., now worth intrinsically 5 s.; and also gold coins of Greece still smaller, and which could not have passed for more than two drachmas of silver.

STATEA ROMA, or fleecyland, a name given to the Roman balance.

STATES, a term applied to the several orders, or classes, of a people, assembled to consult of matters of the public good, See Estate.

States-general, the name of an assembly, consisting, under the former government, of the deputies of the Seven United Provinces.

In this assembly, the deputies of each province, of what number soever they were, had only one voice, and were elected as but one person, the votes being given by provinces. Each province prefixed at the assembly in its turn, according to the order settled among them; Guelderland prefixed first, then Holland, &c.

This assembly was the representative of the sovereignty of the Union, which redressed properly in the general assembly of the states themselves of all the several provinces; but as that assembly ordinarily consisted of seven or eight hundred persons, it was resolved, after the departure of the earl of Leicester, in order to avoid expense, and the confusion of no numerous a body, that the provincial estates should, for the future, be ordinarily represented by their deputies, under the name of the States-general; who were always to reside at the Hague, and who alone were called states-general.

States-general of France, assemblies which were first called A.D. 1302, and were held occasionally from that period to the year 1614, when they were discontinued, till they were summoned again at an interesting period, viz. in the year 1789. (See France.) These states-general, however, were very different from the ancient assemblies of the French nation under the kings of the first and second race. There is no point with respect to which the French antiquaries are more generally agreed, than in maintaining that the states-general had no suffrage in the passing of laws, and posseffed no proper jurisdiction. The whole tenor of the French history confirms this opinion. The form of proceeding in the states-general was this: the king addresed himself to the whole body assembled in one place, and laid before them affairs on account of which he had summoned them. The deputies of each of the three orders, of nobles, of clergy, and of the third estate, met separately, and prepared their "pétitions," or memorial, containing their answer to the propositions which had been made to them, together with the representations which they thought proper to lay before the king. These answers and representations were construed by the king in his council, and generally gave rise to an ordinance. These ordinances were not addressed to the three estates in common. Sometimes the king addresed an ordinance to each of the estates in particular. Sometimes he mentioned the assembly of the three estates. Sometimes mention is made only of the assembly of that estate to which the ordinance is addressed. Sometimes no mention at all is made of the assembly of estates which suggested the propriety of enacting the law. Thus the states-general had only the privilege of advising and remonstrating; the legislative authority resided in the king alone.

Sta*s of Holland, an assembly consisting of the deputies of the council, or colleges of each city; in which the deputies, or members of that assembly first known, 441 but the sovereign, or the higher estates, had seats, in the sense, or the rights, which they had in the assembly of the states-general.

Originally, none but the nobility, and the six principal cities, had seats, or voices, in the states. Afterwards they were the deputies of eighteen cities. The nobility had the first voices, which were pronounced by the grand penonary, as penonary of their order. The other provinces of the Union had likewise their states, representing their sovereignty, deputies from which made what they called the States-general.

STATESBURG, in Geography, a port-town of South Carolina, and the capital of Clermont county, on the E. side of Breech creek, which unites with Sharks creek, and discharges itself into the Waterree, a few miles below the town. It contains 10 or 12 houses, four court-houses and a jail; 20 miles S. by E. from Camden.

STATEs-lAND, a township of Hancock county, in the district of Maine, containing 71 inhabitants.

STATESVILLE, a port-town of Iredell county, in North Carolina; 441 miles from Washington.

STATHEL, in Agriculture, a term sometimes employed to signify any fork of a road for either corn, hay, straw, or any other kind of farm produce. See Staddle and Stand.

STATHENI, in Ancient Geography, a people of India, in the number of those who were subjugated by Alexander.

STATHUSIS, formed of cotis, a word used by the old writers to express the torrefaction, or roasting of the medicines before a flow fire, as is done frequently at present with rhubarb, &c.

STATHOLDER. See Stadtholder.

STASYCAL Baroscope. See Baroscope and Barometer.

Statical is sometimes applied in a peculiar sense to the experiments made as to the quantity of perpiration, and other excretions of the human body.

We have a very particular account of some experiments of this kind in the Philosophical Transactions, No. 472, or Abr. vol. ix. p. 475, made by Dr. John Lining of Charles Town, in South Carolina.

STASTICAL Hydroscope. See Hyscroscope.

STASLY, in Botany, a name adopted from the Greeks, whole stem is reported to have been so called from ὁσσός, to stop, or arrest, because of its allirgent quality. What the ancient plant may have been, can scarcely be guessed with any probability. The modern application of the name to our Thrift, or Sea-Gillflower, seems to have originated with Dalechamp, whom Tournefort followed. Hence it has become appropriated to a fine and extensive genus, whole hairy and entangled stems, to well formed to impede the progress of a foot passenger, may literally almost justify its present use.—Linn. Gen. 153. Schreb. 205. Wild. Sp. Pl. v. 1. 1522. Mart. Mill. Dict. v. 4. Sm. Fl. C. Brit.
S. Limonium. Common Sea-Lavender Thrift. Linn. Sp. Pl. 394. Willd. n. 6. Fl. Brit. n. 2. Engl. Bot. t. 102. Fl. Dan. t. 315. (Limonium, et L. parvum; Ger. Em. 411.)—Stalk panicked, round. Leaves obvate-lanceolate, smooth, without ribs, tipped with a deciduous awn.—Common about muddy sea-shores throughout Europe, from Sweden to Greece, flowering in July and August. (See LIMONIUM.) This species varies greatly in size and luxuriance, or perhaps some of its reputed varieties ought to be considered as distinct. Usually its leaves are three or five inches long and one broad, tapering downward, leathery, somewhat waved, very smooth, rather glaucous. Stalk near a span high, hard and rigid, panicked, bracteated, its branches ending in close imbricated scales of handsome blue flowers, whole calyx is pale pink in a recent flate, white when dry, delitute of awns; its tube closely enveloped in a flower, feathery, membranous-edged involucrem, of a tangle leaf.

S. caroliniana. Carolina Sea-Lavender Thrift. Walt. Carol. 118. Pursh n. 2.—"Stalk round. Panicle much branched, divaricated. Calyx acute. Leaves lanceolate-oblong, blunitif, smooth, flat-edged."—In salt-marshes along the sea-coast, from New Jersey to Carolina, flowering in August and September. Flowers blue. Pursh. We are not certain of having seen this species, which Limnuez appears to have confounded with the last. Mr. Walter observed the separation of the capule into five valves at the base; a character of Julieu's Plumbagines. See that article.

S. bellidifolia. Daily-leaved Thrift. Sm. Prodr. Fl. Græc. Sibth. n. 733; Fl. Græc. t. 295, unpublished.—Stalk panicked, round. Leaves obvato-apatulate, abrupt, smooth. Calyx blunitif, without awes.—Gathered by Dr. Sibthorp, on the shores of Rhodes, and several islands in the Archipelago. The root is woody, crowned with large tufts of spreading, green, abrupt or emarginate leaves, an inch or inch and half long, convex at the edges, very smooth. Stalk a foot high, panicked copiously near from to bottom, rather zigzag. Flowers purple, loosely spiked. Calyx with a hairy tube, and white limb, with five brown ribs. Petals emarginate.

S. globularifolia. Globularia-leaved Thrift. Desfont. Atlant. v. 1. 274, by the description. Sm. Prodr. Fl. Græc. Sibth. n. 734. Fl. Græc. t. 296, unpublished. (Limonium medium, globularia folio; Barrel. l.c. t. 793, 794.)—Stalk panicked, round; with level topped branches. Leaves obvato-apatulate, pointed, smooth. Calyx acute.—Native of Barbary and Sicily, by the sea-side. The leaves are more glaucescent than in the last, somewhat bordered, acute, and tipped with a sharp point. Branches of the panicle shorter, more dense and level-topped. Flowers rather smaller, and of a lighter purple. Calyx hairy, and similarly coloured, but the segments of its limb much narrower, more taper and acute. The common flower-stalk does not begin to branch so near the base, nor is it so finely haired.

torn upwards. Calyx bluish. Leaves spatulate, obtuse, pointlets, smooth, glaucous.—Native of the coast of Barbary. Flowered in August 1811, in the garden of Mr. W. Pringle at Sydenham. Mr. Aiton marks it as introduced in 1804. This differs from the Iiat in having blunt leaves, without points, in which respect it also differs from the coast of England, which Ilat is perhaps Barrerier's t. 759, and very nearly accords with our present plant, in its crowded spikes of flowers twice the size of the lat, and a much Iefs branched fruit. We have not been able to ascertain how far this and Vahl's curvata folia, Willd. n. 12, are distinct. Specimens from Narbonne, supposed to be the latter, agree in every thing with the figure of stricta folia, except in having a point to the leaf.

S. latifolia. Broad-leaved Thrift. Sm. Tr. of Linn. Soc. v. i. 250. Willd. n. 9. Ait. n. 7. (Limonium folio Emuile, flabelnis thalisminis rosamollis, floribus parvis caralis; Gerber's MSS.)—Stalk panicked, very much branched. Leaves downy, with minutely Iurry hairs. Calyx somewhat pointed, without awns.—Native of Ruffian Tartary, on the banks of the Don, near Afohp. It flowered in Shon gardens, under the care of Mr. Hoy, in 1788, as mentioned in the Linnaean Transactions, so that the date of 1791 in Hort. Kew. is an error, though the name of Mr. Bell, as the introducer of the plant, is probably right. This species is distinguished by the great size of its oblong leaves, a foot or more in length, besprinkled with Iurry tufts of soft hairs, and the vast profusion of its small blue flowers, which compose a spreading, rather level-topped, panicle, often two feet wide. It is a hardy perennial, flowering from May to July. Willdenow gives as a synonym S. tauriensis, Pallas Ind. Fl. Tur. and remarks that the lower branches are barren, as in S. reticulata and others. This is not very evident in our specimens, though it may possibly be so.

S. oleifolia. Olive-leaved Thrift. Sm. Prodr. Fl. Grec. n. 735, excluding probably the synonym of Willdenow. (Parvum Limonium marbanense oleifolium; Lob. Ic. 295. Limonium parvum; Ger. Em. 411.)—Stalk panicked, round; its lower branches barren. Leaves oblong-spatulate, obtuse, smooth, with scarcely any point.—Native of the sea-coasts of the south of France, Italy, and Greece. The roots are woody and tufted. Leaves an inch or inch and half long, not above a quarter of an inch broad in any part; tapering at the base; minutely dotted on both sides; a little hoary, or reflexed, but not awned, at the extremity. Stems a foot high, more or less, roughish; their branches copious, zigzag and somewhat divaricated, about half of them all naked and barren; the upper branches level-topped, rather lax, spikes of slender flowers, all turned one way. Tube of the calyx slender, hairy; the segments of its limb ovate, acute, awnless.

S. dictamnus. Many-fooked Thrift. Cavan. Ic. v. i. 37. t. 50. Sm. Prodr. Fl. Grec. n. 736. (Limonium minus oleo folio, Παπαδάκης; Barcel. Ic. t. 790.)—Stalk erect, panicked; its branches rough with points; the lower ones barren, in many capillary segments. Leaves obovate, smooth.—Native of Spain, about two miles from Madrid, according to Cavallines. Dr. Sibthorpe found it in Greece. The leaves are four times as large as the Iat, and perfectly obtuse. Stem eighteen inches high; its lower branches repeatedly and minutely forked, almost like S. reticulata, but not prostrate. Inflorescence like the Iat. Calyx with a hairy tube. Flowers pale blue. Willdenow quotes Barrerier's t. 790 for his oleifolia; a species whose branches are described as angular and winged, and which, therefore, does not answer to Scopoli's oleifolia, Del. Ins. v. r. t. 10, nor are we able to determine what Willdenow intended.

S. reticulata. Mattet Thrift or Sea-Lavender. Linn. Sp. Pl. 354. Willd. n. 16. Fl. Brit. n. 3. Engl. Bot. t. 328. Hill Fl. Brit. t. 25. f. 2.—Stalk prostrate, panicked, zigzag; its branches rough with points; the lower ones barren. Leaves wedge-shaped, rather acute, without points.—Native of salt-marshes on the north coast of Norfolk, flowering copiously in July and August. It is also found in the south of Europe. This is smaller than the last, and differs in having the flowers quite prostrate, their branches much flouter, matted and entangled together. Flowers light purple, few in each spike. Calyx hairy below. Willdenow makes the preceding a variety of this, nor can we be positive of the contrary.

S. palmaris. Humble Frosted Thrift. Sm. Prodr. Fl. Grec. n. 737. Fl. Gr. t. 297, unpublished.—Rough with hoary dots. Stalk panicked, round, erect, and rather close. Leaves spatulate, obtuse.—Gathered by Dr. Sibthorpi on the sea-coast of Asia Minor. The root is woody, crowned with many tufts of numerous spreading leaves about an inch long, frosted as it were, and rough with tubercles, like the whole herbage. Stems many, three or four inches high, composed of four or five alternate, erect, simple, lax spikes of handsome pink flowers, without any barren forked branches. The calyx is smooth, brown, with short ovate segments.

S. echinoides. Buglofs-leaved Thrift. Linn. Sp. Pl. 394, excluding Magnol's synonym. Willd. n. 172. Ait. n. 13. Fl. Gr. t. 298, unpublished.—Rough with hoary dots. Stalk panicked, round, jointed, very much branched, zigzag, divaricated. Leaves spatulate.—Native of the flours of Cyprus and Crete. The root is strong and woody, crowned with many fow-leaves of frosted leaves, much like the last. The flowers, however, are very different, a foot or more in height, hoary, repeatedly branched, flout, and strongly divaricated, almost at right angles. Spikes very zigzag and lax. Flowers light purple. Calyx with a hairy tube, and white obtuse limb, whose segments are very hollow. Linnaeus confounded this with the following, which he appears to have known from Magnol's work only.

S. arizolus. Awned Annual Thrift. Sm. Prodr. Fl. Grec. n. 739. Fl. Gr. t. 299, unpublished. (Linnum minus annuum, bullata folis, vel echinoides; Magn. Monsp. 157. t. 156. Tourn. Inst. 342.)—Stalk panicked, round, dotted; its branches loosely spiked. Leaves obovate, rough. Calyx of the fruit awned.—Native of the sea-flours of the south of France, and island of Cyprus. The root is fimple, small, and annual. Leaves fowler, radical, an inch, or two long, green, rough with tubercles. Stalks fowler, from fix to twelve inches high, erect, branch- ing from near the bottom into numerous long, fender, spreading, lax spikes of small pink flowers. Calyx with a fow smooth tube; its membranous limb so delicate, that it fow leaves the strong brown ribs, in the form of naked awns.

S. lapidosa. Plantain-leaved Thrift. Linn. Sp. Pl. 395.—Willd. n. 18. Ait. n. 14. Curt. Mag. t 656. (Sm. n. 15. Gmel. Sib. v. 2. 221. t. 91. f. 1.)—Stalk panicked; its branches angular and somewhat winged. Flowers crowded. Branches dilated, pointed, longer than the bluntness. Calyx. Leaves obovate or lanceolate, pointed.—Frequent throughout Siberia, in open, dry, billy places. Gmelin. Sometimes seen in our gardens, but seldom long preserved. The root is marked by biennial. The leaves are rough fow to the touch, usually about two inches long and one broad. Stalk from six to eighteen inches high, erect;
fimple, naked, and almost round, in the lower part; but
terminating in a large, angular-branched, dense panicule, of
handsome pink flowers. General and partial bracteas ovate
with a sharp point, the latter moss dilated and membranous
at the edges. Tube of the calyx hairy, concealed, like the
flattish involucrum by the bracteas; its limb white, mem-
branous, obtuse, crenate, not lobed, nor awned.
S. conficcus, Curt. Mag. t. 1629, appears to us, with-
out any doubt, a variety of this with narrow leaves; there
being in reality no material difference in the bracteas.
S. arboreus. Tree Thrift. — Stem arboreous, leafy.
Leaves obovate, thickly. Flower-flalks panicked; their
branches angular and winged. Flowers crowded. Bracteas
ovate, flothating, much shorter than the involucrem.—Gath-
ered on the maritime rocks at Barra and Rambula in
the life of Teneriffe, by Mr. Matthew, whose specimen, given
to the younger Linnaeus, is marked "Staftic arboreus of Sol-
lander," but we find nothing published under this name.
The Spaniards call the plant Stampsprewel del mar.
The stem is faid to be arboreceil, six feet high. The branches
are round, woody, one-third of an inch in diameter, scoured
with the crowded bafes of old footflalks, refembling thin
anlalar flpitkus. Leaves fix or eight at the end of each
branch, spreading every way, two or three inches long, and
about half as broad, obtufe, smooth; way at the edges;
tapering at the base into a rigid angular footflalk, dilated
and clipping the stem at the bottom. Flower-flalks terminal,
folitary, a foot or more in length, complifed and winged,
bearing a very large compound corymbs panicule, of in-
umerable crowded flowers, whose partial flalks are dilated
into a wedge-shaped, leafy, two-lobed form. Bracteas short,
ovate, membranous, the partial ones in pairs, fheathing
the base of the involucrem, which is thrice their length, involute,
coriceous and ribbed, refembling that of S. Liniunum
and its allies. Tube of the calyx smooth, concealed in the
involucrem; limb of a delicate light permanent blue, in the
dried fpecimen, spreading, with five red ribs, and as many
shallow lobes. We can discover nothing of the colour of
the corolla. This noble plant would be a great acquisition
to our greenhouses.
Wild. n. 26. Fl. Grec. t. 300, unpublished. (Echinus, id eft
Tragacantha altera; Alpin. Exot. 57.
t. 56. Liniunum carpitiofum, folic aculeatfis; Buxb.
Cent. 2. 18. t. 10.) — Branches clothed with awl-shaped,
spiny leaves. Flowers somewhat fpikes. — Found by Buxbaun in
the deferts of Media, flowering in July. Dr. Sibthorpe gathered it on the Spaciote mountains of Crete,
as well as on the Bithynian Olympus. The long and woody
black root is crownet with dense tufted leafy flalks and
branches, two or three inches high. "Leaves about an inch
long, spreading every way, rigid, linear, channelled, smooth,
entire, with a fpiuous point. Flowers of a bright pink,
very beautiful, three or four together, in terminal, foliarly,
nearly fofife, spikes. Involution of two fpheating pointed
leaves. Calyx white, with five brown ribs, a smooth tube,
and a pentagonal, scarcely lobed, border. Such indeed is
the alpine plant, found by Alpinus and Sibthorpe. The
flower-flalk in the figure of Buxbaun is elongated, naked,
and somewhat branched, 1 2 an inch long; but the Liniune
specimens, intermediate between the two, prove this to be
a mere variety, owing to flitution. It is pity this elegant
species is unknown in gardens.
Wild. n. 22. Thumb. Prodr. 54. (S. peregrina; Berg.
Cap. 82.) — Stem shrubby, leafy. Leaves ovate-whel-
ded, three-ribbed, flalked, pointed, smooth. Panicle
level-topped; its branches roughhith, somewhat angular,
without wings. — Native of the Cape of Good Hope.
The habit of this plant approaches that of our leaf species
but S. arboreus, but its flalk is left. The stem is shrubby,
with round, smooth, woody branches, leaty towards their
extremities. Leaves fheathed, rounded, obtufe or emar-
ginate, with a small point; smooth on both fides, with three
long equal ribs; tapering down gradually into a rigid footflalk,
whose dilated, membranous, fheathing base furrounds the stem.
Each leaf is about two inches long; the footflalks about half as much. Panicule corymbose and
level-topped; its branches quite defiitute of wings, rough
with minute points; the ultimate ones zigzag and molt an-
gular. Bracteas roundifh-ovate, acute, with a membranous
edge. Flowers not very numerous. Calyx with a hairy
tube, and broad, membranous, purple border, which is
very slightiy angular rather than lobed. Corolla purple.
Bergius's description hardly answers to the Linnean plant,
except perhaps what he fays concerning a variety. S.
chothiodes has no resemblance to purpurea.
S. aroja. Rofe-coloured African Thrift.— Stem shrubby,
leafy. Leaves obovate-oblong, single-ribbed, flalked,
pointed, rough on both fides. Branches of the panicle
rough, somewhat angular, without wings. Flowers
crowded.—We are obliged to fir Samuel Young, bart. of
Formoas, Berks, for fpecimens of this beautiful fpecies,
gathered at St. Helen's bay, on the coaft of Africa. Its
fize, shrubby habit, and leafy branches, agree with the left;
but the roundifhes of the whole plant, and particularly both
fides of the leaves, with minute tubular points, the want of
lateral ribs in the foliage, and the far more abundant,
crowded flowers, whose permanent calyx is rofe-coloured,
rather than purple, induce us to consider it as diftinct.
The tubular flalks involucrem, with two short fheathing
membranous-edged bracteas at its basis, is the fame in both
thefe fpecies.
Wild. n. 27. Ait. n. 20. (Liniunm lignolatum, &c.; Bocc. Sic. t. 16, 17.) — Stem shrubby, leafy. Leaves
lanceolate, fleshy, fcaly, with fheathing flalks. Flowers
diyantly fpikes. Corolla monopetalous; its tube longer
than the calyx. — Native of unculivated ground in Sicily,
as well as the fouth of France. It is not an unfrequen
green-house shrub, flowering in July and August.
Boccase fays the red woody root is fometimes thicker than a man's leg.
The stems are buoyfhy, but diffuse, unlefs artificially sup-
ported. Leaves numerous, obtufe, an inch or two long,
various in breadth, thick, fiblefes, glauccous and minutely
feci all over, tapering down into a footflalk, whose fcape is
cylindrical and fheathing. Flowers large, pink, in foliarly
or aggregate lax fpikes. Involution very hard and tight,
nealy concealing the calyx and its small border. Claws of
the petals combined.
Wild. n. 54. Ait. n. 22. Curt. Mag. t. 71. Fl.
Grec. t. 301, unpublished. (Liniunm folio simulato;
Ger. Em. 412.) — Stems herbaceous, winged. Radical
leaves finated; those of the flalk awl-shaped, decurrent,
three in a whorl. Calyx undivided, without awns.—Native
of Sicily, Barbary, and Palestine. Dr. Sibthorpe found it
very frequent on the inundated shores of the Greek iflands,
and fuppefted it might be the real /. 201/10; of Diffcorides.
The modern Greeks call it p6cox. In gardens it has been
known ever fince the days of Parthenis. The stem, which
endures long, even in a green-house. The numerous radical
leaves are pinnatifid, with numerous rounded lobes, green,
obtufe, and hairy, three or four inches long. Stems de-
cumbent,
Leaves are delicately cut-leaved, hardy, and form nice edgings. The involucre is of much finer texture, with rigid, recurved, spinous points, but above all the yellowish, not purple, limb of the calyx has five acute lobes, the strong ribs of which, soon denuded, as in our S. ariflata, become recurved brilily awns.

S. loba. Lobed Spinosus Thrift. Linn. Suppl. 187. Willd. n. 35.—Stems herbaceous, without wings. Leaves radical; undivided, with awns.—Native of Barbary. This species is hardly known, except in the Linnaean herbarium. The specimens came from Morocco. The root is simple, long and taper, apparently annual. Leaves all radical, an inch and half long, hairy, much like thofe of S. finuata. Stalks round, three or four inches long, decumbent, panicled, with an awl-shaped leaf or two at their divisions. Bracteas wedge-shaped and decurrent, as in the leaf, but much smaller, and rough at the edge with hooked prickles. Leaves of the involucre rough, with long, spinous, spreading points. Limb of the calyx white or yellowish, like the leaf; but entire and without awns, like S. finuata.

S. stellata. Capped Thrift. Linn. Suppl. 187. Willd. n. 37. Ait. n. 23. L‘Her. Stirp. Nov. 25. t. 13.—Stem branched, winged with a triple crifped border. Leaves radical, ovate, pointed. Flowers spotted, crowded, all turned one way.—Native of the coast of Barbary, flowering in July. Sometimes kept in greenhouses. The partly decumbent stems are much branched, and remarkable for their crifped, not very broad, wings. Leaves on longish footstalks, ovate, but tapering at the base, slightly wavy at the margin, rather glaucous or scaly. Flowers blue-purple, crowded, in aggregate level-topped spikes. Bracteas, as well as involucre, reddish, obtuse, pointles, concave, not keeled; their margins broad and membranous. Limb of the calyx scarcely pentagonal, neither lobed nor awned. A very distinct species, unlike any of the rest.

In the first fort there are several varieties: as with red flowers, with scarlet flowers, with white flowers; great thift with red flowers, with white flowers; and small Sea-pink, with fcfh-coloured flowers.

The second species has also several varieties: as common great Sea-lavender, great late-flowering Sea-lavender, olive-leaved Sea-lavender, deep blue-flowered Sea-lavender, and white-flowered Sea-lavender.

In the twelfth or laft fort there are two varieties, which differ in their leaves, flems, and flowers.

Method of Culture.—All the farts of these plants are capable of being increafed by parting or fipping the roots. This, with the firft kind, fhould be performed in the autumn, or very early spring feafon, planting them immediately as edgings, or in the borders: they fhould not, however, be parted too small. And when planted out as edgings, a quantity of slips should be obtained in these feafons from old plants, by flipping or dividing the off-fets of their roots, each fip being furnished with roots and tops; then, having made up the edge of the bed or border even and firm, planting them either with a dibble in one range, two or three inches diftance in the row; or to form at once a close edging, to near as to touch one another, or in a small trench, close, as in planting box-edgings. These edgings fhould, every fummer, immediately after flowering, be trimmed with garden-hears, or a knife, to cut off all the decayed flower-flalks close to the bottom; likewise to trim in any projecting irregularity of the edging, at the fides or top; also, when it spreads confiderably out of the bounds, it fhould be cut in evenly, on each fide, in due proportion; performing those trimmings in moist weather, and not too late in autumn, otherwife the drought of summer, or the cold of winter, will be apt to injure them when newly cut, and cause them to have a flabby disagreeable appearance. But when these edgings grow confiderably out of bounds, or become very irregular, it is necefary to take them up, fit the plants small, and immediately replant them as before, in a neat regular edging. They fometimes require replanting every three or four years in this manner.

The fefcond forts may likewife be increafed by parting the roots in the autumn, or very early spring, preferring some mould to them, and planting them out again immediately, being placed in an eaf! border, where the foil is loamy.

They may also be raised from feeds obtained from abroad, fowing them on a fimalar border, keeping the plants clean; and when of fufficient growth, planting them out in pots. It is the common practice, in treating the fefcond fort, according to Martyn, to confider it as a greenhoufe plant; and it appears to the greateft advantage in a pot, as it is much dilpofed to throw up new flowering-flems. By hav-
ground, in a rather funny situation, where they generally
left the longe.

**STATICS, Statics,** formed of *statis,* I weigh, a branch
of mathematics, which considers weight or gravity, and the
motion of bodies arising from it.

Those who define mechanics the science of motion, make
statics a subordinate part of it; viz. that part which con-
siders the motion of bodies arising from gravity.

Others make them two distinct doctrines, reining me-
chanics to the doctrine of motion and weight, in reference
to the structure and power of machines; and statics to
the doctrine of motion, considered merely as arising from
the weight of bodies, without any immediate respect to
machines. On which footing, statics should be the doc-
trine or theory of motion; and mechanics, the application
of it to machines.

For the laws of statics, see **Gravity, Descent, &c.**

**Statics, Static,** in **Medicine,** a kind of epileptic, or
persons seized with epileptics.

**Statics** differ from **catleptics,** in that these last have no
sense of external objects, nor remember any thing that
passes at the time of the paroxysm; whereas the statici
are all the while taken up with some very strong,
likely idea; which they remember well enough when out of
the fit.

**STATICULA,** among the Romans, those little figures
with which it was usual to adorn their drinking cups, called
staghi.

**STATICULL,** among the Romans, a kind of dancing
pantomimes. See **Pantomime.**

**STATION,** in **Geometry, &c.** a place pitched upon
to make an observation, take an angle, or the like.

An inaccessible height, or distance, is only to be taken
by making two stations, from two places whose distances
are known. In making maps of provinces, &c. stations
are fixed on all the eminences, &c. of the country, and
angles taken thence to the several towns, villages, &c.

In surveying; the instrument is to be adjusted by the
needle, to answer the points of the horizon at every station;
the distance from the last station to be measured, and an
angle to be taken to the next station; which includes the
whole business of surveying.

In levelling, the instrument is rectified, that is, it is
placed level at each station, and observations made forwards
and backwards.

We have a method of measuring distances at one station
in the Philosophical Transactions, N° 71, by means of a
telecope. But the practice of this method does not an-
swer to the theory.

**STATION, Line of, in Perspective.** See **Line.**

**STATION, in Astronomy,** the position or appearance of a
planet, in the same point of the zodiac, for several days.
As the earth, whence we view the motions of the planets,
is out of the centre of their orbits, the planets appear to
proceed irregularly; being sometimes seen to go forwards,
that is, from west to east, which is called their direction;
and sometimes to go backwards, or from east to west, which
is called their retrogradation.

Now between these two stations there must be an inter-
mediate one, in which the planet neither appears to go
happier forwards nor backwards, but to stand still, and keep
the same place in her orbit; which is called her station.

**Station, in Britifh History.** The stations, or stations,
fortresses erected along the line of Severus's wall, were so
called from their liability, and the flated reedence of gar-
rifons. They were also called caftell, which hath been con-
verted into caflerz, a name which many of them still bear.
These were by far the largest, strongest, and most magni-
ificent of the fortreses, which were built upon the wall, and
were designed for the head-quarters of the cohorts of troops
which were placed there in garrison, and from whence de-
tachments were sent into the adjoining counties and turrets.
These stations, as appears from the writings of them, which
are still visible, were not all exactly of the same figure, nor
of the same dimensions; some of them being exactly
square, and others oblong, and some of them a little larger
than others. These variations were no doubt occasioned
by the difference of situation, and other circumstances.
The stations were fortified with deep ditches and strong
walls, the wall itself coinciding with, and forming the north
wall of each station. Within the stations were lodgings
for the officers and soldiers in garrison; the smallest of them
being sufficient to contain a cohort, or 600 men.
Without the walls of each station was a town, inhabited by labourers,
artificers, and others, both Roman and Britton, who chose
to dwell under the protection of these fortresses.

The number of the stations upon the wall was exactly eighteen;
and if they had been placed at equal distances, the interval
between every two of them would have been four miles and
a few paces: but the intervention of rivers, marshes, and
mountains; the convenience of situation for strength, pro-
fpect, and water; and many other circumstances to us un-
known, determined them to place these stations at unequal
distances. The situation which was always chosen by the
Romans, both here and everywhere else in Britain, where
they could obtain it, was the gentle declivity of a hill, near
a river, and facing the meridian sun. Such was the situa-
tion of the far greatest part of the stations on this wall.
In general we may observe, that the stations stood
thickest near the ends and in the middle, probably be-
cause the danger of invasion was greatest in those places.
But the reader will form a clearer idea of the number of
these stations, their Latin and English names, their situa-
tion and distance from one another, by inspecting the fol-
loving table, than we can give him, with equal brevity,
in any other way. The first column contains the number
of the station, reckoning from east to west; the second
contains its Latin, and the third its English name; and the
last its distance from the next station to the wall of the
well of St., in miles, furlongs, and chains.

Length of the wall 68 3 3
STATION, Station, in Church History, is applied to the fall of the fourth and fifth days of the week, that is; Wednesday and Friday; which many among the ancients observed with much devotion, till three of the clock in the afternoon. St. Peter of Alexandria, in his Canonical Epistle, can. 15, observes, that it was appointed, conformably to ancient tradition, to fall weekly on those days; on Wednesday, in memory of the counsel the Jews took to put our Saviour to death; and on Friday, on account of his passion. Some regard to which is still had by the church of England. See Absinthe.

Station is also used in the church of Rome, for a church where indulgences are to be had on certain days.

It was St. Gregory that fixed the stations at Rome, i.e. the churches where the office was to be performed each day of Lent, and on solemn fast-days. These stations he marked down in his Sacramentary, as they now lstand in the Roman Missal; appropriating them chiefly to the patriarchal and titular churches; but though the stations were fixed, the archdeacon did not fail, at each station, to publish to the people the following station.

Station is also a ceremony in the Romish church, in which the priests or canons go out of the choir to sing an anthem before the crucifix, or the image of our Lady. This ceremony is ascribed to St. Cyril.

Station. Station, exaeq, in the Ancient Muses, was sometimes used for any fixed pitch, or degree of sound, whether produced by intention or remission.

Station-Line, in Surveying. See Line and Surveying.

Stationa, in Ancient Geography, a town of Italy, in the interior of Etruria, according to Strabo.

Stationarii, were men, thus called in the middle ages, who trafficked in books, made large fortunes by lending them out to be read, at exorbitant prices, not in volumes, but in detached parts, according to the estimation in which the author was held.

Stationary, in Astronomy, the state of a planet when it seems to remain immovable in the same point of the zodiac. The planets having sometimes a progressive, and sometimes a retrograde motion, there will be some point in which they appear stationary. Now a planet will be seen stationary, when the line, that joins the earth's and planet's centre, is constantly directed to the same point in the heavens, that is, when it keeps parallel to itself. For all right lines drawn from any point of the earth's orbit, parallel to one another, do all point to the same star; the distances of those lines being indefinite, in comparison of that of the fixed stars.

Saturn is seen stationary at the distance of somewhat more than a quadrant from the sun; Jupiter at the distance of 55° and Mars at a much greater distance; Venus at 45°, and Mercury at 28°.

Saturn is stationary eight days, Jupiter four, Mars two, Venus one and a half, and Mercury a half; though the several stations are not always equal; because the orbits of the planets are not circles, which have the sun in their centre.

Stationary Fevers, an hypothetical term, used by Sydenham to denote those fevers which continue to prevail through a certain number of fevers; connected with some particular constitution of the atmosphere, according to his hypothesis; and giving a particular epidemic character to the maladies of those fevers; and as contrived with those casual and short occurrences of particular diseases, which are now and then intermixed with the prevalent epidemics, and which he denominated intercurrent fevers.

(See Sydenham, Observat. Medice circa Morb. Aen. Historiam et Curat. fac. i. c. 2, and lect. vi. c. 1.) Although he was able to trace several successive changes in epidemic constitutions, or stationary fevers, at different periods of his practice; he is compelled to admit, that these changes could not be ascribed to any sensible variations of the atmosphere, such as heat and cold, dryness and humidity; and adopted, therefore, a conjecture, that they originated in some occult and inexplicable contamination of the air by certain effluvia from the bowels of the earth. See Sydenham.

STATIVA, among the Romans, a standing camp kept for the defence of the frontiers of the empire. These camps gave rise to a great many towns, which took their names from the legion stationed there.

Statius, Publius Pappus, in Biography, an eminent Roman poet, was born at Naples, in which city his father was settled as a teacher of oratory, and was in great reputation both for his lectures and poetry, in which he gained several prizes. Statius was born probably about the year A.D. 61. He early displayed a lively disposition and good talents, and soon became a votary of the muses with so much facility, that during his father's life he obtained the crown in the poetical contests of his native place. He wrote a work in the poetical games celebrated at Alba. The poems which he addressed to several of the principal persons in Rome, are proofs of the friendships which he contracted with men of rank in that city; and a piece, which he recited in the quinquennial games instituted by Nero, and renewed by Domitian, procured for him a golden crown from that emperor, and the honour of admission to his table. He was vanquished at a contest in the Roman games, on which occasion he recited a part of his principal work, the Thebaid. According to Juvenal, he was heard with delight by a crowd of auditors in other public recitations of this poem: the latusril at the same time intimating, that notwithstanding this applause, the author might have faltered, had he not held his "Agraw," apparently a new composition, to a celebrated actor, a favourite of Domitian. He polluted a small estate and country house near the seat of the ancient Alba, and lived in a decent state of mediocrity. Having no children of his own, he adopted a son, whose death he tenderly laments in one of his miscellaneous poems. The time of his own death is not known; but it is thought to have been about the year 96, when he was only 35 years of age. He is not even mentioned by any contemporary poet, except Juvenal. Martial, who celebrates many other poets, takes not the least notice of him. The existing works of Statius consist of the "Thebaid," or miscellaneous pieces, in five books; the "Thebaid," an epic poem, in twelve books; and two books of an unfinished poem, entitled "Achilles." "They all," says his biographer, "display a considerable share of genius and real talent, and are vitiated by the false taste which then began to infect Latin poetry, and gave a turn to turgid and unnatural thoughts and expressions. Several pieces in the "Thebaid" are, however, pleasing and elegant. His principal work, the "Thebaid," holds no mean rank among epic poems, and once it was a great favourite among the remains of antiquity. For this preference it was indebted to its swelling sentiments, verging to bombast, and to the farce and fantastic character of its incidents, which suited the times of chivalrous turbulence. But with these faults it exhibits strokes of the real sublime, and considerable force and novelty in natural description, especially in the families." The best editions are those of Cæsar Barthelemy, 4to. 1664; of Veenhuyzen, Lug. Bat. 8vo. 1671; and
and the Delphin, 2 vols 4to. 1685. Markland's edition of the "Syria" is highly esteemed.

STATO della Chiesa, State of the Church, or Papedom, a name given to the dominions of the pope in the central part of Italy. These dominions were bounded on the N. by the Venetian States, on the E. by the Adriatic and part of the kingdom of Naples, on the S. by the Mediterranean, and on the W. by the Mediterranean, the duchy of Tuscany, and the duchy of Modena; and consisted of several states or provinces. See Ecclesiastical State.

The secular power of the popes is traced back to the age of Pepin and Charlemagne; and the forged collection of papal ercels, published in the 9th century under the name of Hidorus, led to successive accumulations of dominion. The small territory, granted in the eighth century, was increased by the acquisition of Benevento in the eleventh, after which there was a pause; and the papal spheres were conjoined to reside at Avignon. In 1513 Bologna was acquired by Julius II.; the marquisate of Ancona followed in 1532; Ferrara in 1598; and Urbino in 1626. But since the French revolution, the temporal power of the pope was annihilated by Bonaparte (see Italy); and again restored after the expulsion of the French emperor.

Where the papal power predominates, no great industry can be expected, and the soil is not likely to derive much accession to its natural fertility from cultivation. The principal, and, indeed, almost the only exports from the Papal States, are a superior kind of alum, prepared from a whitish argilloaceous rock at Tolfa, near Civita Vecchia, from which place also is exported puzzolanum (what fee). The chief city of the papal territory is Rome (which fee); and its revenue has been computed at about 350,000l. per cent. But by exactions in foreign countries it is said to have been raised to 800,000l., subject, however, to a large debt, being per cent. Interett; and this strikingly evinces a defect of industry and prosperity. See Ecclesiastical State, Italy, and Pope.

STATO de Gis Prefidii, a name given to a part of Tuscany, which was ceded to Philip II., king of Spain, and belongs to Naples. It is situated on the coast of the Mediterranean, and consists of the towns of Orbistello, Porto Hercule, the principality of Piombino, and the island of Elba, with a few villages. By the peace signed at Florence, between the king of Naples and the French republic, this country was given to France. See Naples and Tuscany.

STATORIES, among the Romans, made a part of the emperor's life guard.

STATUARY, Statuaria, a branch of sculpture, employed in the making of statues. Statuary is one of those arts in which the ancients surpassed the moderns; indeed it was much more popular and more cultivated among the former than the latter. It is disputed between statuary and painting, which of the two is the most difficult, and the most artful. See Sculpture.

The invention of statuary was at first very coarse. Leon Battista Alberti, who has an express treatise on statues, imagines, that it took its rise from something casually observed in the productions of nature, that, with a little help, seemed disposed to represent the figure of some animal. The common story is, that a maid, full of the idea of her lover, made the first eflay, by the assistance of her father's implements, who was a potter. This, at least, is pretty certain, that earth was the first matter upon which statuary was practised.

Statuary is also used for the artificer who makes statues. Phidias was the greatest statuary among the ancients; and Michael Angelo among the moderns.

STATUARY Column. See Column.

STATUARY Fountain. See Fountain.

STATUARY Marble, among our artificers, the name of the fofter white marble usually wrought into statues, the fame with the Parian marble of the ancients.

STATUE, Statua, a piece of sculpture in full relief, representing a human figure.

Daviler more scientifically defines Statue, a representation in high relief, and inlute, of some person distinguished by his birth, merit, or great actions; placed as an ornament in a fine building, or exposed in a public place, to preserve the memory of his worth.

In strictures, the term statue is only applied to figures on foot; the word being formed from the Latin status, the size of the body; or from stare, to stand.

Statues are formed with the chisel, of several matters, as stone, marble, plaster, &c.

They are also cast of various kinds of metal, particularly gold, silver, brass, and lead. For the method of casting statues, see Foundery of Statues.

Dedalus, the son of Upalnasus, who lived not only before the siege of Troy, but even before the expedition of the Argonauts, among many other notable contrivances ascribed to him, is said to have been the inventor of statues. And yet it is certain, there were statues before him; only it was he who first found how to give them action and motion, and to make them appear as if alive. Before him, however, they made them with the feet joined together, never intending to express any action. He first loosened the feet of his, and gave them the attitudes of people walking and acting.

The Phorcians are said to have been the first who erected statues to the gods. The Greeks succeeded in their statues beyond the Romans, both the workmanship and the fancy of the Roman statues being inferior to the Grecian. Indeed we have very few remaining that have escaped the injuries of time.

Statues are usually distinguished into four general kinds. The first are those less than the life; of which kind we have several statues of men, of kings, and of gods themselves. The second, those equal to the life; in manner which it was that the ancients, at the public expense, used to make statues of persons eminent for virtue, learning, or the services they had done. The third, those that exceed the life; among which, those which surpafs the life once and an half, were for kings and emperors; and those double the life, for heroes. The fourth kind were those that exceeded the life twice, thrice, or even more; and were called colossifer.

Every statue resembling the person it is intended to represent, is called statua iconica. See Sculpture.

Statue, Allegorical, that which, under a human figure, or other symbol, represents something of another kind, as a part of the earth, a seafon, age, element, temperament, hour, &c.

Statue, Caryatic. See Caryatides.

Statue, Colossifer. See Colossus.

Statues, Curule, those which are represented in chariots drawn by biges, or quadriges, that is, by two or four horses; of which kind there were several in the circuses, hippodromes, &c. or in cars, as we see fome, with triumphal arches, on antique medals.

Statue, Equestrian, that which represents some illustrious person on horseback; as that famous one of Marcus Aurelius at Rome, and that of king Charles I. at Charing-Crofs.

Statue, Greek, denotes a figure that is naked and antique,
tique, it being in this manner the Greeks represented their
deities, athletes of the Olympic games, and heroes. The
rest of this nudity, by which the Greek statues are distinc-
tuished, is, that those who exercised wrestling, in which
the Greek youth placed their chief glory, always performed
naked.

The statues of heroes were particularly called Achillian
statues, by reason of the great number of figures of that
prince in most of the cities of Greece.

Statue, Hydraulie, any figure placed as an ornament of
a fountain, or grotto, or that does the office of a jet d'eau,
a creek, fount, or the like, by any of its parts, or by any
attribute it holds. The like is to be understood of any ani-
mal serving for the same use.

Statue. Pedestrian, a statue standing on foot; as that
of king Charles II. in the Royal Exchange; and that of
king James II. in the Privy-Gardens.

Statue, Persian. See Persian.

Statues, Roman, is an appellation given to such as are
clothed; and which receive various names from their various
dress.

Those of emperors, with long gowns over their armour,
were called statue paludata; those of captains and cavaliers,
with coats of arms, thoracata; those of soldiers, with cuir-
salas, loricae; those of senators and augurs, trabeata; those
of magistrates, with long robes, togae; those of the people,
with a plain tunic, tunicae; and lastly, those of women,
with long trains, flabellae.

The Romans had another division of statues, into divine,
which were those consecrated to the gods; as Jupiter, Mars,
Apollo, &c.; heroes, which were those of the demi-gods;
as Hercules, &c.; and Augustus, which were those of the
emperors; as those two of Caesar and Augustus, under the
portico of the Capitol.

Statues, Foundery of. See Foundery.

Statues, Pedestal of. See Pedestal.

Statues, Plinth of. See Plinth.

Statue, Repairing a. See Repair.

Statute, the size, or height of man; derived from the
Latin statuia, of stature, to stand.

The statue, or pitch, of a man, is found admirably well
adapted to the circumstances of his existence. See Dwarf
and Giant.

It is a common opinion, and has been so ever since Ho-
er's time, that people in the earliest ages of the world
much surpassed the moderns in stature; and, it is true, we
read of men, both in sacred and profane history, whose
pitch appears surpassing; but then, it is true, they were,
even then, eftemmed giants.

The ordinary stature of men, Dr. Derham observes, is,
in all probability, the same now as at the beginning; as
may be gathered from the monuments, mummies, &c. still
remaining. The oldest monument in the world is that of
Cheops, in the first pyramid of Egypt, which, Mr. Greaves
observes, fearfully exceeds the measure of our ordinary coffins.
The cavity, he says, is only 6.488 feet long, 2.218 feet
wide, and 2.165 feet deep; from which dimensions, and those
of several embalmed bodies observed by him in Egypt,
that accurate writer concludes, there is no decay in nature;
but that the men of this age are of the same stature as those
three thousand years ago.

To these, we have other and later inferences to add from
Hakewell: the tombs at Pisa, which are some thousands of
years old, are yet no longer than ours. The fame may be
said of Athelian's in Malmsbury church; and of Sheba's
in Paul's, of the year 693, &c.

The like evidence we have from the ancient armour,
fully contradictory to common reason, they are, with regard to such consequences, void. 8 Rep. 118.

The method of citing acts of parliament is various. Many of our ancient statutes are called after the name of the place where the parliament that made them was held; as the statutes of Morton and Marleberge, of Westminster, Gloucester, and Winchester. Others are denominated entirely from their subject; as the statutes of Wales and Ireland, the articuli clerici, and the prærogativa regui. Some are distinguished by their initial words, as the statute of quia emporium, and that of circumfeltæ againit. But the most usual method of citing them, especially since the time of Edward II., is by naming the year of the king's reign in which the statute was made, together with the chapter or particular act, according to its numeral order; as 9 Geo. II. c. 4. For all the acts of one session of parliament taken together, make properly but one statute; and, therefore, when two sessions have been held in one year, it is usual to mention both. Thus, the bill of rights is cited as 1 W. & M. R. c. 2. c. 2, signifying that it is the second chapter, or act, of the second statute, or the laws made in the second sessions of parliament, held in the first year of king William and queen Mary. Blackit. Com. book i.

Abridgments of the statutes have been made by several, from Magna Charta to the times of the respective abridgers. The first by Rafal, published in 1559; the second by Pulton, in 1606; the third by Wingate, in 1641; and others since by Hughes, Manby, Washington, Bott, Nelfon, Cay, &c.

Statute is also a term provincially employed to signify a hiring day for farm-servants.

Statutes of a Corporation, are those bye-laws, or private regulations, which it is empowered to make for its own better government, and which are binding upon the members, unless contrary to the laws of the land, and then they are void. This right of making bye-laws, under the preceding restriction, was allowed by the law of the Twelve Tables at Rome; but no trading company is, with us, allowed to make bye-laws which may affect the king's prerogative, or the common profit of the people, under the penalty of 46L. unless they be approved by the chancellor, treasurer, and chief justices, or the judges of assize in their circuits; and even though they be so approved, still, if contrary to law, they are void. Blackit. Com. book i.

Statute. Accessory by. See Accessory.

Statute. Alien upon the. See Alienation.

Statute. Guardian by. See Guardian.

Statute-Merchant is a bond of record, purgatory to the statute 13 Edw. 1. de mercatoribus, acknowledged before one of the clerks of the statutes-merchant, and mayor, or chief warden of the city of London; or two merchants of the said city for that purpose aligned; or before the mayor, chief warden, or master, of other cities or towns; or other sufficient men for that purpose appointed; sealed with the seal of the debtor, and of the king, which is of two pieces, the greater to be kept by the mayor, chief warden, &c. and the lesser by the said clerks. Its effect is, that if the obligor pay not the debt at the day, execution may be awarded against his body, lands, and goods; and that the obligee shall hold the same till the debt be levied. See Statute-Staple.

Statute-Seffions, called also Petit-seffions, in Law, are meetings in every hundred, to which constables repair, and others, both maidens and servants, for deciding differences between masters and servants, rating of wages, bellowing people in service, who, being fit to serve, either refuse to seek, or cannot get masters.

Statute-Staple is a fort of statute-merchant, relating to merchants and merchandizes of the staple; which fee.

The statute-staple is of two kinds: proper and improper.

The proper is a bond of record, acknowledged before the mayor of the staple, in the presence of one or more constables of the staple; by virtue of which the creditor may forthwith have execution of the body, lands, and goods, of the debtor, on non-payment.

This and the statute-merchant are both securities for debts, originally permitted only among traders for the benefit of commerce; by which the lands of the debtor are conveyed to the creditor, till out of the rents and profits of them his debt may be satisfied, and during such time as the creditor so holds the lands, he is tenant by statute-merchant, or statute-staple.

Improper is a bond of record, or recognition, founded upon the statute 23 Hen. VIII. cap. 6. of the nature of a proper statute-staple as to the force and execution of it, and acknowledged before one of the chief justices; or, in their absence, before the mayor of the staple, and recorder of London; which extends the benefit of the mercantile transaction, already mentioned, to all the king's subjects in general.

Statuto Mercatorio, a writ for the imprisoning him that has forfeited a statute-merchant bond, until the debt is satisfied; and of these writs there is one against lay persons, and another against persons ecclesiastic.

Statuto Statula, a writ that lies to take the body to prison, and seize upon the land and goods of one who hath forfeited the bond called statute-staple.

Statutum de Laborariis, an ancient writ for the apprehending such labourers as refuse to work according to the statute.

Stavanger, in Geography, a sea-port town of Norway, in the Christian era, situated on a bay of the North sea; anciently the see of a bishop, but removed, after the town was burnt in the year 1688, to Christiania; 86 miles S. of Bergen. N. lat. 58° 6’. E. long. 5° 44’.

Staveni, in Ancient Geography, a people of European Sarmatia, according to Ptolemy; who also gives the same name to a people in the northern part of Aria.

Stavelot, in Geography. See Stablo.

Stavenau, a town of Brandenburg, in the Mark of Pregnitz; 7 miles N.W. of Perleberg.

Stavenhagen, a town of the ducy of Mecklenburg; 24 miles E. of Gütrow. N. lat. 53° 40’. E. long. 19°.

Staveren, a town of Holland, and the most ancient of Friesland, supposing to have been built one year before the commencement of the Christian era, and to have taken its name from an ancient idol, worshipped by the inhabitants, called "Stavon." Great part of the ancient town having been destroyed by the sea, the inhabitants rebuilt it in the place where it now stands, as being less exposed. It was anciently a very rich, powerful, and populous city, with the best harbour in that country. The ancient kings of Friesland made it their ordinary residence, in a palace built by Richolde, the first king about the year 400. Richolde VI., after he had conquered all the country as far as Utrecht, called his conquests the Kingdom of Staveren, which flew the flourishing state of the town at that time, and was the occasion of its being included in the league of the German Hanse towns. It was surrounded with walls and ditches, about the year 339, by Obidale VI. duke of Friesland. It is since reduced very much from its ancient grandeur, the harbour being choked up; however, there remains enough of its former splendour to make it a considerable town;
STA 

Town; and they still carry on some trade, especially in fishing, and in passage-boats over the pools and lakes of the neighbourhood. In 1799, the town was taken by the British fleet; 40 miles N. of Amsterdam. N. lat. 52° 50'. E. long. 6° 46'.

STAVES. Flag. See FLAG-STAVES.

STAVES. Leveelling. See LEVELLING-STAVES.

STAVES. Tip. See Tip-STAVES.

STAVESACRE, STAPHISAGRIA, in Botany; for the characters, see DELPHINIUM.

Staveacre, Delphinium flavissagria, grows in Provence, Launedoc, and many other southern parts of Europe.

The seeds, which are the only part of the plant directed for medicinal use, are usually imported here from Italy; they are large, rough, of an irregular triangular figure, and of a blackish colour on the outside, but yellowish within; their smell is disagreeable, and somewhat fetid; to the taste they are very bitter, acid, and nauseous. Their virtues are extracted partially by water, and completely by rectified spirit.

These seeds seem to have been known to the ancients, by whom they were employed as a medicinal for, on being chewed they excite a copious flow of saliva, and on this account were recommended in tooth-aches, and other painful affections of the face and gums. The ancients also prescribed them with a view to their emetic and cathartic effects in doses of ten or fifteen grains: but the deleterious narcotic qualities of staveacre were discovered to be so powerful as to forbid its internal use. Schultz, only by keeping it some time in his mouth to relieve a tooth-ache, was for a time deprived of his senses; and Hillefeld has related, that a dog, by taking five simples of these seeds, became convulsed, and soon died. Staveacre is now, therefore, confined to external use in some kinds of cutaneous eruption, but more especially for destroying lice and other insects; and by its efficacy in this way, this plant, in most of the European languages, is distinguished by the name of louse-wort.

STAUFO, in Geography, a castle of Germany, in the principality of Nassau Saarbrueck Utngen.—Allo, a castle of Germany, in the principality of Anspach, with a citadel; 30 miles S.E. of Anspach.

STAUFO, a town of the Britiag, on the Mehlbach; 24 miles N.N.E. of Bâle. N. lat. 49° 54'. E. long. 7° 48'.

STAUFO, a town of Upper Hesse; 5 miles N.N.E. of Gießen. N. lat. 50° 40'. E. long. 8° 45'.

STAVITESTI, a town of Walachia; 42 miles E.S.E. of Tergovia.

STAVANTON, a port-town of America, in the state of Virginia, and capital of Augusta county; situated on the S.E. side of Middle river, a water of Patowmac, N. of Maddington's cove. It contains about 160 houses, mostly constructed of stone, a court-house and gaol; 100 miles S.W. by S. of Winchester. Allo, one of the principal branches of Roanoke river, which rises on the western side of the Blue Ridge, where it has the name of Roanoke, but when it has passed through the ridge, it takes the name of Staunton, and prefers it to its confluence with Dan, there refuming the name of Roanoke. It might be made navigable for 100 miles from its mouth. It receives several streams.

Staunton's Island, a small island near the east coast of China. N. lat. 36° 27'. E. long. 122° 17'.

STAVRES HOVED, a cape of Denmark, on the east coast of the island of Fyen. N. lat. 55° 29'. E. long. 10° 46'.

STAUROS, in Ancient Geography, a people of Asia, in the environs of Hrycaort. Plane.

STAUROBIT, Granitse of Sauffur and Werner, and Staurus, of Haisty, in Modern Geography, a stone of the fideous genus according to Kirwan, of a reddish or blackish-brown colour, which forms always crystallized. Its crystals are of an hexagonal prismatic form, four faces of which are the largest; meeting in pairs, and forming two obtuse angles, measuring 129°. This prism is either entire or truncated on the obtuse angles. It is not uncommon to find two crystals penetrating each other obliquely, or at right angles, so as to form a crofs; sometimes even three prisms are thus arranged, forming a triple crofs, whence its name of "Crofs-Hone." Its surface is smooth or uneven, and its lustre varies considerably. Internally it is more or less finking, with a lustre between vitreous and resinous. Its fracture, parallel to the axis, is imperfectly lamellar; in the opposite direction it is small-grained uneven, palling to conchoidal. It is brittle, and somewhat harder than quartz. Sp. gr. 3.28. Exposed to the blowpipe, it undergoes no other change besides that of fritting a little on its surface. Its component parts, according to an analysis by Vauquelin, are

33. Silex.
44. Alumin.
3.84. Lime.
13. Oxid of iron.
1. Oxid of manganese.

94.84
5.16 Lofs

100.

This mineral is found in St. Gothard, in Switzerland, in small crystals, imbedded in micaceous chittora, and accompanied with cyanite: in Brittany, near Quimper, in middling-sized crystals, imbedded in a micaceous clay, apparently produced by the decomposition of some primitive rock; also at St. Jago of Compoedella, in a primitive rock. Akin.

STAUROPHORI, Σταυροφοροι, compounds of Σταυρος, a crofs, and φοροι, I carry, in Church History, certain ecclesiastics, whose business it was to carry the crofs in processions.

STAUROPHYLAX, Σταυροφυλαξ, derived from Σταυρος, a crofs, and φυλαξ, I keep, a dignified officer in the church of Constantinople, to whose care the keeping of the crofs, found by St. Helena, was committed.

STAUROPOLE, in Geography, a town of Russia, in the government of Simbirsk, on the Volga; 44 miles S.S.E. of Simbirsk. N. lat. 53° 44'. E. long. 48° 52'.—Allo, a town of Russia, in the government of Caucaus, on the Volga; 88 miles W.N.W. of Ekaterinograd. N. lat. 44° 56'. E. long. 41° 50'.

STAVROS, or STAVROS, anciently Stagira, a town of European Turkey, in Macedonia, the native place of Aristotle; situated in the gulf of Contesa; 46 miles E.S.E. of Saloniki.

STAVOTIDE, in Mineralogy, the name given by Haisty to granitse. See STAUROBIT.

STAUSEE, Fort, in Geography, an American fort, just above the falls of the Niagara, and eight miles above Queen's Town.
STAUSTADT, a town of Switzerland, in the canton of Underwalden; 6 miles S.E. of Lucerne.

STAXIGO HARBOUR, a bay of Scotland, on the east coast of the county of Caithness; 1 mile N. of Nols Head.

STAXIS, a word used by the ancient physicians to express a distillation of the blood in drops from the nose.

A flask, in the doctrine of critics, is justly esteemed as indicating a weakness and decay of strength in nature; whereas, on the contrary, free and copious discharges of blood from the nose are esteemed good indications, and often make happy critics.

STAY, in Sea Language, a big strong rope employed to support the masts on the fore-part, by extending from their upper end at the main-head towards the fore-part of the ship, as the shrouds are extended to the right and left, and behind it.

The stays are denominated from the masts, as the lower stays, topmast stays, top-gallant stays, flag- stay or royal stays, &c.

Back-stays, brace, hinging, and flanging, are stays which support the topmasts and top-gallant masts from above; they reach from the heads of the topmast and top-gallant mast to the channel on each side of the ship, and affix the shrouds, when strained by a press of sail. The hinging back-stays change according to the action of the wind upon the sails, whether aft or upon the quarter. Bob-stays are stays used to confine the bowprit down upon the stem, and counteract the force of the stays which draw it upwards. Stay-fall stays are those on which the stay-falls are extended. The ship's-fall is similar to the fall-stays, and extends the jib. The martingale-fall supports the jib-boom, as the bob-stays support the bowprit.

Preventer-spring-stays are subordinate stays to support their respective stays, and supply their places, in case of any accident. The practice of placing the spring-stays before the foremost crosstrees, and of bringing the catarpins and futtock-shrouds to the main, is now strictly forbidden in the navy, as the placing of the spring-fall before the foremost crosstrees was with a view to separate it from the flanging fall: it is for the future to be effected, by placing the collars live or fix feet apart on the bowprit. Skittles-stays are ropes used for hoisting or lowering buoys in or out of boats. Stay-rope have four strands, with a heart running through the middle, which keeps the rope true; and when hawser-laid as a rope, prevents it from stretching, and the strands have each their proper bearing. The stays are made of fine yarn, spun from the beet top hemp. Twenty threads a hook make a rope three inches in circumference, and so in proportion for any fize. The yarn is warped to the length and fize for the fall wanted. The strands are warped long enough for one strand to make two, when hauled about and hung upon the back-hook. By this an eye is left for the upper end of the fall to go through and form a collar, to go over the main-head. For falls of nine inches in circumference, each strand should be 3/4 inch, and so in proportion. The heart must be near the fize of the strand, or the rope will not lie round and true. Particular attention should be paid to making the falls, as on them the safety of the man, &c. greatly depends. Main, fore, and mizen-topmast, and some top-gallant-mast-stays, are cabbel-laid.

The fall of the fore-mast, called the fore-fall, reaches from the main-head towards the bowprit-end; the main-fall extends over the fore-cable to the ship’s head; and the mizen-fall is fletched down to that part of the main-mast which lies immediately above the quarter-deck; the fore-topmast-fall comes also to the end of the bowprit, a little beyond the fore-fall; the main-topmast-fall is attached to the head or bounds of the fore-mast; and the mizen-topmast-fall comes also to the bounds of the main-mast; the fore-top-gallant-fall comes to the outer end of the jib-boom; and the main-top-gallant-fall is extended to the head of the fore-topmast.

Stay a Ship, To, or bring her on the Stays, is to manage her tackle and falls, so as that she cannot make any way forwards, which is done in order to her tacking about.

STAY, in the Manoeuvres. To fall, or furlain your horse, is to hold the bridle firm and high. We likewise fall or furlain a horse with the inleg, or in-wheel, when he makes his crouse go before his shoulders upon volts; as also when we hinder him to traverse, and ride him equally, keeping him always subject, so that his crouse cannot flip out, and he cannot lose either his cadence, or his ground, but marks all his times equal.

STAY-Sail, in a Ship, a fore or triangular sail extended upon a fall. See SAIL.

STAY-Sail, TABBLE. See TACKLE.

STAY-Tackle Pendants. See PENDANTS.

STAYNER, Sir Richard, in Biography, was the gallant commander of a ship of war during the protectorate; and, in conjunction with captain Smith, took a Dutch East India ship of 800 tons burden, having on board four chests of silver. In 1656 he was appointed to the command of three frigates, and with this small squadron he fell in with the Spanish flotilla, consisting of eight sail, of which he captured two, burnt one, sunk another, and drove two on shore. The treasure captured on this occasion amounted to fix hundred thousand pounds sterling, so that captain Stayner returned to England not only crowned with glory, but laden with wealth. In the following year he again failed with the fleet, under the chief command of Blake, for the purpose of intercepting the Spanish West India fleet, which had taken shelter in the bay of Santa Cruz. Reconnorning the force and position of the enemy, the English admiral found it impossible to bring off the enemy's ships, though he thought they might be destroyed. Stayner was immediately detached to begin the attack, and being supported by Blake with the remainder of the fleet, the Spaniards were, in a very few hours, driven out of their ships and breast-works. The former were instantly taken possession of by the English, and, as they could not be brought off, they were all set on fire, and burnt to the water's edge. "The whole action," says lord Clarendon, "was so miraculous, that all men, who knew the place, wondered that any sober men, with whatever courage endowed, would ever have undertaken it; and they could hardly persuade themselves to believe what they had done! while the Spaniards comforted themselves with the belief that they were devils, and not men, who had destroyed them in such a manner." Cromwell thought so highly of the conduct of captain Stayner, that he immediately conferred on him the honour of knighthood. On the restoration, Sir R. Stayner had a command under Montague, afterwards the earl of Sandwich, was again knighted, and was constituted rear-admiral of the fleet. He first hoisted his flag in the Swiftsure, and afterwards in the Mary. After this, the nation being at peace, no opportunity was offered to this brave man of adding to those services which he had already rendered his country; and it is thought he died very soon after. Campbell’s Lives of the Admirals, vol. iv.

ST. CLAIR, in Geography. See CLAIR.—Also, a township in Butler county, in the state of Ohio, containing
STEADMAN'S CREEK, a river of America, in New York, which runs into the Niagara, above Fort Schloffer.

STEADY, a word of command at sea, given by the pilot to the man at the helm, in a fair wind, to keep the ship ready in her course, without deviating to the right or left, or making angles (or yaw, as they call them) in and out. The helmman accordingly answers steady; thus denoting his attention and obedience to the pilot's orders.

STEAL, in Agriculture. See STEAL.

STEALING an Horse. See FORCIBLE ABDUCTION.

STEALING, in Law. See LARCENY.

STEAM, in a general sense, is a term used to signify the visible cloudinefs arising from the condenfation of aqueous vapour.

In those arts and manufactures where the vapour of water is employed, such as steam-engines, the term steam is used for water in its elastic form, at or above the temperature of 212°, and when it is invisible. It is in this form that we can properly call it steam; as we shall see, that in the visible milky form in which we see it in the atmosphere, both in the form of clouds, and as it passes from a warm medium into a colder one, it is not steam but water in minute globules.

Some have confined the word steam to the vapour of water not less than 212°, as if water did not assume the elastic form at a lower temperature; conceiving it to exert the full force of steam the moment it arrives at that point, and to be wholly converted into water when reduced below the fame. Nothing, however, can be more absurd than this notion; steam can exist at the lowest known temperature. At 50° below the cypher of Fahrenheit, if the barometer could shew it, the pressure of ice would afford an elastic fluid of some force. We want no other proof of this fact than the experiments of different philosophers to ascertain the force of aqueous vapour, answering to different temperatures; and before we proceed further on our subject, it may not be amifs to give the table of these facts, formed by Mr. John Dalton of Manchester. In order to make these experiments, Mr. Dalton took a barometer of the common fize. The mercury was first boiled, to free it from air. He then put a little water into the tube, and poured it out again, leaving its fides wet; and next introduced the mercury, inverting the tube so as to exclude the air. The water, being the lighteft fluid, rose above the surface of the mercury about one-eighth of an inch. He then surrounded the tube, from the top downwards, with another tube, 14 inches long and 2 inches diameter; forming a cavity between the tubes, capable of holding water of different temperatures. The temperature of this water was constantly marked by a thermometer placed in it; and the elasticity of the vapour, in the upper part of the barometer, was constantly marked by the height of the mercury. The outer tube being of glass, the whole could be seen. This apparatus was used for all the temperatures below 155°. For the higher temperatures, as high as 212°, he used an outer tube of tin, with a siphon barometer.

These results he found to agree with similar experiments made with the air-pump. The air-pump was provided with a mercurial gage of considerable extent. Some water was first made to boil in a Florence flask, in which a thermometer was placed. In this state it was put under the receiver, and then the air being withdrawn, the fteam alone affected the barometer; the thermometer, at the same time, marking the temperature.

From these facts Mr. Dalton conftructed his table. The altitudes of the mercury, answering to the degrees of temperature, he found not to have a constant ratio; nor did they vary by any regular progressIon. When the degrees were in arithmetical progressIon, the columns of mercury answering thereto were not in the fame, but something approaching to a geometrical feries. The increafe, although not ftrictly geometrical, of the ratios themselves diminished regularly, which enabled him to calculate with fufficient exactnefs those degrees which he could not afcertain by experiment. We seldom find any of nature's laws attended with any thing fo indefinite; and Mr. Dalton very properly observes, that the defect is not in nature, but in the imperfect scale of our thermometers, which, M. de Luc and others have fhewn, do not mark equal increments of heat.

</table>
STEAM.

In answer to some references which may be required, we have thought proper to add a third column to this table, showing the weight of aqueous vapour contained in a cubic foot of space, when a sufficient quantity of water is present at the given temperature. This column has been formed on the fact, that when the force of vapour is 30 inches, the aqueous vapour in a cubic foot of space is equal to 253 grains. And since the density must be as the pressure; therefore, as 30 inches is to 253 grains, so is the force of vapour of any other degree to the number of grains in the cubic foot at the same.

This table, from 30° to 212°, was the result of careful experiment. The facts below and above were determined by calculation, and will doubtless be much more correct than by experiment, from the great difficulty and uncertainty which the high and low temperatures would occasion. For a more detailed account of Mr. Dalton's experiments, see the Manchester Transactons, vol. v., and Nichollon's Journal, vols. vi. and vii.

There will be found a valuable reference in all practical applications of steam, and will not be of less importance in allaying any inquiry into the procés of evaporation, as connected with the arts of life, and the natural evaporation in the air. With a view to affirm our conception of the nature of steam, or of the elastic vapour of water, we shall condense a number of facts, which may be very proper to commit to memory.

1. A cubic inch of water forms a cubic foot of steam, when its elasticity is equal to 30 inches of mercury.

2. One pound of Newcastle coal converts four pounds of boiling water into steam.

3. The time required to convert a given quantity of boiling water into steam, is six times that required to raise it from the freezing to the boiling point, or from 32° to 212°, supposing the supply of heat to be uniform.

4. A quantity of water evaporated is equal at a given temperature, the quantity of steam formed in a given time will be as the surface, all other things being equal. The quantity will also be jointly as the force of vapour answering to each degree of heat, and the surface.

The depth of water evaporated, in a given time, will be as the force of vapour, whatever the surface, if the mbs be uniformly of the same temperature.

When the force of vapour is 30 inches, and the temperature at 212°, this degree being most preferred, the depth evaporated is 1.3 inch in one hour. This will be near the truth for this temperature. For lower temperatures, the rules given with the table will point it out.

5. When a quantity of water is raised to the boiling point, or 212°, it requires as much heat to give it the elastic form as would raise the same quantity of water 900° higher. If its volume were not changed by the heat, that is, if it could be prevented from expanding, its temperature would become 112°, with the same quantity of caloric. Thus, agreeable to the 3d, the heat required to convert water of 212° into steam, is six times that required to raise the temperature from 32° to 212°.

6. The same weight of water, in the form of steam, contains the same quantity of heat, whatever may be its temperature or density; that is, the temperature at which the steam is formed, added to the degrees required to give it the elastic form, is always a constant quantity. The meaning of this is, that if a given weight of aqueous vapour, at 100° for instance, were compressed till its elasticity became equal to that at 212°, no heat being allowed to escape, its temperature would become 212° by the condensation; and it would, of course, contain the same heat as steam formed at the same temperature, viz. 212 + 900, as mentioned in the last fact.

In viewing the second column of the table, and comparing it with the temperature in the first column, we shall be far from concluding that all the steam in the cylinder of a steam-engine is condensed by the bell means employed. Owing to the circumstance of the rapid decrease of the force of vapour from the boiling point, some have been led to imagine that there is no medium between steam at 212° and liquid water. By referring to the table, we shall see that, by a decrease of temperature from 212° to 180°, the column of 30 inches is reduced to 15. This column is again bifefted or reduced to 7.5, by the temperature falling to 150°.5. At 124°.5, the steam exerts a force equal to 3.75 inches of mercury; and this will be reduced to 1.875, at the temperature of 100°.5.

We here see the importance of Mr. Watt's discovery of condensing his steam in a separate vessel. The spring of the residual vapour in his cylinder, after condensation, is only equal to the force of vapour answering to the temperature of his condenser, while the cylinder itself is kept at 212° nearly.

We have the old method of condensing in the cylinder, so much cold water would be added as would reduce the temperature as low as Mr. Watt's condenser, in order to produce as perfect a vacuum; and on filling the cylinder again the next time, it would require to be raised to its original heat, at the expense of fresh steam. The effect of cold water in condensing steam, whether in the cylinder or a separate vessel, may be easily known by calculation, and the aid of the preceding table.

Let C = the capacity of the vessel containing steam in cubic feet.

S = the weight of a cubic foot of steam.

T = its temperature.

b = the degrees of heat to convert water into steam.

d = the temperature of the steam.

q = the weight of condensing water.

n = capacity of steam for heat, water being 1.

Then, according to a theorem for finding the resulting temperature by mixing bodies of different temperatures together, \( t = \frac{qT + (b + d)CSn}{q + CSn} \); in this, will come out as if the steam in the vessel, after mixture, were condensed into water; when, in fact, the heat is divided between the remaining steam and the water, one part giving the whole; a common temperature, and the other in a latent form giving elasticity to the vapour. But, according to fact the 6th, as before given, this steam contains as much heat above its own temperature as would raise it to 1112°; hence the real temperature added to the latent heat will be equal t.

The conclusion from these facts will be, that \( \frac{b + d}{t} \) will be nearly in the same ratio with the density of the steam, before and after condensation, and, therefore, as the respective force of vapour. If p be the force of vapour of the steam before the experiment, and f that after condensation; then \( \frac{b + d}{t} = \frac{p}{f} \), and \( f = \frac{pt}{b + d} \). If we now
STEAM.

now refer to the table with this force of vapour, we shall find the temperature after condensation. To illustrate this theorem by an example.

Let \( C = 1 \) cubic foot.

\( S = 253 \) grains, the weight of a cubic foot of steam.

\( q = 253 \) grains of water.

\( T = 60. \)

\( b = 900. \)

\( d = 212. \)

\( n = .9. \)

\[ \begin{align*}
\frac{b + d}{t} &= \frac{f}{t} = 1112, \quad \text{or} \quad \frac{30}{558} = \frac{f}{t} = 15 \text{ inches of mercury.}
\end{align*} \]

Then \( q = \frac{b + d - t}{t} = 253 \times 60 + (900^0 + 212^0) \times 253 \times .9 = 558. \)

The quantity of steam of this density will be as \( p \) to \( f \); therefore, as

\[ 30 : 15 :: 253 : 126.5 \text{ grains; hence the whole weight, which is 558 - 126.5 = 431.5 grains, the weight of water.} \]

Hence, if the capacity of the steel-veil be known, and the degree of condensation at the same time be given, the supply of cold water for that purpose may be ascertained. This will be

\[ q = \frac{b + d - t}{t} = 253 \times 60 + (900^0 + 212^0) \times 253 \times .9 = 558. \]

We have before hinted at the vulgar idea of there being no medium between steam at \( 212^0 \) and liquid water. A doctrine strongly favourable to such an opinion is at present held by several philosophers of eminence. The elastic form of water, at all temperatures below \( 212^0 \), is supposed to be a solution of water in air. Does any thing like this appear to be the case in the detail of Mr. Dalton's experiments, to determine the force of vapour of steam at different temperatures? We would ask, where was the air to diffuse the water above the column of mercury, in which water and mercury alone existed? It is admitted on all hands, that steam at \( 212^0 \) can exist independent of air, and where have we become acquainted with any rule, that souseous vapour cannot exist in a separate state at other temperatures? This is certainly the case with respect to water; and it is highly probable, that a portion of all the solid and liquid matter on the globe exists in the elastic form, in proportion to the temperature. What is the smell we perceive from melted metals, and at a much lower temperature with some of the metals? This is very confusively observed in heating copper-plates and sheet-lead. The odour of cast-iron is particularly striking.

There can be no doubt that elastic mercury exists in the space above the mercury in a barometer, since the condensed mercury is seen frequently to coat the interior surface.

These appearances would be often observed, if it were not for the difficulty with which evaporation takes place, from the body affording the vapour being surrounded with vapour of its own and others. The presence of any elastic fluid mechanically refills further evaporation, to a degree more than is conceived. If water be exposed to a vacuum, a quantity of vapour depending upon the temperature would in a little time occupy the space; the first portion would project itself with great rapidity, and the last very slowly. The temperature being raised, would cause successive portions to rise, the limit being what we have shown in the table. If at any temperature the vapour, already suspended over the water, be removed by a current or by an air-pump, the process would be greatly facilitated, as we observe in the drying of the ground in a brisk wind. This shows that the vapour of water refills evaporation more than the air itself; perhaps, in the same medium, its retarding power increases as the density. The advocates for the solution of water in air have said, that the capacity of air for moisture is inverely as the density, whether this difference of density arises from the nature of the gas, or from rarefaction. This is contrary to all laws of solution. If air can chemically combine with water, every particle of air may combine with a particle of water; and the quantity of water in a given space would be the greatest, when the air was the densest. If we had no direct proof that a given space will contain the same quantity of water, whether air be present or not, the hypothesis of the chemical solution of water in air could not be defended.

We have seen that the quantity of water in a given space is as the force of vapour in inches of mercury, because the density must be as the pressure. Mr. Dalton has ascertained, by experiment, that the rate of evaporation, at a given temperature, is as the force of vapour at the same. See Nichol's Journal, vol. vii. p. 5.

This fact leads to the conclusion, that since the density is also as the force of vapour, the velocity of diffusion through the air is the same at all temperatures. Since, however, the atmosphere always contains some moisture, the next evaporating power will be as the difference between that force of vapour anfwering to the temperature at which dew would begin to fall, and the temperature to which the evaporating substance is exposed. That point in the atmosphere where dew falls, is called by Mr. Dalton the dew-point. The manner of finding this is as follows: Take a tall cylindrical bottle, about one foot high and three inches in diameter; or, if this is not at hand, a common decanter. Fill it with water so much colder than the air, that the bottle may appear milky, when it is put into it. If no appearance of this mist is observed, the water is not cold enough; and ice, or some freezing mixture, must be added to it. The bottle, when filled, must contain a thermometer. When the dew appears upon it, wipe it off with a clean dry cloth; and continue to do so till no more dew appears. Then observe at what degree the thermometer stands in the bottle, which will never be greater than the temperature of the air, which must also be noted. Then find in the table the force of vapour at the temperature of the dew-point, and allow of vapour anfwering to the temperature of the atmosphere, or that of the mist which is the source of the vapour. The difference between these two columns of mercury will be expressive of the rate of evaporation.

In order to obtain absolute data for these purposes, we shall make use of Mr. Dalton's facts, which were derived from careful and judicious experiments. He exposed water to different temperatures, to observe the weight evaporated in a given time. These vessels were of a cylindrical form, one being \( \frac{3}{4} \) inches in diameter, and the other \( \frac{5}{4} \) inches. The former vessel, when the water in it was jilt made to boil, lost from \( 35 \) to \( 45 \) grains per minute; this difference being explained by a greater current of air over the second vessel. The quantities evaporated at different temperatures were found to agree exactly with the force of vapour.
STEAM.

From a vessel of six inches in diameter, he found that at 212° the mean quantity evaporated in one minute was 154 grains. Then since the mean of the small vessel was about 40, if the quantity be as the surface, we ought to have
\[ \frac{154}{40} = \frac{(60)}{(3-25)}^3 \]
which is very near; for if the small vessel had been 3.05, then the two squares would have been in the ratio of 154.

Mr. Dalton has constructed a table on these data, which, from its great utility in all inquiries relating to the moisture in the atmosphere, cannot fail to be acceptable.

Table, showing the Force of Vapour, and the full evaporating Force for every Degree of Temperature from 20° to 85°, expressed in Grains of Water raised per Minute, supposing no Moisture in the Atmosphere at the Time.

</table>

In order to apply this table to practice, in finding the rate of evaporation at any time, suppose the dew-point found, as above directed, to be 45°, and the temperature of the air at the same time 70°. We find in this table, that the mean rate of evaporation at 45° is 1.62 grains in a minute; the rate at 70° being 3.72. Then 3.72 = 2.08 = 2.08 grains, the quantity evaporated in a minute, under such circumstances. If the example were to ascertain the rate of any artificial evaporation, the temperature of the mass exposed must be taken, instead of the temperature of the air. It must also be observed, that if a brisk wind prevails, the grains evaporated must be taken from the column marked "greater extreme." If there be no wind, look at the "less extreme" column; and in a moderate breeze, take the "mean" column. By this means we are enabled to ascertain, at any time, not only the rate of evaporation, but the quantity of water contained in a cubic foot of space.

From the decrease of temperature in the upper regions of the atmosphere, and the greater decrease of the force of vapour at those temperatures, the greatest part of the water which rises from the earth will be precipitated at a very small height. If the temperature were taken by a thermometer, the degrees of which should have equal increments of heat, aqueous vapour at any temperature would become of half this density,
STEAM.

Aty, by a decrease of temperature equal to 25°. And since, at the intervals of every six miles above the surface of the earth, the preasure, and of course the force of vapour, is halved; the quantity of water in a cubic foot of space will diminish very full with the height. At the temperature of 50°, when the atmosphere contains as much moisture as the temperature will admit, it contains only 3.5 grains in a cubic foot; and if the temperature upward were to vary no more than 25° for every six miles, at 20 miles high there would be little more than one grain of water in a cubic foot of space. But the temperature is known to vary much more rapidly; and hence we should have much less water in the same space, on account of the condensation resulting from this greater decrease. Still, however, some portion of water must exist in the very limits of our atmosphere, in a state of steam or vapour of some density; and this vapour is still within the limits of fact the 5th, before given, viz. If such vapour were compressed till its density was equal to 253 grains in the cubic foot, its temperature would be 12°, whatever might be its temperature previous to its compression. The same thing, as Mr. Dalton has very ingeniously supposed, would be the case with the air itself; that is, if the rarest part of our atmosphere were condensed to the density of that at the surface, its temperature would also become the same. This change of temperature in elastic fluids, by rarefaction or condensation, is evidently owing to a change in their specific heat. We have lately heard of a fact, which has excited the curiosity of some philosophers, and furprised others, which is as follows. When steam, of very considerable density from preasure, is made to issue from the mouth of a pipe, a perfon may place his finger close to the aperture, without feeling any unpleasant effect from the heat. The feaible heat of this steam, which would otherwise act, is absorbed by the sudden change of specific heat, by the expansion of the steam. This fact is very analogous to an experiment which has been long known. When the bulb of a thermometer is placed within the nozzel of a pair of bellows, and a blast fent through them, the mercury rises above the common temperature; but if the bulb be placed at a little distance from the nozzel, the mercury falls below the common temperature. In the firft instance, the air was compressed, and the heat given out; in the fecd, heat was abforbed, and consequently the temperature lowered. The cold produced by the exhaustion of the receiver of the air-pump is to be explained in the fame way. The change of temperature of the atmosphere is doubtlefs more regular at considerable elevations, than near the surface; hence the air in which we live is frequently in a strong evaporating state, while condensation is taking place in the superior regions. This gives rise to numerous clouds, which are nothing more than water in small globules, having lost their elastic form by condenfation. The changes of temperature, which take place from the various currents arising from the action of the sun upon the earth, materially and constantly change these appearances; sometimes causing the disappearance of opaque clouds, and at other times darkening the air by sudden condenfation. We can but, therefore, regard the water in the air as existing in two flates, namely, in the liquid and in the elastic state, between which there can be no medium: for evaporation or condenfation must be the refult of the flight of change of temperature; at least we may conclude, that one of these procedes will commence with the change, and will progresively go on till as much water is either precipitated or taken up as the temperature will admit. Evaporation, as we have before obferved, can never be instantaneous; even if the air did not mechanically refiit it, the presence of the vapour already formed would have that effeet. Although there appears to be no medium between water and steam, the actual precipitation of the water is progressive, and is more or lefs rapid at different times. The clouds which appear to be suspended in the atmosphere are condfuted by an affembly of small globules of real water, which in vacuo would be precipitated with a rapidity agreeing with the laws of falling bodies; but in consequence of the refiance of air, their defcent is retarded, being dependent upon the ratio between their surface and solidity.

There are good reafons for supposing that these globules are prevented from uniting by the presence of electricity, as we know that they must repel one another when they are similarly electrified. On the contrary, when particles are intermixed having contrary flates of electricity, the condenfation will be much facilitated, as we perceive in rain immediately preceding thunder. In all thofe situations where fleam undergoes condenfation, we do not fee water immediately precipitated. The milky appearance is caufed by small globules of real water falling towards the earth with a small but progressive velocity. If the change of temperature causing the condenfation be very slow, the globules are extremely small in the firft infance, and are with more difficulty united. This is doublefs the cafe with all bodies which are perfect liquids. Globules of mercury are united with greater difficulty the smaller they are. The flate in which mercury exifts in lard in the form of union, is in thefes minute globules produced by the mechanical action in mixing it. If boiling water be poured upon mercurial ointment, the fat is feparated and floats upon the water: this may be poured off, and the mercury will be left in minute globules, which are united with great difficulty. It occupies a much greater space than when united, having the appearance of froth. Such is the flate of water forming the white fleey clouds which we frequently obferve at a great height; the dense dark-coloured clouds being compofed of larger globules, which seldom remain long before they are more completely formed into drops of rain.

The clouds, therefore, are not to be confidered as absolutely fepafed, but as water in globules of different magnitudes, falling with a velocity in the inverse ratio of their magnitudes. There is nothing hypothetical in this idea; since it is within the limits of calculation to ascertain the magnitude even of particles of lead falling through any affignable space in a given time. We cannot demonstrate the principle better than by solving the following problem.

What must be the diameter of a globule of water, to be capable of falling one inch in a fecd, after it has acquired an uniform velocity.

Let \( e \) = the specific gravity of the air through which the steam falls, water being 1.
\[ \rho = 3.1416, \&c. \]
\( g \) = the space a body falls in one second by gravity.
\( v \) = the velocity.
\( a \) = the diameter of the globule which is required.

Then, since the particle will ceafe to be accelerated when the reftaftance is equal to its weight, the velocity at that point will be \( a \), which it will uniformly retain, till other things remaining equal. The space fallen through to give \( a \), will be \( \frac{a^2}{4} \) : this, multiplied by \( \frac{\rho}{e} \), will give \( \frac{\rho a^2}{e} \), from which, the

\[ \text{U. 2} \]
content of the cylinder of air, and \( \frac{dF \cdot \rho \cdot r^2 \cdot s^2}{g} \) = the weight of the cylinder. This would be equal to the resistance, if the surface presented to the refilling medium had been a plane perpendicular to the direction. The resistance of such a surface to that of the spherical one, is as 1 to 2.

Hence the resistance will be \( \frac{dF \cdot \rho \cdot r^2 \cdot s^2}{16g} \).

The weight of a globule of water of the diameter \( a \), will be \( \frac{1}{6} \pi a^1 = \frac{dF \cdot \rho \cdot r^2 \cdot s^2}{16g} \). Then, since \( v = 1 \) inch, \( g = 194 \) inches, \( e = .0018 \), \( \rho = 3.1416 \),

\[
\therefore \ x = \frac{3}{8} \times 1 \times \frac{1}{194} \times .0018 \times 3.1416 = .00001643 \text{ of an inch, and in weight only .00000000000027 of a grain.}
\]

When we consider how inconceivably small the atoms of water must be, it will be easy to conceive globules of water much smaller than the above calculation gives.

We are quite aware of the difficulties attendant on the bell theory of clouds and rain. If the view we have given is supported by facts and observation, which at present appears to be the case, we may expect it to stand on firmer grounds than has hitherto been the fate of numerous hypotheses, as it is free from any thing gratuitous or hypothetical.

Steam is at present applied to many economical purposes, as well as in various manufactures, independent of its important office in the steam engine.

In dyeing, bleaching, and many other similar departments, it is used to communicate heat to water, instead of having separate fire-places and boilers. The vessels to contain hot water, which were formerly separate pans or boilers, are now supplied from one principal close boiler, similar to those used for steam-engines, by separate steam-pipes. When the economy of the steam is considered an object, the pipes for conveying the steam should be cast with wood, or otherwise covered with some bad conductor of heat, which will not be attacked by the heat of 212°.

The boiler, which supplies the steam, should be placed lower than any receiver of water which it has to heat, as in that case the water, which may sometimes condense in the pipes, may run back into the boiler. This affords a little economy, by varying the degrees of heat between the hot water and the cold, with which the boiler is supplied. Another advantage is in the pipes not being liable to be choked by the condensing water not being allowed to get out of the way of the steam. For heating water in brewhouses, wash-houses, dyeing-vats, &c. the steam-pipe comes directly into the water, the steam passing into the same making a loud noise, like the rapid cracking of a whip. For heating large baths and buildings, the steam is condensed in the pipes which pass round the baths or around the rooms, and the water shoul in this case run back into the boiler. The pipes, or other metallic vessels in which the steam is condensed for the purpose of warming rooms, should be coated with paint, the blacker the better. This is found to give out heat much more rapidly than the metallic surface, and in a still greater excess above a polished metallic surface.

When steam is employed for the purpose of heating water, the supply for a given quantity of water will be easily calculated by the data already given.

Let \( L = \) the heat required to convert water into steam at 900°.

\[ W = \text{the weight of the water to be heated by steam.} \]

\[ T = \text{its temperature.} \]

\[ t = \text{the temperature to which it is required to be heated.} \]

\[ b = \text{the weight of steam required.} \]

Then \( t = \frac{(L + h) S + W T}{S + W} \), and \( S = \frac{t - T}{L + h - t} W \).

A simple rule for finding the quantity of steam required to raise a given weight to any given temperature arises out of this formula. Multiply the water to be warmed by the difference of temperature between the cold water and that to which it is to raised for a dividend. Then to the temperature of the steam add 900, and from the sum take the required temperature of the water. This last remainder being made a divisor to the above dividend, the quotient will be the quantity of steam, in the same terms as the water.

What quantity of steam at 212° will raise 100 gallons of water at 60° up to 212°? \( \frac{212 - 60}{900} \times 100 = \frac{152}{900} = 17 \) gallons of water, formed into steam. This quantity of steam from a boiler containing about 27 cubic feet, with a fire applied to the belt advantage, will be furnished in 2 hours and 16 minutes, supposing no heat to be lost by the heated masts being exposed. The coal consumed for this purpose will be about 25 or 24 lbs., depending on its quality.

The theorem above given will apply to any temperature above 212°, when the steam is under greater pressure than 30 inches of mercury. It will also appear from the table of the force of vapour, that any degree of heat short of endoergic the vessels, may be given by steam under different degrees of pressure. Such means are at present employed for evaporating water from fagis, flax, and other fluids requiring a greater degree than 212. It will be equally obvious, that an uniform heat may be kept up below 212°, by adjusting the steam-cook through which the medium to be heated is supplied. In giving heats above 212°, the vessels should be completely steam-tight, and very strong. The boiler should have a safety-valve, which should always be kept clean and free to act.

Steam is employed to great advantage for culinary purposes. It is made to communicate with vessels in the form of boilers, as a substitute for having fires under them, which is a great advantage, both in the economy of fuel, and in avoiding at the same time the nuisance of ashes and smoke.

The most convenient application of steam for culinary purposes is, when it directly acts upon the substance to be heated. This has been generally effected by placing the substance, whether meat or vegetables, in a vessel without water, and allowing the steam to enter and condense upon it. The most convenient apparatus of this kind we have yet heard of, consists of a cast-iron plate about 30 inches or three feet square, standing horizontally in a reef or in the wall, like a table. Round the edge of this plate is a groove, about half an inch wide and two inches deep. Into this groove fits an inverted tin-veil, like a diffusion. This is capable of being elevated and depressed by a pulley and chain, having a counterpoise,
STEAM.

terpoile, in order to expel the table at any time. The
steam comes under the table and enters in the centre. The
dishes to receive the heat are placed on any part within the
groove, the steam being common to all. The water re-
resulting from the condensation runs into the groove, and at
a point short of the top runs off. The water which re-
 mains forms a complete water-lute, to prevent the escape
of steam. The table being placed in a recce, like a common
stone hearth, a small flue is placed over it to take away
any steam that may escape when the cover is lifted up.

The great quantity of hot water required in a scullery
should be perpetually kept up by a supply of steam. For
this purpose a large cylindrical vessel of cast-iron should be
erected in a corner of the scullery, in order that water
may be drawn from it by a cock. This vessel should be
connected from the bottom with a cold-water ciline, the
bottom of which is level with the top of the cylinder, by
which the latter is kept constantly full. The hot-water
cylinder is closed firmly at the top, and therefore, when
the air is allowed to escape, the water rises to the top. If
now a pipe be connected with the top, coming down to
where it is to be drawn off, if any portion be drawn out
here, as much will come in at the bottom of the cylinder
from the refevoir above. So far we have described this
cylinder without its steam-vessel. Within this cylinder, and
about the middle, is a distinct vessel, nearly of the width of
the cylinder; but having a free space round the inner
vessel about an inch wide. The depth of the inner vessel
must be about one-fifth that of the outer one. This inner
vessel must have no connexion with the outer one, and must
be for water-tight, that although it is surrounded with the
water of the outer one, none should get in. The inner
vessel is on one side connected by a pipe with a steam-boiler,
having another pipe to allow the condensed water to run
eff, which may be preferred as distilled water, and is valuable
for many purposes. The heat arising from the condensa-
tion is communicated to the water in the outer vessel, the
hotest being at the top, where the mouth of the exit-pipe
is placed. When, therefore, a portion of hot water is
drawn from the cock, the pipe of which comes from the top
of the vessel immediately under the cover, an equal
quantity comes in at the bottom from the refevoir. This
useful apparatus is the invention of an ingenious economist
of Derby, and is at present in use in his kitchen.

When steam is properly applied to the warming of baths,
the economy is so great, that if it were known, these ex-
quisite luxuries would soon become more fashionable. The
steam is condensed in pipes about two or three inches in
diameter, which are placed round the bottom of the bath.
These pipes are concealed in a recess, which is afterwards
covered by thin stone plinths, perforated with holes to allow
the water to circulate.

We shall point out the economy of these baths, by giv-
ing some facts of a bath in common use. Its size is about
10 feet square, and its depth such as to contain about 520
 cubic feet. The steam at 212°, to first raise it from 32°
to 56°, will be found by the above theorem to be as much
as will condense it into 33 cubic feet of water. This will be
produced by 36 lbs. of coal, including that required to
raise the 33 cubic feet of water from 32° to 212°, which
is always about 4th of what will afterwards make it into
steam.

Supposing the bath to have double doors, and a small sky-
light instead of common windows, it will be found, when
the outer air is 45°, that the bath will not cool more than
4° in 24 hours. To restore this every day, will require
only 1/4th of what was required to raise it from 32°. This
will be about 23.5 lbs. Supposing the whole of the water
to be changed by a regular inlet and outlet every 14 days,
then the weekly supply of coal for such a bath will be
about 350 lbs.

It is suggested by Dr. Darwin, that the art of boil-
ing vegetables of all kinds in steam instead of water,
might probably be managed to advantage, as a greater
degree of heat might be thus given them, by contriving
to increase the heat of the steam after it has left the
water; and thus the vegetable mullage in roots and seeds,
as in potatoes and flour-puddings, as well as in their leaves,
fluits, and flower-cups, might be rendered probably more
nutritive, and perhaps more palatable; but that many of
the leaves of vegetables, as the summits of cabbage-sprouts,
lose their green colour by being boiled in steam, and look
like blanched vegetables. This vitiation of some vegetables
by steam is probably owing to its diffusing their colouring
matter, which may then become decomposed, and may ren-
der them less agreeable to those who choose by the eye
rather than by the palate; which green colour is, however,
heightened by boiling them in some hard waters which con-
tain diffused lime of sea-salt, or by a flight admixture of
common salt with soft water; an effect which is owing to
the evaporation of a part of the marine acid, and to the
remaining alkali which was the basis of it, when applied to
blueish vegetables converting them into green, as in the
common experiment of adding salt of tartar to syrup of
violets, or according to the custom of some cooks who add
a little potash, or fixed vegetable alkali, to the water in
which young peas are boiled, to make them green, and
afterwards a very little sugar to sweeten them. And the
fame effect of making vegetables green, when boiled in an-
other kind of hard water, is probably produced by the lime
which abounds in them, and which, like the vegetable
alkali, when the aerial acid which was united with it evap-
orates, is said to convert blueih vegetable colours into
green ones.

Steam has likewise lately been applied in gardening to the
purpose of forcing plants of different kinds in the winter
season, in order to have their produce at an early period, as
to the cucumber, and some other vegetables of a somewhat
similar nature; but the exact manner of its application in
this intention, to far as we know, has not yet been commu-
nicated to the public; it is, however, by some mode of flues,
pipes, and other contrivances for conveying and containing
it, so as that its heat may be unblurredly, equally,
and regularly afforded to the roots of the plants which it is
so desired to push forward into the fruiting state. It is said
to have been used in some instances in different parts of Lan-
cashire with great success. But how far the expense and
advantage of such a method may admit of and encourage its
being introduced into general practice, have not, probably,
yet been well or fully ascertained. If it should be found
capable of perfectly succeeding in this use, on more full
and correct experience, it will, however, constitute not
only a neat and clean, but a elegant mode of forcing plants
into fruit at early season.

It has been found that subterranean steam often affect
the surface of the earth in a particular manner, and promote
or retard vegetation more than almost any thing else.

Steam-Engine, or Fire-Engine, a machine very generally
employed in this country as a first mover of other engines
and machines, its mechanical force or moving power be-
ing obtained from the expansion or contraction of the
steam of boiling water. Until of late years this machine was
called the fire-engine, because it is in reality actuated by
the fire which cauful the water to boil.
STEAM-ENGINE.

The steam-engine is an invention highly creditable to human genius and industry, and is amongst the most valuable applications of philosophical principles to the arts of life. The invention of a ship, with all her accessories, and the degree of knowledge requisite to conduct her through a distant voyage, are more striking instances of the power of the mind of man, and of his enterprising disposition; whether we consider the number of sciences which must be applied to practice in the construction and management of a vessel; or the advantages which mankind have derived from such an invention, and the improvements which it has occasioned in the state of civilization, by uniting, in a great degree, all the inhabitants of the globe in one society, who mutually supply each other's wants, and who all contribute their share to the general stock of knowledge.

The steam-engine follows next to the ship in the scale of inventions; but in an English Cyclopedia it will take the lead, from the circumstance of its being wholly invented, and brought into general use, by our own countrymen, within the space of a single century; and also as having been the principal means of effecting those great improvements which have taken place in all our national manufactories within the last thirty years; and the increase of our commerce which has ensued.

The art of navigation is the result of the combined ingenuity and experience of all nations, from the earliest period of history to the present time; and the successive and almost imperceptible improvements by which it arrived at its present state of perfection, have many of them been the productions of accident, and for which we do not exactly know to whom we are indebted. But the steam-engine is the invention of a few individuals, all of them Englishmen, and brought into general use within a century. In the first beginning it was the result of reflection, and the production of a very ingenious mind; and every alteration in its construction and principle was also the result of philosophical enquiry.

General Principle of the Steam-Engine.—The force of the steam-engine is derived from the property of water to expand at an amazing degree, when heated above the temperature at which it becomes changed into steam, or vapour, which being an exceedingly elastic fluid, it can be retained within the close vessel or boiler to which the heat is applied, even when it has an expansive force sufficient to make it fill, if left at liberty, 20 or 30 times the space in which it is confined. In this state the steam will exert a proportionate force or prehure to burst open the sides of the vessel in which it is retained; which force may be applied either to expel or raise up water from any vessel into which the confined steam is admitted, or to give motion to a moveable piston, which is so accurately fitted to the interior capacity of such vessel, as not to permit the escape of the steam between them.

Another source of the power of the steam-engine is the facility with which steam of a great expansive force can be cooled by the application of cold water, and condensed into the small quantity of water from which it was originally produced. A partial vacuum can thus be made, in a very large vessel, in an instant, and even in the same vessel, which was, a moment before, filled with confined steam, exerting a great force to escape. The prehure of the atmosphere which tends to fill up this vacuum, can be made to produce the ascent of water into the vessel to any height less than twenty-four or twenty-five feet. Or the prehure of the atmosphere may be made to give motion to a piston, by admitting the atmospheric air to prehure upon one side of the pylon, whilst there is a vacuous space formed by the condensation of the steam which filled the cylinder on the other.

Notwithstanding the great variety of different constructions of the steam-engine, they all derive their force from one of these two principles, or from the combination of the two; but before entering upon any description of the manner in which these forces are applied, it is necessary to have clear ideas of the nature of steam, and of the law by which it expands by heat, in order to form a precise judgment of what pahes in the interior part of a steam-engine when it is at work. In the common acceptance of the word steam, it is that hot white vapour which we see every day rising in a cloud from a tea-kettle or boiling-pot; but this is not exactly the state of the steam employed in an engine; it is there perfectly transparent, and is more or less hot than boiling water, according as it is retained under a leffer or greater degree of compreure. The ordinary prehure of the atmosphere, bearing upon the surface of water, will retain it in a state of fluidity, until it is heated to what is generally called the boiling point, and is marked 212° in Fahrenheit's thermometer. If the heat is increased above that degree, and if the water is unconfeined, except by the prehure of the atmosphere, the water immediately assumes the aeriform state, and flies off in elastic vapour, which we call steam; but if the fame water is retained under the prehure of the atmosphere by enclosing it in a close vessel, and exhausting the air from it, a certain proportion of steam or vapour will rise from the same at any temperature, even when it is as low as freezing; and if this vapour is conveyed off from the vessel as fast as it rises, the water, although cold, will boil, and such vapour will rise as fast as the boiling kettle does in the open air. If the vapour is retained in the vessel, it will only accumulate, until it has acquired a certain degree of elastic force to prehure upon the surface of the water, which will then cease to yield any more vapour, until the heat is further increased, or that the vapour is drawn off to relieve the water from the prehure which confines and retained it in its fluid state. On the other hand, water which is retained in a close vessel, under a greater degree of prehure than that occasioned by the prehure of the atmosphere, will not boil or rise in vapour, until it becomes heated to a higher temperature than 212°. It is even probable, that water might be compréllled to that degree, that it would not boil until heated red-hot; but this would require such an enormous strength in the vessel which should contain the steam, that it is far beyond the practicability of an experiment.

In this manner the reader is to bear in mind, that vapour or steam, when confined in close vessels, is always more or less elastic, in proportion to the degree of heat which is applied to it; or, in other words, that the temperature of the steam is an exact index of the elastic or expansive force with which it prehures upon the surface of the water, and against the interior surface of the vessel which contains it.

The following tables show the law by which the expansive force increases with the increase of the temperature. They were made from the experiments of Mr. John Dalton, which he published at length in the "Memoirs of the Literary and Philosophical Society of Manchester," and experiments have been also made in France by M. Betancourt, which do not differ from this table so much as to affect the results in any great degree, when applied to practice, in calculating the force of steam-engines. These experiments were made by enclosing water in a close vessel, from which the air was carefully exhausted, so as to make a vacuum. A thermometer was applied, so as to indicate the
STEAM-ENGINE.

the temperature of the interior of the vessel; also there was a communication made from the vessel to the lower part of a fiphon barometer tube, that is, an inverted glass fiphon filled with mercury, from one leg of which the preffure of the atmosphere was excluded, and the other leg communicated with the interior of the vessel. In this way, when there was a vacuum in the vessel, the surface of the mercury in the two legs of the fiphon would stand at the same level, because it would not be preffed upon at all on either side; but when any vapour was raised in the vessel, it would preff upon the interior surface thereof, and also upon the surface of the mercury in one of the legs of the inverted fiphon; and as the surface of the mercury in the other leg would not be preffed upon at all, the mercury would mount in one leg and descend in the other, and the difference of the level between the two being measured, would express the elaltic force of the vapour, which was found to inerease with the inereace of the heat, according to the second column of the table. For the convenience of eflimating the force of the vapour, we have added the third and fourth columns to Mr. Dalton's table. The third, to eflpress the preffure by the altitude of a column of water, instead of mercury; and the fourth column to shew the preffure upon each square inch of the surface upon which the vapour acts, in pounds avoirdupois and decimals. The table also shews, in the three laft columns, the difference of preffure between the vapour and atmospheric air in three different terms, viz. in the column of mercury, column of water, and in pounds on the square inch.

In the flrst table, which is for every 10° of temperature up to 212°, or the heat of boiling water when in the open air, the three laft columns shew how high the preffure of the atmospheric air, when the barometer is at 30 inches, will force up mercury or water in a tube, which at the upper end communicates with the vessel containing the vapour, and the lower end is immerfed in the mercury or water. And in the second table, which is for the degrees of heat above 212°, the same columns shew to what height the force of the vapour will caufe mercury or water to mount up in a tube, which at the lower end communicates with the vessel containing the steam, and the upper end is open to the atmospheric air.

Table of the expansive Force of the Vapour of Water, or Steam, when enclosed in a close Vessel, and relieved from the Preffure of the Atmosphere; taken at every 10° of Temperature, from the Congelation of Mercury, or 40° below the Zero of Fahrenheit, up to 212°, or boiling.

History of Invention of the Steam-Engine.—The great clastic force of steam has been long known in the instrument called the aeolipile (see that article); and its property of condensation was also experienced in the use of the same instrument: the manner commonly practised for filling the ball with water being to plunge it into cold water, when heated and filled with steam; by which means the steam is condensed, and forms a vacuum sufficient to draw the water into the ball, although the orifice is so small that water could not be introduced by any other means. At the same time, the true principles of its action were so little understood, that the steam which flowed from it, when placed on the fire, was supposed to be air produced by the decomposition of the water; and nearly all the old philosophers, who have described this instrument, propofed to employ it for blowing furnaces. The first idea of employing this force of steam to produce motion was by Brancas, a philosopher of Rome, who contrived a great number of different kinds of mills to be worked by the steam coming from a large aeolipile, and blowing against the floats or vanes of a wheel. We are obliged to this author for a number of other ingenious inventions, which he dedicated to M. Cenci, governor of Loretto, in 1628, and published his work (Le Machine) at Rome the year following. The representation of his fire-machine is given in the twenty-fifth plate; but the force which he could have thus obtained from steam would have been found altogether inconsiderable, if he had ever put it in practice.

The first real steam-engine was invented by the marquis of Worcester; but it was only for raising water, and that by the expansive force of steam alone. The next engine was by captain Savery, and operated, both by the expansive force and the pressure of the atmosphere, to fill up the vacuum which was produced by the condensation of the steam, after it had ceased to operate by its expansion. These actions were employed alternately to raise water. The third inventor, Newcomen, abandoned the force of expansion, and only employed the condensation of the steam to obtain a vacuum, and cause the pressure of the atmosphere to act, unbalanced upon a piston, fitted into a cy-inder; and as the force was thus exerted upon a moveable piston, his machine is capable of being applied to give motion to pumps or other machines, whereas his predecessors were obliged to confine themselves to the raising of water. Soon after this invention, engines were propofed to be actuated by the expansive force of the steam only, without the vacuum. Lastly, Mr. James Watt invented the engines now in general use, which are actuated both by the pressure of steam, and the vacuum acting at the same time upon the opposite surface of the piston.

We owe too much to these inventors, as well as many others, to pass over their discoveries with such a flight of notice; and shall, therefore, give a detailed history of the progress of this valuable invention, drawn from the best authorities we have been able to obtain.

The Marquis of Worcester's Steam-Engine.—The earliest description
description which we have of a machine for raising water by fire, employed in raising steam from boiling water, is from the marquis of Worcester, who, in the reign of king Charles II., and in the year 1663, published a small pamphlet, entitled "A Century of the Names and Scantlings of the Inventions of Worester's Inventions," written in 1665.

This little work, it appears, was addressed to the king and parliament, and published with a view to obtain an encouragement from the public for the prosecution of 100 projects, which it details. No. 68. of this Century contains as follows:—No. 68. An admirable and most forcible way to drive up water by fire; not by drawing or sucking it upwards, for that must be as the philosopher calles it *iniria sphaerae adhibita*, which is but at such a distance. But this way hath no bower, if the vellid be strong enough: for I have taken a piece of a whole cannon, wherein the end was burnt, and filled it three-quarters full of water, stopping and screwing up the broken end, as also the touch-hole; and making a constant fire under it, within twenty-four hours it burnt, and made a great crack; so that having a way to make my vellids, so that they are strengthened by the force within them, and the one to fill after the other. I have seen the water run like a constant fountain stream forty feet high: one vellid of water, rared by fire, driveth up forty of cold water. And that a man tends the work is to turn two cocks, that one vellid of water being confumed, another begins to force and re-fill with cold water, and so successively; the fire being tended and kept constant, which the self-same perfon may likewise abundantly perform in the interim between the necessity of turning the said cock.

This passage certainly contains a description of an engine for raising water by the repellent power of steam; and from his expression, of one vellid of water, converted into steam, forcing up forty vellids of cold water to the height of forty feet, it is very probable that he had actually tried the experiment by a working model.

The marquis concluded his Century of Inventions by a promise to leave to posterity a book, wherein under each head the means of putting his several inventions in execution were to be described, with the affordance of plates; but as this work never appeared, we can only judge of his abilities by this specmen. He appears to have been a person of much knowledge and ingenuity; but his obscure and enigmatical account of these inventions seems not so much intended to instruct the public as to raise wonder; and his encomiums on their utility and importance are, to a great degree, extravagant, reminding more the puff of an advertising tradesman, than the patriotic communications of a gentleman. The marquis of Worcester was indeed a projector, and very important and mysterious with his applications for public encouragement.

It does not appear that he met with any public encouragement to his propositions; and though, at first sight, it seems surprizing that an invention, by which the steam of boiling water is lifted to be capable of producing a power equal to that of gunpowder, should be neglected for almost forty years; yet if we consider that the greater part of this Century of Inventions confunds of things highly in the style of legendarie, and some of them absolutely impossible, and contrary to all established rules of science, we need not so much wonder at the neglect which the whole experienced. For example, the 99th number of the Century is as follows:—"How to make one pound weight to raise an hundred as high as one pound falleth, and yet the hundred pounds defending the weight nothing less than one hundred pounds can effect."—Vol. XXXIV.

It must be also further considered, that these projects were published at a time when true science was beginning to take place of empiricism.

The Century of Inventions appeared about three years after the establishment of the Royal Society, during the time of Mr. Boyle, Dr. Hooke, Dr. Wallis, Sir Christopher Wren, Sir Isaac Newton, and others equally skilful in calculations, as in the inventive parts of mechanics.

Under all these circumstances, it is not astonishing that the marquis's propositions in general should meet with a cool reception, or that this celebrated invention should be condemned to obscurity, amongst the other wonders with which it was accompanied.

We do not with it to be understood, that all the marquis's propositions, except the fire-engine, are of the same nature as No. 69: on the contrary, several have been re-invented, and proved true, since the marquis's time; for example, short-hand telegraphs, floating baths, carriages from which the horses can be disengaged if unruly, combination locks, secret escutcheons for locks, candle-moulds, &c. It is also probable that others may be brought to perfection yet the marquis's is so much in the style of the wonderful, that it is to be wished that the marquis had published nothing but No. 69, which at once would have rendered his name immortal, and without any tarnish or alloy to the glory of so great an invention.

Captain Savery's Steam-Engine.—The next attempt upon record is that of captain Thomas Savery, a commissioner of the fick and wounded, who, in the year 1698, obtained a patent for a new invention for raising water, and occaafioning motion to all sorts of mill-work, by the impellent force of fire. This patent bears date the 25th July, in the tenth year of the reign of William III., that is 1698. The patent states that the invention will be of great use for draining of mines, serving towns with water, and for working all sorts of mills.

In June 1699, he shewed a working model of his engine to the Royal Society, and in their Transactions for that year, viz. No. 253, vol. xx. there is the following regifter:

"Mr. Savery, June 14th, 1699, entertained the Royal Society with shewing a small model of his engine for raising water by the help of fire, which he set to work before them: the experiment succeeded according to expectation, and to their satisfaction."

The above is accompanied with a copper-plate figure, with references by way of description, from whence it appears, that the engine then shewn by captain Savery was for raising water not only by the expansive force of steam, like the marquis of Worcester's, but also by the condensation of steam, the water being first raised by the preasure of the atmosphere to a given height from the well into the engine, and then forced out of the engine up the remaining height by the expansive force of steam, in the same manner as proposed by the marquis. This action was performed alternately in two receivers, so that while the vacuum formed in one was drawing up from the well, the preasure of the steam in the other was forcing up water into the reservoir; but both receivers being supplied by one suction-pipe and one forcing-pipe, the engine could be made to keep a continual stream, or so nearly so as to suffer very little interruption.

The inventor afterwards published an account of his engine in a small book, entitled "The Miner's Friend, or an Engine to raise Water by Fire described, and the Manner of fixing it in Mines, with an Account of the several Ufes it is applicable unto, and an Answer to the Objections made against it," printed at London in 1702, by Thomas Savery, gentle-
STEAM-ENGINE.

This little book was separately addressed to king William III., to whom the engine had been shown at Hampton Court, to the Royal Society, and also to the Mine Adventurers of England, who were invited to adopt the invention.

This engine displays much ingenuity, and is almost as perfect in its contrivance as the same kind of engine has ever been made since that time: we have on that account copied the principal figure, and Captain Savery's own description, as given by Dr Harris, in his Lexicon Technicum. See Plate 1. Steam-Engine, fig. 1.

Captain Savery's Description of his Fire-Engine.—A denotes two furnaces, whole fire-places are marked B 1 and B 2, and their common funnel or chimney C.

In these two furnaces, whole fire-places are marked B 1 and B 2, and their common funnel or chimney C.

These furnaces have each a gauge-pipe, as G and N, of which G goes within eight inches of the bottom of the small boiler, but N reaches only half way down into the great boiler.

By these pipes, before the engine can work, you must fill the small boiler quite full, and the great boiler two-thirds full of water. Then light the fire under the large boiler at B 1, and make the water therein boil, by which means the steam of it being quite confined must needs be wonderfully compressed, and therefore will, on the opening of a way for it to issue out (which is done by pulling the handle Z of the regulator from you), rush with a great force through the steam-pipe O 1, into the receiver P 1, driving all the air before it, and forcing it up into the force-pipe through the clack R 1, as you will perceive by the noise and rattling of the clack; and when all the air is thus driven out, the receiver P 1 will be very much heated by the steam. When you find it is thoroughly emptied, and is grown very hot, as you may both feel and feel, then pull the handle Z of the regulator towards you, by which means you will stop the steam-pipe O 1, so that no more steam can yet come into the receiver P 1, but you will open a way for it to pass into O 2, and by that means fill the other receiver P 2 with the steam, as the other was before.

While this is doing, let some cold water be poured on the first-mentioned receiver P 1, by which means the steam in it being cooled and condensed, and contracted into a very little room, and consequently preying but very little (if at all) on the valve or cock R 1, at the bottom of the receiver P 1, there is nothing there to counterbalance the preyness of the atmosphere on the surface of the water, in the lower part of the sucking-pipe T, wherefore it will be pressed up, and ascend into, and fill the receiver P 1, driving up before it, as it riles, the clack or valve R 3, which afterwards falling down again and fluttering close, hinders the descent of the water that way.

Then (the receiver P 2 being in the mean time emptied of its air) pull the handle of the regulator from you, and the force of the steam coming from the boiler, will act upon the surface of the water contained in the receiver P 1, where it forces or presses hard upon it, and still increases its elasticity or spring until it exceeds the weight of the column of water in the receiver and pipe S, which then it will necessarily drive up through the piaffage Q R 1, Q Q 1, into the force-pipe S, and at last discharge it out at the top, as is represented in the figure.

After the same manner, though alternately, is the receiver P 2 filled and emptied of water, and by this means a regular stream is kept continually running out at the top of the force-pipe S, and so the water is raised very easily from the bottom of the mine, &c. to the place where it is designed to be discharged.

1. Only I should add, that after the engine begins to work, and the water is risen into and bath filled the force-pipe S, it fills also the little cittern X, and by that means feeds the pipe Y Y, which I call the condensing pipe, and which can be turned sidways over either of the receivers, and will then be open: by this cold water is conveyed down from the force-pipe to fall upon the outsi des of the receiver, when thoroughly heated by the steam, in order to condense the steam within, and make them suck (as it is usually called) the water out of the well up into the receiver.

Alfo a little above the cittern goes the pipe E, to convey water from the force-pipe into the leffer boiler D, for the purpose of replenishing the great boiler L, when the water in it begins to be almoft consumed. Now when there is need of doing this, turn the cock E, so that there can be no communication between the force-pipe S and the leffer boiler D; and putting in a little fire under the small boiler B 2, the water will there grow prefectly hot; and when it boils, its own steam, which hath no vent out, preying on its surface, will force the water up the pipe H, through K, into the great boiler L, and so long will it run till the surface of the water in the boiler D gets to be as low as the bottom of the pipe H, and then the steam and water will run together, and by its noise, and rattling of the clack I, will give us that works the engine sufficient assurance that the small boiler hath emptied and discharged itself into the greater one L, and carried in as much water as is then necessary; after which, by turning the cock E again, you may let new cold water out of S into the leffer boiler D, as before, and thus there will be a conflant motion and a continual supply of the engine, without fear of decay or disorder.

Alfo, to know when the great boiler wants replenishing or no, you need only turn the gauge-cock N, and if water come out there is no need to replenish it, but if steam only come, you may conclude there is want of water; and the like will the cock G do in reference to the leffer boiler D, showing when it is necessary to supply that with fresh water from S; for that in working the engine there is very little skill or labour required; it is only to be injured by either a stupid or wilful neglect.

The engine above described does not differ essentially from that represented in the print in the Philosophical Transactions, but it is more neatly put into form, and improved in some of the minor particulars. For instance, the original engine had only one boiler, and there was no means of supplying it with water, to replace the water occasioned by the evaporation of the steam, without stopping the action of the engine whenever the boiler was emptied to such a degree, as to risk the burning of the vessel. And after the boiler was replenished, the engine could not begin to work again, until that water which was introduced cold was made to boil.

The engine which we have just described from the Miner's Friend has a subsidiary boiler, in which a quantity of water is reduced to a boiling heat in a short time for supplying the great boiler, and the power of the steam raised in the subsidiary boiler is employed to force the water contained in it into the other, or great boiler, which actuates the engine: by this means the transposition of the feeding water is not only instantly performed, but being at a boiling heat, it is immediately ready to produce steam for carrying on the work. There is also another grand improvement in the construction of this engine. His first engine was worked by four separate corks, which the operator was obliged to turn
STEAM-ENGINE.

turn separately at every change of stroke; and if he turned them wrong, he was not only liable to damage the engine, but he prevented its effect, and lost a part of the operation; whereas in this second engine the communications are made by the double sliding-valve, or regulator, as it has since been called. This is a brass plate, shaped like a fan, and moving on a centre with the boiler, so as to slide horizontally in contact with the under surface of the cover of the boiler, to which it is accurately fitted by grinding, and thus to prevent or reduce the escape of steam from the receivers alternately. This regulator acts with less friction than that of a cock of equal bore; and by the motion of a single handle backwards, at once opens the proper steam-pipe from one receiver, and closes that which belongs to the other receiver.

The contrivance of the regulator has since proved of more confidence, as having been universally adopted in the cylinder engines.

Captain Savery, in the Miner's Friend, above referred to, in addition to the description of his engine, enumerates the following uses to which it may be applied, and which he describes rather fully, as follows; viz. 1st, to raise water for turning all sorts of mills; 2dly, supplying palaces, noblemen's and gentlemen's houses with water, and giving the means of extinguishing fires therein, by the water fo raised; 3dly, the supplying cities and towns with water; 4thly, draining lands and marshes; 5thly, for ships; 6thly, for draining mines of water; and 7thly, for preventing damps in the said mines.

Dr. Harris, in his account of the fire-engine, speaks of captain Savery as one that he was acquainted with, and as a man of great merit and ingenuity. He first mentions another machine of Savery's, for rowing a ship in a calm by paddle-wheels placed at the vessel's side, of which the captain published an account in 1692; and it is worthy of remark, that the same kind of wheels, when actuated by improved steam engines, is the only method, amongst an infinite number of others, which at present has been found to answer for rowing vessels. Dr. Harris, in proceeding to the fire-engine, says, "The other engine is for raifying water by the force of fire, in which he has shewn as great ingenuity, depth of thought, and true mechanic skill, as ever discovered itself in any design of this nature." Notwithstanding this, Dr. Defaguliers, by endeavoring to take away all the merit of the invention of the fire-engine from captain Savery, as if he had merely copied it from the marquis of Worcester. The account given by Dr. Defaguliers has been so frequently copied by different writers, that it is generally considered as correct; and we therefore think it a piece of justice to the memory of captain Savery, to set his pretensions in a clearer light than has been generally done. The doctor says, "Captain Savery having read the marquis of Worcester's book, was the first who put in practice the raising water by fire, which he proposed for the draining of mines. His engine is described in Harris's Lexicon, (see the word ENGINE,) which, being compared with the marquis of Worcester's description, will easily appear to have been taken from him, though captain Savery denied it; and the better to conceal the matter, bought up all the marquis of Worcester's books that he could purchase in Paternoster-Row, and elsewhere, and burned them in the presence of the gentleman, his friend, who told me this. He said that he found out the power of steam by chance, and invented the following story to make people believe it; viz. that, having drunk a flask of Florence at a tavern, and thrown the empty flask upon the fire, he called for a bason of water to wash his hands, and perceiving that the little wine left in the flask had filled up the flask with steam, he took the flask by the neck, and plunged the neck of it under the surface of the water in the bason, and the water of the bason was immediately driven up into the flask by the pressure of the air. Now he never made such an experiment then nor designedly afterwards, which I thus prove:"

"I made the experiment purposely with about half a glass of wine in a flask, which I laid upon the fire till it boiled into a bason; then putting on a thick glove to prevent the neck of the flask from burning me, plunged the mouth of the flask under the water that filled a bason, but the pressure of the atmosphere was so strong, that it beat the flask out of my hand with violence, and threw it up to the ceiling. As this must also have happened to captain Savery, if ever he had made the experiment, he would not have failed to have told such a remarkable incident, which would have embellished his story."

This conclusion of the doctor's is altogether unphilosophical, and does not at all invalidate captain Savery's account. We know that the marquis of Worcester gave no hint concerning the contrariety or sudden condensation of steam, upon which all the merit of the modern engine depends. The marquis of Worcester's engine was actuated wholly by the elastic power of steam, which he either found out, or proved by the burling of a cannon, in part filled with water; but he gave not the least hint that steam so expanded is capable of being again so far contracled in an infant, as to leave the space it occupied in a vesel in a great measure a vacuum. This grand discovery was referred to captain Savery, and his account of its accidental origin is not at all improbable. The captain tells us in the Miner's Friend, that he did not bring his design to bear, until after a great number of fatiguing inquiries; and he actually erected several machines before he obtained his patent in July 1658. Many objections were made against the grant of that patent being passed; but in the hearing of these objections, the discovery of the marquis of Worcester's prior claim was not mentioned: and, indeed, it is certain that the account given in the Century of Inventions could not instrute a person who was not sufficiently acquainted with the properties of steam to be able to invent the machine himself. Defaguliers seems to have been too hastily in concluding that the captain had never had any experience as that of the wine-flask, because, in the single instance in which he tried it himself, he found the effect of the condensation took place in a much higher degree than reported by the captain. It is not difficult to conceive that a very small difference in the heat of the steam which filled the flask, and other circumstances, might create the whole of the difference in the result. And, on the whole, there is no reason to hesitate in believing that the captain actually took his hint of the condensation of steam from such an accident, and being of a very mechanical genius, he would naturally turn his thoughts towards the condensation of such a power; and the most obvious application of it would be to a machine on a construction similar to that described by the marquis. Or, if he really had been acquainted with, and confidered the marquis's engine, he would easilie see that the new principle of condensation might, with great advantage, be combined with the former, and thereby produce an effect more powerful than either of them could do alone. The only thing in the doctor's account which cannot now be disproved is, that captain Savery destroyed the marquis of Worcester's books. Even if this is true, it may be accounted for; the captain must, first or last, have become acquainted with what had been before made public by the marquis of Wor-
STEAM-ENGINE.

celler; and after having in his books spoken of his invention, and his new power or cause of motion, and finding the marquis's inventions to be but little known, he might be tempted, in order to secure the whole credit and expected advantage to himself, to buy up the marquis's books and burn them. But the grounds for this affirment are very slight, and will never prevent the conclusion, that the great principle of obtaining force from the preßure of the atmosphere, by the condensation of the steam of boiling water, was a discovery for which we are indebted to captain Savery, who had also the merit of first reducing it to practice in a most complete manner, in combination with the prior discovery of the marquis.

M. Amontons' Fire-Wheel.—The French writers who have treated of the steam-engine, seldom fail to mention Papin and M. Amontons as the first inventors of the method of raising water by steam, and speak of Savery as a person who put their ideas in execution, and brought them to perfection: we think it right on this account to relate what was done by M. Amontons and Papin, although the attempts of the latter to employ the force of steam are not entitled to any notice, either from their originality, or from their real merit. It is probable, that the news of the patent granted to Savery in 1698, for raising water, and occasioning motion to millwork by the impelling force of fire, excited the attention of the French academicians, before the means by which it was to be accomplished were made public, so as to be known abroad, and that they were thus induced to attempt the same thing; for in June 1699, which is the same month that captain Savery flewed his machine at work before the Royal Society, M. Amontons delivered a memoir to the Royal Academy of Sciences at Paris, entitled "A commodious Way of substituting the Action of Fire instead of Men and Horses to move Machines."

This may be regarded as the first attempt to produce a circular motion by the means of fire, otherwise than by the aeolipile, or the fly of a smoke-jack; but as the motion of M. Amontons' wheel was to be produced by the alternate dilatation and contraction of air, and not of the steam of boiling water, it is nothing in common with Savery's machine, except that the first cause of motion is that of fire.

M. Amontons' fire-wheel, as he called it, confids of a number of clofe buckets, or chambers, placed in the circumference of a hollow wheel, and communicating with each other by valves opening in one direcHon; and a sufficient quantity of water is put into these buckets to fill about one half of the number: another circle of similar buckets, but of larger dimensions, are placed on the outside of the circle of the former buckets; these large buckets contain air, and each one has a pipe conducted from it to one of the water-buckets which are nearer to the centre: a part of the circumference of the wheel, which is about the level of the centre, is exposed to the fire of a furnace, so that each air-bucket that paffes will be heated; and also the lower part of the wheel is immerfed in a ciferion of cold water, fo as to cool the fame bucket again. The action of the machine may easily be underflood. The air contained in the large bucket which is opposite the fire becomes heated and expanded, and by the pipe of communication it enters into that water-bucket which is at the lower side of the wheel, and preffing upon the surface of the water therein, causes it to mount up through the other chambers, in the direcHon in which the valves open from one chamber to the next; the water, being thus accumulated in the chambers at one side of the wheel, will give it a prepondering power to turn round upon its axis. This motion brings another air-bucket opposite to the fire, and the air therein expands in its turn, and again elevates the water in the interior chambers as much as it had defcended by the motion of the wheel; a continual succession is thus kept up, and the air-buckets which have paffed the fire defcend into the cold water, and the air is thereby cooled and reduced to its former bulk. By the communication with the water-buckets, the preßure of the expanded air is removed from within them, and puts them in a situation to repeat their action.

This machine is ingenious, and if a better application of fire, by rarefying water into steam, had not been discovered, it is poSSible that the invention of M. Amontons might have been further prostituted. From his computations it would appear, that the machine he proposed would act with a confiderable power; but as he exhibited no working model, or actual trial, it was never proved that the machine, if put into practice, would be capable of producing any thing near the effect promised by his calculations. Leopold, in his "Theatrum Hydraulico." 1724, propofed an improved form of this fire-wheel; and steam-engines have been fince made with mercury, or fluid metal, contained within a hollow wheel, which is to be always kept on one side with the mercury by the force of the steam; they have never been found to equal other modes of applying the force of steam. Such of our readers as are curious to know more of the construction of M. Amontons' machine, can consult the original memoir; and they will also find a full account of it, with a figure, in Martin and Chambers' Abridgment of the Philofophical Hitory and Memoirs of the Royal Academy of Sciences at Paris, vol. i.

Papin's Patent for the Invention of the Steam-Engine.—M. Papin, to whom the French attribute the invention of the steam-engine, was a doctor of phyfic, and profeflor of mathematics at Marburg, in Germany, and in 1697 he was elected a fellow of the Royal Society of London. In the following year, and while in London, he invented and published a method of difolving bones, and other animal foulds, in water, by confining them in clofe veffils, which he called digefters, and which he made sufficiently strong to retain the steam and prevent all evaporation, fo as to acquire a great degree of heat. About the fame time Dr. Hooke, the moft inquisitive experimenfal phyfician of that inquisitive age, obferved that water could not be made to acqurie above a certain tempefrature in the open air, and that as soon as it begins to boil, its temperature remains fixed, and an increase of heat only produces a more violent ebullition, and a more rapid waft. Papin's experiments with his digefler rendered the elafic power of steam very familiar to him, and when he left England, and settled as profeflor of mathematics at Marburg, he made many attempts to emply this force in mechanics, and even for raising water.

By his own account, it appears that he had made some experiments with this view in 1698, by order of Charles, landgrave of Hefse, but without effecting any thing. This is all the reafon the French have to confider him as the first inventor of the steam-engine. Nine years after Savery's paient he published an account of his invention, in a tract, entitled "Ars nova ad aquam igni cannabinoids efficacilem elevandum"—"A New Method of raising Water by the Force of Fire," printed at Caffel, 1707. This machine, which is described in Belidor's "Architecture Hydraulique," vol. ii. does not essentially differ from that of the marquis of Worcester, but is far left perfect than Savery's: it works wholly by the repellent power of steam; the only advantage is, that the receiver being made cilindrical, the steam is separated from the cold water by a floating piston, and that the water is made to flow in some degree constantly, by being thrown into a large air-vessel. In this publication, Papin admits
STEAM-ENGINE.

admits that he had seen a draft of Savery's engine, but says, that in the year 1698 he made a great number of experiments, by order of his serene highness Charles, landgrave of Hesse, in order to raise water by the force of fire, which he communicated to several persons, and particularly to M. Leibnitz, who answered, that the same thought had occurred to himself. He also acknowledged that captain Savery was about that time working upon the same subject in England, and that Savery had first published the fruit of his researches; that from 1698 the affair had lain dormant till the year 1707, when he received a letter from M. Leibnitz, then in London, which contained a draft of captain Savery's engine, and defied Papin's opinion upon it. On viewing this draft to the landgrave, he ordered Papin to reuse the work, and perfect the inventions which he had begun; and which Papin then published, not with a view to make it suppos'd that captain Savery had taken the thoughts from him, but to shew the world its obligation to the landgrave, in having form'd a design so noble, and in having brought it to its present degree of perfection; and he labours much to shew that his engine is preferable to that of the steam, which was now in 1707, to permit the steam which has performed its office; then the weight of the water with which the velfel Y is always filled, opens the valve R, and introduces itself into the body of the pump G H, and makes the piston S T to rise up again: the water contained in the tube K O is not to be considered in this effect, because a valve at K prevents it from descending. When the water which is introduced into the body of the pump is come to an equilibrium with the water in the velfel Y, the cock F is to be shut, and E is to be opened; the steam comes again to pref on the piston, which it forces to descend, and, as in the former instance, expels the water through the tube K O into the cylinder M N, where it cannot introduce itself without furmishing the resistance arising from the elafficity of the air of which it comes to occupy the place.

The cylinder M N, which is three feet high, can contain about 86 cubic feet of water, or about 2.86 cubic feet at every foot in height; therefore, when it is filled to within two feet of the top, the air will be reduced to occupy only one-third of the space in which it was at first shut up, and it will have acquired an elafficity capable of making it furfern a column of water of 64 feet, in addition to the 32 feet with which it is in equilibrium in its ordinary state of condenfation; under these circumstances, if the cock Q is opened, the water will fly out as high as the piston, and the fame velocity as if it was 64 feet high in the cylinder M N; but by degrees, as the water paffes out, it will be driven with less velocity, because the air occupying a greater space, its elafficity diminishes: but according to Papin's statement, there should always be at least a foot of water in the cylinder, and the air, in its smallest condenfation, should not occupy more than two-thirds of the space which it occupies in its natural state; and in that cafe it will have a sufficient preffure to furfern a column of 16 feet of water.

M. Papin's machine is, on the whole, far inferior to the engine of captain Savery, as it wants the advantage of the grand principle of condenfation, and is only a return to the marquis of Worcester's idea: it cannot therefore be called an improvement on Savery's, although it must be allowed that the separation of the hot steam from the cold water by a diafphragm, piston, or float, is a considerable improvement on the marquis of Worcester's, and would be also an advantageous addition to Savery's, if the condenfing water could be as well applied to run down the outside of a cylindrical velfel as an oval one.

Long after Papin's publication, some English engineers made this addition to captain Savery's engine, and attempted
STEAM-ENGINE.

to introduce it in opposition to the cylinder or atmospheric engines, of which we shall hereafter speak; but the con-
sumption of fuel was too great to balance the advantage of simplicity in the structure of the engine.

Captain Savery must have been employed a considerable time with his machine prior to the 14th of June 1699, and
even previous to his patent, as may be inferred from his Miners’ Friend, printed in the year 1702, where, in his
address to the Royal Society, he says, that since the time he exhibited his model to them, “I have met with great dif-
ficulties and expense to instruct handicraft artisans to form my engines according to my design; but my workmen, after
much experience, are become such masters of the thing, that they oblige themselves to deliver what engines they make me
exactly right, and fit for service, and as such I dare warrant them to every body that has occasion for them.”

In his address to the gentlemen adventurers in the mines of England, he says, that the frequent disorders and cum-
erbomeloses of water-engines then in use “encouraged me to invent engines to work by this new force; that though I
was obliged to encounter the oddeff and almost insuperable difficulties, I spared neither time, pains, nor money, till I had
absolutely conquered them.”

Application of Savery’s Engine, and its Defects.—Repea-
ing the real use which was made of captain Savery’s in-
vention, it appears that the number of small engines were
erected, under the authority of the patent, for the supply of
noblemen’s and gentlemen’s feats in different parts of Eng-
land, and for such purposes they succeeded very well; but for
the supply of towns, and the drainage of mines, where great
quantities of water, and great perpendicular preßures were
required, they were not well adapted. With respect to the
raising water for turning mills, an application which readily
suggested itself to the ingenious inventor, we do not think
it was ever attempted, for at that period there were nearly
any mills which could have supported the expense of the erec-
tion, and maintenance of such engines, even where coals
were cheap.

For the drainage of fens they were not well adapted, be-
cause the height to which water is most generally required
to be raised in such cafes is small, and the quantity very
great; on this account several engines would always be
wanted for one drainage, and a great part of the power
would be lost, because the perpendicular height would be very
much less than the height to which the atmosphere would
raise the water. To ships we may conjecture that they never
were applied, and this reduces their use to a very small
compartment.

The principal reasons why they could not be so generally
employed in mines as the captain was led to expect, and
which he laboured to bring about, was, that the working
part of the engine must necessarily be placed from 22 to 26
feet above the bottom of the mine; and if, by any accident,
the water should happen to rise above that level, the engine
would be drowned and irrecoverably lost, without some other
engines to recover it.

As the power of fuction in this engine cannot extend
more than 26 feet, the ret of the perpendicular lift must
be obtained by the expansive force of the steam; and for
every 33 or 34 feet of altitude of this column, a preßure
equal to the atmosphere must be exerted on the inside of the
boiler and receivers, tending to burst them open.

It is not found practicable, in constant work, to force
the water by steam of more than three atmospheres’ preßure,
or about 67 feet above the engine; and this limits the whole
power of an engine, on Savery’s plan, to about 90 feet.

On this account it would require a separate engine for
every 14 fathoms of the depth of a mine, and they must
raise from one to another; but if any one engine is de-
renged, the rest must flop likewise.

Another difficulty was in the quantity of water which
could be raised with safety: the size of his large boiler did
not exceed 30 inches diameter, and the capacity of the re-
ceiver could be but small; and, therefore, the generality of
mines would require more than one engine at the same
level. The charge, trouble, and difficulty, attending such a
number, would naturally prevent their introduction, even in
cases where they would really have been of great service.

Add to this, the consumption of fuel in Savery’s engines
was enormous, compared with the modern engines, and
they were always in danger of blowing up, particularly
when they were employed to raise water to any considerable
height.

Suppose, for instance, the water is to be raised 100 feet;
25 may be done by suction, and the remaining 75 feet must
be lifted by the force of the steam. To effect this, the
preßure within the vellum must be more than three atmo-
spheres; and it will be seen by our table, that every square
inch of the interior surface of the boiler and receiver will
be preßed with a force of more than 32 pounds, tending to
burst them open. This moderate height, will therefore,
require very strong vellums, and all the joints must be made
with the greatest care; for although it is true that the preß-
ure is much less than is usual in pumps, and other hydraulic
machines, in which there is a greater column of water, yet
there is much greater danger of the vellums being burst by
steam of such great elasticity, than by an equal preßure of
a column of water; because the force of the steam is always
hable to be suddenly increased to a very great extent, on
any accession of the heat; and the heat also tends to weaken
the vellums, particularly the boiler, which sooner or later
must be reduced in thickness at the bottom, and will then
burst.

According to Mr. Dalton’s experiments, from which we
have formed our tables of the expansive force of steam, it
must be heated to a temperature of 285° of Fahrenheit’s
thermometer, before it can overcome a column of water of
75 feet in altitude; and as this steam must come immediately
in contact with the surface of the cold water in the receiver,
which is perhaps as low as 40°, the condensation of the
steam is excessive for some time, and must continue until the
surface of the water acquires nearly the same temperature as
the steam; which, however, it will soon do, because the heat
is transmitted downward very slowly in fluids. When
the surface of the water is sufficiently heated, the steam,
which before was condensed as fast as it came in contact with
the water, will begin to press upon the water; and as the heat
and claffity increase, it will lift the column. But when it
has expelled any of the water from the receiver, a new force
of condensation is produced, from the cold surface of that
part of the receiver which was before filled with the cold
water; and this condensation will be even more rapid than
the former, because the vellum, being necessarily made of
metal, will transmit the heat more rapidly than the water
did, and delay the process of forcing out the water until
the interior surface of the receiver is made as hot as the
steam. Captain Savery seems to have been fully aware of
this, as he says in the “Miner’s Friend,” that you may
see on the outside of the receiver how the water goes out,
as well as if it were transparent; for as far as the steam
is contained within the vellum, so far it is dry without, and
so hot as fiercely to endure the least touch of the hand; but
as far as the water is, the said vellum will be cold and wet
where any water has fallen on it, which cold and moisture
vanish.
STEAM-ENGINE.

Vapour as fast as the steam, in its descent, takes the place of the water. Also, he says, the force of the steam proffes upon the surface of the water, which surface, being only heated by the steam, it does not confide.

Improvement upon Savery's Engine.—The rapid condensation which must take place, when steam of a great elastic force is brought into immediate contact with the water, is an incompressible bar to the raising of water to any considerable height, on Savery's plan. The most obvious improvement was to employ a cylindrical receiver, with a floating piston, in the manner of Papin's; but this was only a partial remedy, because the condensation from the sides of the vessel till took place; and it was not until the piston was made to fit exactly into the cylindrical receiver, and the water kept out of it altogether, that the steam-engine was rendered an efficient machine. But this change, which was invented by Newcomen, introduces much complexity into the work. It becomes necessary to have a separate receiver, with a piston, or, in other words, a pump, to raise the water, and also machinery to communicate the motion of the steam-piston to that of the pump. The simplicity of Savery's engine, and the certainty of its action, rendered it very desirable to obviate its defects so far that it could be employed for mines, even after the more perfect engines were introduced. To avoid returning to the description of Savery's engine, we shall give a brief account of these attempts, before proceeding to the other engines.

The first improvement of Savery's engine was to introduce a small jet of cold water into the inside of the receiver, to perform the condensation, instead of throwing cold water upon the outside of the receiver; by this means a more perfect condensation obtained until after a short space of cold water than by the original plan. The water is conveyed by a small pipe, which branches out from the great forcing-pipe, and enters into the receiver, where it turns down, and terminates with a ball, perforated in all directions, like the spout of a watering-pot, so as to disperse the water in a flower within the receiver. A cock is placed to stop the communication at pleasure; and this cock is opened to admit the cold water, when the receiver is to be condened. But it must be observed, that water cannot enter through this cock into the receiver the first instant that it is opened, because the preflure of the water in the force-pipe must be less than that of the steam within the receiver; but, therefore, the injection will not commence until after the walls of the water is free from yeat, and then the condensation, or lots of heat, which always takes place within the receiver from the coldness of the water, will very soon diminish the heat, and consequently the preflure of the steam so far, that it will no longer balance the preflure of the water, which it had just before lifted into the force-pipe. This being the case, the injection-water begins to run, and falls in a flower through the steam contained in the receiver. The sudden effect of this flower to produce the condensation is really surprising. The injection, being a portion of the steam, which has just before quitted the receiver, must have the same temperature as that which was then in contact with the steam; and the difference in the rapidity of the condensation arises only from the dispersion of the water into drops. When the cold water is contained in the lower part of the vessel, the surface only of the water is exposed to the steam, and soon becomes so heated that it will not condense with that great rapidity which it does at first.

On the other hand, a quantity of water dispersed in drops will be completely exposed to the steam, and will take up therefrom, in an instant, as much heat as will reduce the temperature of the steam, and increase the heat of the injection-water, until they approach to an equality of temperature. This being the case, it will easily be seen that the degree of condensation which can be obtained within the receiver will be in a ratio to the coldness and quantity of the injection-water; but the quantity required for injection is far less than when applied on the outside of the receiver, because the receiver will not transmit the heat of the steam through it so quickly, but the water must run down the outside of the receiver, and descend into the well, without being much warmed, and without having extracted much heat from the steam within.

The next improvement in Savery's engine was the addition of the safety-valve to the boiler. This was invented by Papin for his digester, to permit the steam to escape from the boiler into the open air, when it arrives at such a degree of preflure as to endanger the rupture of the vessels. The safety-valve, which is shown in the figure of Papin's engine, fg. 2, is nothing more than a valve opening outwards, and well fitted to close any aperture which is made in the top of the boiler, and is kept shut by a weight or a lever, which is loaded with a weight, capable of opening upon the lever in the manner of a level yard; so that the pressure of the weight upon the valve can be regulated at pleasure, according to the strength of steam which is required; but, in all cases, it must be loaded so as to permit the steam to lift it up and escape, when it arrives at a pressure which would endanger the boiler or receiver.

With a view to strengthen the boiler, hoops and internal radiating bars were tried, according to the idea of the marquis of Worceher; but this was found of very little service, because, on account of the condensation of the steam, it is much better to divide the boiler into or spherical top, of the boiler, and in the middle of the cone several spouts are fixed, radiating from it like the arms of a wheel; the pipe must be carried up above the boiler, fo as to have a column of a sufficient height to overcome the preflure of the steam, and also enter into the boiler with a considerable force; and by the radiating spouts it is dispersed in a flower upon the interior surface of the iron cone, and is thus converted into steam, which flies up to the copper-head, and is carried off by a pipe to the engine. The inventor proposed to make the tube with the radiating spouts to revolve, for the purpose of distributing the water more completely; but he probably never tried the experiment, or he would have found that the boiler would have been soon destroyed by the rapid oxidation of the iron which must take place from throwing water upon it when red-hot; and copper would have melted.

In 1717, Dr. Defaguliers made an engine on Savery's plan in an improved form. He says, that in considering Savery's engine with Dr. Gravfando, they thought there was a great waste of steam, by its constantly acting upon the receivers without intermission, the steam becoming useless until it had heated the surface of the water in the receiver, and also to a certain depth below the surface; but
STEAM-ENGINE.

if it were so contrived, that after the steam had prefled up one receiver full of water, instead of being thrown into another, it should be confined in the boiler till the receiver was refilled by the atmophere, and thus turned upon the water, the steam would have acquired so much force from its confinement, that it would pref suddenly upon the surface of the water, and dil»charge a confiderable portion of it even before it had heated the surface. In purfuit of this idea, they had a model made which could either be used with one or two receivers, and found, on experiment, that one receiver could be discharged three times in the fame time that two could be discharged once. They also learned that captain Savery had made an engine at Kenfigton with only one receiver, which acted very well. Defaguliers then made feveral engines with a spherical boiler, provided with a safety-valve, and a receiver of about one-fifth of the capacity of the boiler, and of a cylindrical figure, tall, and of small diameter in proportion. The steam and the injection-water were alternately admitted into the receiver at top through a faddle-pajaged cock, the handle of which being turned towards the boiler, admitted steam; or, being turned towards the force-pipe, admitted the jet of cold water; but only one of these pafages could be open at the fame time. The small branch from the force-pipe which conveyed the injection-water to the double-pajaged cock, had another cock in it to adjuf the aperture, and regulate the quantity of water which should flow into the receiver. The fuction-pipe and force-pipe were the fame as Savery's; but the valves were conveniently situated, fo as to be readily accelfible when they required repairs. Dr. Defaguliers tells us that he made feven of these engines: the firft was for the czar Peter the Great, for his garden at St. Peterburgh, where it was fett up. The boiler of this engine was spherical (as they were all in his way where the steam was fo much stronger than air), and held between five and fix hogheads; the receiver held one hoghead, and was filled and emptied four times in a minute. The water was drawn up by fuction, or the preffure of the atmophere, twenty-nine feet high out of the well, and then prefled up eleven feet higher. The pipes were all of copper, but felled to the fuction-piece withfof folder, which held very well for that height; but he did not venture either upon a greater quantity for that height, or a greater height for that quantity; for if the quantity was larger than above, the boiler muft have been greater, and the steam of the fame force would have had a greater surface to act upon, which might have burft the boiler, or would have required it to be made much thicker. Another engine of this fort, which he put up for a friend in 1730, drew up the water twenty-nine feet from the well, and then it was forced up by the preffure of the steam twenty-four feet higher, into a cifern holding thirty tons, placed at the top of a tower, in order to run down again through a pipe or conduit, and play feveral jets in the garden. But sometimes, no jets being played, the water was defcharged at the height of fix or eight feet out of the force-pipes to fill the ponds and water-meadows in dry weather, which it did with a fefs strength of steam than what drove the water into the tower; or if the fame steam was kept up, it would make eight or nine strokes in a minute, instead of about fix, as when the water was driven up into the cifern. Upon the safety-valve there was a fleeyard, the place of whose weight fved the strength of the steam, and how high it was capable of raising water; but when the weight was at the very end of the fleeyard, the steam, being then very ftrong, would lift it up and go out at the valve, rather than damage the boiler. Twenty-five years after this engine was made, a man, who was entirely ignorant of the nature of the engine, without any instructions, undertook to work it; and having hung the weight at the farther end of the fleeyard, in order to collect more steam, to make his work the quicker, as also a very heavy plumber's iron upon the end of the fleeyard, the steam not being able to lift the safety-valve, the fleeyard, loaded with all this unufual weight, burft the boiler with a great explosion, and killed the poor man who found near with the pieces that flew almoft.
STEAM-ENGINE.

cock, and a third short arm has a piece of chain, to link it to the chain before-mentioned, at the part where the same extended horizontally between the two pullies. The arms, which act upon the cocks, are so placed, as to shut the steam-cock the moment before the injection is opened, and vice versa.

To put the engine in motion, press down the arm of the axis, which raises the float within the receiver, and the counter-weight of the chain will bring the balance over to the right side, and in motion will open the steam-cock, and shut the injection-cock: also open a small gauge-cock in the top of the receiver, that the air may be discharged by the entrance of the steam into the receiver. This being done, shut the air-cock, and let go the arm of the balance: the weight at the end of the chain will bring over the balance to the left, and in motion will shut the steam-cock and open the injection-cock, to admit a small jet of cold water into the receiver, which presently condensing the steam into water, in a great measure leaves a vacuum in the receiver. In this situation the pre rare of the atmosphere will cause the water to mount through the injection-pipe into the receiver, where, as follows, the receiver makes the other ascend, and depreting the arm on the outside of the receiver, draws the chain and raises the balance, till it has passed the perpendicular, when it will fall ever suddenly by its own gravity: in falling, the roller of one of its arms takes hold of the handle of the steam-cock, and opens it, whilst the other one shuts the injection-cock. This fall of the balance takes place when the receiver is almost filled with water, and the balance cannot return till the surface of the water therein subsides, and suffers the float to descend. This takes place as soon as the steam ceases to be condensed by the cold receiver, and acquires sufficient elastic force from its heat to fill the receiver and drive out the water from the forcing-pipe. When the surface of the water descends the float sinks, and suffers the counter-weight to draw up the chain. By the short chain it draws the balance beyond the perpendicular towards the left, when it falls of its own accord; and in falling, the one arm takes hold of the handle and shuts the steam-cock, whilst the other opens the injection-cock, as before.

In the "Machines approvées par l'Académie for 1744," is a description of an engine by M. Genflanes, which very closely resembles M. De Mora's, but is more completely described.

Mr. Blakey's Engine on Savery's Principle.—Long after steam-engines superior to Savery's had become general, an ingenious engineer, Mr. Blakey, made many attempts to introduce Savery's engine in an improved manner. He obtained a patent in 1766, from the specification of which it appears, that his improvement was to employ oil floating upon the surface of the water in the receiver, to form a pillow or disc between the hot steam and the cold water, to prevent the steam being condensed as soon as it touches the surface of the water; or air was to be admitted into the receiver for the same purpose. In this case, two receivers were to be used, one in the same situation as Savery's, which was to receive the air; and the hot steam, when admitted into it, forced the air to descend by a pipe to the second receiver, which was at the bottom of the well, and expel the water therefrom, and elevate it in the force-pipe. By this means he hoped to prevent the steam coming in contact with the water, and avoid the condenstation.

Mr. Blakey afterwards made some alteration in the form of his engine, which is described as follows by Mr. Fergusou: (see Plate I. fig. 3.) E is the boiler, set in a furnace so as to be surrounded with flame; F is the gauge-cock, to ascertain the depth of water in the boiler: D the steam-pipe, to which is soldered the cock and funnel C, for filling the boiler before the engine is set to work: I is an air-valve, and T T an injection-pipe, which passes through across the top of the receiver, and has small holes pierced in it for the cold water to drop through and fall in a shower in the air-valve I, in order to form a condensation: the end of the injection-pipe is carried into the steam-pipe D, to admit a small quantity of water to run down through the pipe D, and supply the boiler: V is a receiver, communicating with the air-valve I by a pipe: in the upper part of it is a cullinder S, with small holes to discharge the injection-water, which falls from the air-valve I, equally through the receiver V: O is a valve to admit air, which comes through the cock P into the receiver; and H is an occasional cock, to let out the air and steam when the engine is first set to work: Q is a pipe from the receiver V, to the box which contains the valves B and N at the bottom of the forcing-pipe A, which conveys the water up to the reservoir: M is the injection-pipe, to draw the water from the well up to the receiver: G is the fire-place belonging to the furnace, in which the boiler is set, and beneath it is an ash-hole. It is needles to say anything of the scaffold or the well, they being left to the builders, according to the size of the machine, and in proportion to the place in which it is to be erected. All the vessels and pipes of this engine are made of strong copper.

In order to set this engine at work, the receiver and pipe A A must be filled with water, which will be retained in the clack B; then more water must be poured into the funnel C, which is on the steam-pipe D; from thence it falls into the boiler E, and rises to the level of the cock F, which must be open; but as soon as the water runs from it, the funnel-cock C, as well as the gauge-cock F, must be shut, and the air-gauge cock H must be opened. The fire is then to be put into the furnace G, and as soon as the water is in ebullition in the boiler it creates steam, which finds its way through the pipe D, and forces the air out of the vell I into the lower receiver V; the air is also forced out at the cock H, the steam following it with great velocity. In a second or two the cock H must be shut, and instantly the injection-cock L must be opened, which lets cold water run through the end of the pipe T T, into the steam-pipe D, to replace that which has been evaporated out of the boiler E; and it also rushes out on all sides from the little holes which are in the sides of the pipe T T, into the air-valve I, and falls on the cullinder S: this cold water makes a sudden condensation in the vessels I and V, and forms a vacuum, which causes the atmosphere to press on the water in such quantity of water to be forced up that the N is immerged, and the air water ascends the said pipe with great rapidity, and passes through the clack N, and through the pipe Q, into the receiver V, till it rises up to O, where is a floating-ball fastened to a handle or lever, which rising turns the key of the cock P, and opens it: there is a valve at that end of the cock which is within the receiver V, so that as soon as the cock is opened, the valve O is forced up by the air, which rushes through with great quickness and noise into the vessel I; and when that vessel is full of air, the vacuum is destroyed and no more noise is heard, which gives the notice to shut immediately the injection-cock L: that being done, the steam recovers its force, and makes its way through the steam-pipe D, into the air-valve I; and as the steam increases, being much lighter than air, it keeps uppermost, and forces the air on the water which is in the receiver V, which water is forced through the pipe Q, and lifting up the clack at B, goes up the pipe A, and empties itself into the receiver at top. When all the water is expelled out of the receiver V, the air follows, and ascends with
with great velocity through the water which is in the pipe A; two or three seconds after the noise of this is heard, the injection-cock L must be opened to let in cold water, and cause the same effect as before. The noise of the air rushing in and out of the receiver gives proper notice when the manager of this hand-engine is to open and shut the injection-cock, which is the only thing required to work this machine, when once it has been put in action, in the manner that has been described above.

This engine was not found to answer any better than Savery's, because the air will not make that complete separation between the steam and the cold water which the inventor expected; and there is a great loss of power to compree the air sufficiently to make it lift the column of water; and in order to get rid of this air it must be forced up the pipe, which takes as much power of steam as would be required to force up as much water as the air occupied the place of when in its condensed state. Mr. Blakey's intention in the injection of a small quantity of water into the boiler at every stroke, was the same as Mr. Payne's red-hot boiler, of which we have before spoken, but he was in practice obliged to employ a steam-cock in the pipe D, otherwise the steam which the boiler produces whilst the injection-cock is open would have been all condensed and lost.

Savery's engine can be usefully employed for lifting water 30 or 35 feet, which can be done principally by the friction, and with a very slight pre-pressure for the remainder; but it is the most advantageous way to raise no more than 24 feet, and perform the whole lift by the friction, and even to allow the water a sufficient depth to empty the receiver by its own gravity, without forcing it in the leak by the steam. In this form of the engine, the steam need have no greater elastic force than the atmospheric air, or jull as much as is sufficient to make it enter into the receiver, as the water runs out. The temperature of the steam, according to our table, will then be only a little above the boiling point, or above 215°, and consequently the loss by the condensation is not so serious; and as the steam is not prepped upon the water, it is not brought into such close contact with the cold water, as in the forcing engines. In this way, the injection must be forced in by a small force-pump.

Mr. Kier's Engine on Savery's Plan.—An engine upon this principle, with various judicious improvements, was erected some years ago by Mr. Peter Kier, at his manufactury of coach axletrees, near Pancras, where, without any material repair, it has almost constantly been worked to produce, to raise water and turn a water-wheel. The proprietor flatters it to answer his purpose very well, because it works without an attendant, and regulates its own motions; and, as might naturally be expected, the wear and tear are also inconsiderable.

Plate I. Steam-Engine, fig. 4, represents this engine, taken in a section through the centre. R represents an oval boiler, seven feet long, five feet wide, and five deep. Mr. Kier considers it as being of dimensions sufficient to work a larger engine; a circumstance which must, in a certain degree, increase the consumption of fuel. It feeds itself with water conveyed through an elevated pipe, at the end of which is a valve. This valve does not open until the fall of the water within the boiler has sufficed a float to subsidence, which by its actual weight suffices to draw the valve open; but the float, by its tendency upwards, as the water in the boiler rises, serves effectually to close it. The water in the boiler, therefore, remains constantly at or near the same level. The steam is conveyed by a pipe, T A V, to a box B, through which, by the opening and shutting of a valve, it can be conveyed to the working chamber E. The axis, C, serves as a key to open and shut the valve; N O is a cillen of water, from which the engine draws its water through a vertical pipe, in which the valve Q is placed, to prevent the return of the water; G G is another cillen, into which the water is delivered through the pipe F, which is provided with a valve H, opening outwards; I M represents an overhot water-wheel, 18 feet in diameter, moving on the axis K L, and communicating its motion to the lathes, and other machines used in the manufactury. The water in both the cillens becomes warmer than the hand, after working a short time; for which reason, the injection-water is forced up by a small pump from a well, supplied from the small cillen on which these works are established. A leaden pipe passes from this forcing-pump to the upper or conical part of the chamber E, for the purpose of injecting cold water at the proper time. Neither of these could be represented with convenience in the present figure.

The manner in which the steam and cold water are alternately admitted into the chamber E, remains to be explained. Upon the extremity, K, of the axis of the overhot water-wheel there is fixed a solid wooden wheel, about four feet in diameter; it is also represented in fig. 5, as seen in the front; a, b, c, d, are four cleats, all or any number of which may be fixed on the wheel at a time. Each cleat has its correspondent block, e, s, f, g, b, on the opposite surface of the wheel. The use of these is to work the engine. Suppose the wheel I M K, with all the revolving apparatus, be turned round by hand, one of the cleats meets in its rotation with a lever, which opens an steam-valve by a bar of communication reaching to the handle of the axis g, c, 2. The steam consequently passes into the chamber E, and the steam-valve shuts again, as soon as the cleat has passed. Speedily after this, the correspondent block on the other side of the wheel meets another lever, which is similarly attached to the handle of the forcing-pump, and, therefore, throws a jet of cold water into the chamber, and condenes the steam. The pre-pressure of the atmosphere then forces the water from the cillen N O, through the valve Q, towards the chamber E. When the engine has been long out of work, two or three strokes may be necessary to raise the water to the top of the chamber E. As soon as this is the case, the rear-entrance of the steam-furners the whole body of water, above the valve H, to flow out of the chamber E, by its gravity.

The water which is raised is furnished by the steam upon the overhot water-wheel, I M, through a sluice; and by that means keeps the work in motion, and replenishes the lower cillen. There is no resevoir for the injection-water, but the requisite quantity is driven up at each stroke.

Hence we see, that in effect this engine is the same as Savery's original engine, except that it is not applied for the immediate purpose of raising water, but gives motion to other apparatus; and it does not force the water by the steam at all. The water merely falls out of the chamber, and consequently never requires steam much stronger than the atmosphere. From the effect of this engine, under circumstances of such advantage, it may fairly be concluded, that the action of steam against water in forcing can never be beneficial, except at places where fuel can be had extremely cheap. It was found, at the first erection of this engine, that the consumption of steam, by contact with the water, was so great, that it could not be worked with advantage. This defect was remedied in the present engine, as well as in another which was at Norwich, by fixing a small air-valve in the steam-box, which is struck open by the machinery for an instant, immediately before the ad-

---

7
STEAM-ENGINE.

million of steam. It may be premised, that, according to Mr. Blakely’s idea, the air occupied a space above the water, and prevented their coming together. Mr. Kier, however, is disposed to think that the effect does not take place in this manner, but by some mixture and dilatation of the two fluids; because he imagines the mischief from the wet surface of the cylinder would remain the same, when the water defeces. To get rid of this air, the steam in the boiler must be made so much stronger than the atmosphere, as to rush into the receiver with sufficient force to drive out the air through the same valve at which it entered, and which opens outwards for that purpose; but will flint, to prevent the air entering when the vacuum is made, except for an instant before the steam is admitted, when it is opened by the machinery. The motion of the overflow water-wheel is regulated by an apparatus called a governor, invented by Mr. Watt, and which will be described in our account of his engine. It is a perpendicular axis, which revolves by communication with the engine, and carries round two pendulous balls; which pendulums move on a joint, fixed to the vertical axis. When the rotation is very quick, the balls fly out, and are applied to draw down a lever, which is connected with the flume of the upper ciftern; the flume, therefore, is made to fall or rise, according as the velocity of the engine is greater or less. By this disposition, when the wheel moves very speedily from lightness of work, or any other cause, the quantity of water thrown down from the upper ciftern is immediately diminished; and, on the contrary, the quantity of water is rendered greater, when the slowness of the movement throws that more is wanted.

The engine here described has been at work many years, and from the simplicity of its construction has yet exhibited no proofs of wear.

Mr. Kier thinks it a profitable engine to himself, and that it would be serviceable for raising water where coals are cheap. It consumes six bushels of good coals in twelve hours’ work, when in its best state, or seven bushels when at the worst. Under these circumstances it gives ten strokes per minute, each throwing out seven cubic feet of water at an aperture of 20 feet above the water beneath. This quantity, namely, 70 cubic feet per minute, will weigh 437 lbs. raised 20 feet high, which being doubled, to reduce it to Defaguliers’ standard height of 10 feet, will amount to 875 lbs. raised 10 feet high; and this divided by 550, the number of pounds in a hoghead, will give a quotient of 16 hogheads raised 10 feet, representing the force of so many men, according to the estimate of that author, who reckons five men equivalent to one horse. The result is not quite half what is performed, with an equal quantity of coals, by the improved engines, with a pillow of fuel fire as to be equal to 20 or 25 horses. Philos. Journ. vol. i.

Several other engines have been erected upon this plan; and where the water which is raised is to be immediately boiled, they are very capital machines, because all the loss of heat is thrown into the water and warming it before entering the boiler, so as to economize the whole: for instance, for the purpose of raising water into the boilers for a salt-work or for a brewery, they are very applicable.

We have no accounts of the quantity of water which could be raised by Savery’s original engine with a given quantity of fuel; but he tells us in the Miner’s Friend, that to lift a three-inch bore of water 60 feet high, would only require a fire-place for the furnace of 20 inches deep, and 14 or 15 wide; the expense of fuel for which, he says, would be inconsiderable, when compared with the advantages to be derived from the use of the engine.

It has been proposed to construct a succession of engines upon Savery’s plan in a mine, to raise water by fuction from one to another, and to have all of them worked by one common steam-boiler. For this purpose, the depth of the pit is divided into lifts of about 15 feet, and at each lift is a ciftern, to receive the water raised by the different engines. Each engine consists of a vertical fuction-pipe, with the lower end immered in the water of the ciftern of the engine below it, and a receiver at the upper end, which communicates with the fuction-pipe through a valve, to prevent the descent of the water from the receiver through the fuction-pipe. There is also a small spout or pipe leading from the side of each receiver into each ciftern, which is to receive the water after it is raised into the receiver; and the ends of these spouts are covered with valves, to prevent the water running back into the receivers from the cifterns. All these receivers communicate with a common air-pipe, which leads up to the top close receiver, or air-vessel, situated at the top of the pit, which vessel is of at least double the capacity of all the receivers and the common pipe together.

Immediately above the air-vessel is the steam-receiver, of equal capacity, and communicating with the air-vessel by a pipe, which descends through the top of the vessel, and reaches nearly to the bottom of the air-vessel, so that if there is any water in this vessel, the end of the communicating pipe will be immered therein.

Suppose the cifterns at the different stages, and also the lower or air-vessel, nearly filled with water, and the air-pipe and the small receivers filled with air, the action of the machine will be as follows: the steam is admitted from the boiler into the upper receiver, and expels the air therefrom through a proper cock or valve; when thoroughly filled with heated steam, the communication with the boiler is shut, and an injection of cold water thrown into the receiver; this concedes the steam, and forms a vacuum in the upper receiver; this being the cause, the air contained in the air-pipe and receiver, by its elastic pressure upon the surface of the water contained in the great air-vessel, causes the water to mount through the pipe of communication into the upper or steam-receiver. This causes the air in the pipes and receivers to occupy a greater space than it did before, and being thus rarefied, it no longer balances the pressure of the atmosphere upon the surface of the water contained in each ciftern; it therefore forces the water up the respective fuction-pipes into the small receivers, and will fill each of them one half with water, and then the air contained in the remaining half of each receiver, and in the great air-vessel above, comes to its equilibrium. The steam is now admitted a second time into the steam-receiver, and prilling upon the surface of the water therein, allows it to descend by its gravity into the air-vessel beneath, from which it expels the air, and by the communication of the air-pipe it enters into the upper part of each of the small receivers down in the pit, and bearing upon the surface of the water in each, suffers it to flow out by its own weight through the spouts into their respective cifterns. When they have thus discharged the water which they had before drawn up, the steam in the upper receiver is again condensed, and this rarefies the air in the air-vessel and several receivers, and draws up more water from each ciftern; and thus the action of the machine continues as long as the boiler affords steam. In this plan, the water in the upper receiver is never changed; but the same water is constantly subjected to the action of the steam, and will thereby become heated so as to avoid the loss of steam by the condensation. But this at the same time introduces another difficulty, which the inventors had not foreseen; viz. that the heat of the water will prevent a sufficient condensation.

G 2
of the steam to obtain a vacuum; for instance, it is not necessary for an engine of this kind to have steam in the boiler of much greater preasure than the atmosphere; suppose it is equal to raising water two feet, by our second table this will be at a temperature of 215°. Now, according to our first table, in order to obtain such a degree of rarefaction of preasure within the receiver a as to lift a column of 30 feet of water, the temperature must be cooled down to 120°; therefore, at every stroke of the engine a change of temperature must be made equal to 95°, viz. between 120° and 215°. On this account, such an engine would require a great quantity of condensing water, and it is probable that it would be better to make the water, which the engine raises, pass through the receiver, on Savery's plan, or at least such a portion of it, as will keep the temperature of the water in the receiver sufficiently low to obtain the condensation which we have above mentioned.

In employing air in this manner to transmit the force of the steam into other vessels, there is always the loss from the effcacy or compreability of the air, which, in the case above stated, will be equal to one-half; because, when a sufficient rarefaction is made within the steam-receiver to cause the atmosphere to preass upon it equal to 15 lbs. upon the square inch, or to suck up water 30 feet, the air contained in the air-reCel and pipes will expand itself so as to balance one-half of that preasure; and, therefore, the degree of rarefaction within the small receivers will be only sufficient to raise the water 15 feet instead of 30. On the other hand, when the steam is admitted into the receiver, it must be in sufficient quantity to refill the air to its original density, before it will balance the preasure of the atmosphere, and allow the water to flow out of the receivers into their cisterns.

**Fig. 5.** Represents a similar contrivance to the above, but it is for forcing. It was suggested by Mr. Kier, in 1783. A is a boiler, and B a steam-reCel: this last communicates with the vessels M, L, K, T, each of which, except the lower one, consists of two vessels; first, an external cisterm, open at the top; and secondly, an interior receiver, immersed in the water of the cisterm, and closed on all sides, except where it communicates with B, by the branches of the receiver, the pipe FGH descending from B, and where the pipes P, O, N, I, enter the upper part of each, and descend withinide nearly to the bottom, and also where there is a valve at the bottom opening upwards. If steam be let pass from A to B, the air will be driven from B through the pipes F, and preass upon the surface of the water in the lower receiver T, and drive the flame up the pipes into the vessel or cisterm K, but not into the receiver K, because the preasure of the air within that receiver keeps the valve in the bottom of the receiver shut.

The next step of the operation consists in closing the cock C, and opening D, out of which a portion of steam will be driven, by the re-action of the water forcing itself through the valve in the bottom of the receiver T, from its natural tendency to rise to the same level as the surface of the water in the pit or well; and on the same account the water will enter into the receiver K, from the cisterm in which it is immersed: the cock D is then to be closed, and C opened; in consequence of which, the contents of the receiver, T, will be forced up to the cisterm, K, by the steam, as before, and the receiver, K, will discharge its contents through the pipe, N, into the cisterm L.

The steam being again shut off at C, and the cock D being opened, as before, the receivers, T, K, and L, will fill as before, by the water from the exterior cisterm entering through the valves in their bottoms, and a larger portion of steam will issue from D. A third repetition of the process will drive the contents of these three receivers a step higher; and a fourth repetition will cause the contents of the upper receiver, M, to flow out at P; after which, every alternation of the work with the cocks C, D, will throw out the same quantity from P.

The vessel B must necessarily contain a quantity of air capable of occupying the whole interior space contained in the closed receiver, with an allowance for the loss of bulk in condensation, under the preasure of a column of water equal to one of the lifts; and the quantity of steam to be discharged at each stroke, must occupy a space equal to that of all the water moved at each stroke; and, in all cases, be considerably stronger than two atmospheres, in proportion to the heights of the lifts.

**Other Proposals for the Improvement of Savery's Engine.**—

In the Memoirs of the Philosophical Society of Laufanne, M. Francois has described a steam-engine on Savery's principle, by which he proposes to be used for draining fens or marishes, and has added machinery to open and shut the cocks; it has otherwise nothing remarkable. See Repertory of Arts, first series, vol. iv.

In the American Philosophical Transactions there is a description of a steam-engine, on Savery's principle, by Mr. Nancarrow, which is applied to raise water for turning a water-wheel. In this engine, the receiver, into which the steam is admitted, is a tall cylindrical pipe, with only a slight enlargement at the top to form the receiver; and the water is only raised by the preasure of the atmosphere; and to prevent the water being changed and continuing cold, so as to condense the steam, it is not suffered to run off immediately from the receiver, as in Mr. Kier's engine, but nearly at the bottom of the tall cylindrical pipe it is joined to a box, as shown by the dotted lines in the figure of his engine, and from this box a second vertical pipe, or force-pipe, ascends to the reservoir which contains the water; the valve to prevent the return of the water is placed at the lower end of this second pipe.

By this means, the portion of water which comes in contact with the steam rises and falls in the receiver, and alternately draws and forces other water through the box below, from the suction-pipe, and into the force-pipe and reservoir. But this water, when it becomes heated, acts like a floating piston on the surface of the cold water to prevent the contact of the steam. Mr. Nancarrow proposed to employ a separate condenser and air-pump to produce the vacuum, instead of making an injection into the receiver; but this would be attended with no advantage; and we have before stated the objections to the water growing heated any more than superficially.

At the same time we think that a very good and simple engine might be made, if this form of the apparatus, in which the water shall never be changed, was applied to forcing by the preasure of the steam only, on the marquis of Worceester's plan, and not to attempt condensation, which it is impossible to effect perfectly, when the water has become very hot; but instead thereof, when the steam has exerted its force, to open a cock, and let off the steam into the open air. An engine of this kind, which only requires the additional receiver, is described in Leupold's Theatrum Machinarum Hydrostaticarum, vol. ii. 1724.

The last improvement which we have noticed in Savery's engine, is by Mr. James Buzza, of Glasgow, who took out a patent in 1805, for several different forms of the engine. In all these the receiver is made cylindrical, and a piston is applied to float upon the surface of the water, upon Papin's plan; and in the same manner as Nancarrow's engine, he
he proposes to employ such an arrangement of the force-pipes, of a second small receiver, that the water which comes in contact with the steam shall not be changed, but shall always remain the same; a method which provides the use of the vacuum by condensation. The specification of this patent is published in the Repertory of Arts, vol. viii.

Newcomen's, or the Atmospheric Steam-Engine.—This engine is named after its inventor, Mr. Thomas Newcomen, an ironmonger of Dartmouth, in Devonshire. He appears to have been a person of ingenuity, and of some reading, and was acquainted with the famous philosopher Dr. Hooke. Newcomen was in the habit of visiting the mines of tin and copper in Cornwall, where captain Savery was well known, from his attempts to introduce his engine for the draining of mines, which, at that period, were nearly all of them at a stand, for want of some more powerful and cheap machines than hand-pumps or horse-machines.

The captain was not successful in his attempts, principally because he employed the direct action of the steam upon the water, which either confined him to the height of 25 feet, or compelled him to employ steam of a great elastic force; in which case it became an indispensible condition, that the boiler and vessels should be very strong, as well as that a large quantity of fuel should be consumed, to produce steam sufficiently dense. It is probable that these inconveniences may have early directed the thoughts of other ingenious men to the application of a piston, but the difficulties of the undertaking seem to have retarded this pursuit for a considerable time.

The first steam-engine with a piston, made by Papin in 1707, which we have described, was not at all calculated to remove the difficulties; and it is to Newcomen, and his associate Cawley, that we are indebted for the application of a piston with machinery, by which the indirect action of steam a little stronger than the atmosphere, or rather the direct action of the atmosphere upon a piston, is made to act with safety and effect against the most severe pressures. It appears that they had brought their atmospheric engine, about the year 1713, to a degree of perfection little inferior to that which are to be seen at present.

Principle of the Atmospheric Engine.—To have an idea of its principles and mode of operation, suppose a very large syringe or cylinder to be placed upright, and a piston or plug inserted at the upper end, the usual aperture being stopped at the lower extremity. If this last aperture is open, the piston will defend by its own weight, neglecting the effect of friction at its circumference. But let it be imagined that the piston is supported by a counter-weight applied at the opposite extremity, a lever, or by any other means; in that case the piston will not defend unless more weight is added to it.

Among the various ways of applying such a weight, there is one which consists in exhausting the air from the internal part of the cylinder, beneath the piston: and if this is done, it is evident that the whole prelure of the atmosphere, amounting to about 14.5 pounds on every square inch, will become active upon the upper surface of the piston. This method of gaining a great force was invented by the famous Otto Guericke: see his Experimenta Magdeburgica, 1672. If the vacuum was to be produced by means of an air-pump on Guericke's plan, it must be allowed that the labour of effecting it would be at least equal to that of any work which could be performed by the frequent defence of the piston; we must therefore seek some other means of producing such a vacuum. We have seen that in Savery's engine the operation of steam is two-fold, namely, by the direct prelure from its elaticity, and by the indirect confluence of its condensation, which affords a vacuum. This last is the only principle employed in Newcomen's engine.

In order to produce the vacuum at pleasure in the interior capacity of the syringe or cylinder, of which we have been speaking, it becomes requisite that several apertures should be formed at the bottom of the cylinder: one to communicate steam from a boiler, and provided with a cock to cut off or open the communication at pleasure; another to admit at pleasure a jet of cold water, to condense the steam during the interval in which the communication from the boiler is cut off; a third, provided with a drain-pipe, called the eduction-pipe, to carry off the condensed steam and injection-water; and fifthly, a small lateral aperture, with a valve, to allow the escape of the air, or permanently elastic fluid, which will not condense by the application of cold water, or run off through the eduction-pipe; this last is called the snifting-clack.

By these provisions the operation of the cylinder is made to take place in the following manner. The piston-rod is attached by a chain to the end of a long lever, at the opposite end of which are suspended the rods of the pumps which are to draw the water; and the weight of these rods exceeds the weight of the piston so much, as to draw the piston up to the top of the cylinder. In this state, the steam-cock is opened, and steam issues from the boiler; but being less than half the weight of common air, it rises to the top of the cylinder, and expels the air through the snifting-valve and eduction-pipe, of which the lower extremity is covered with a flap-valve, in a trough of water. When the noise of its escape through these valves is heard, the steam-cock is shut, and the injection-pipe being opened, throws up a stream of cold water in a jet within the cylinder, and strikes against the bottom of the piston: the steam becomes immediately condensed, and the prelure of the atmosphere forces the piston down into the vacuum. Upon its progress downwards, the injection-pipe is closed; and when it has arrived nearly at the bottom of the cylinder, the steam-cock is again opened. The elastic steam fills the small space between the cylinder and the bottom, and its pressure on the under surface of the piston affiys it to rise, and also affiys the eduction-water which remains in the bottom of the cylinder to pass off through its pipe: the steam also drives the air, or other elastic fluid which will not condense, through the snifting-valve. In this state, therefore, the steam is somewhat stronger than the atmosphere, and rather more than counterpoises its action on the upper surface of the piston; in consequence, the piston itself rises by the action of the counter-weight, or pump-rods, at the opposite end of the lever, and regains its original position at the top of the cylinder.

A second repetition of the process, namely, of shutting off the steam, and injecting cold water, causes the piston again to descend, and in this manner the alternations may be continued without limit.

It is to be understood, that the opening and shutting of the steam and injection-cocks are performed by apparatus fixed to the working lever, in such a manner as to strike the levers of those cocks at the precise instant of time when their effects are required to be produced. The attendant has no other office to perform than that of keeping up the fire. To apply this power to the purpose of raising water for draining a mine, supposing a common sucking-pump placed in the pit to lift the water fifty yards high. If the pump is 10 inches bore, the column of water which must be raised when the rod or bucket of the pump is drawn up, will weigh 3060 lbs; a chain being attached to the upper end of the rod of the pump, and suspended from the extremity of the long
long lever or working beam; and at the opposite extremity of the same beam another chain must be attached, to suspend the piston of the cylinder, which we have just described.

To give this piston a sufficient power of decent to make it draw up the water in the pump at the opposite end of the beam with celerity, the piston must be 22 inches in diameter; the area or surface of the piston will then be 380 square inches. In this case, if each square inch is puffed with a weight of eight pounds, it will balance the weight of the water in the pumps within 20 pounds; for 380 x 8 = 3040, instead of 3060: but the pressure on each square inch will be considerably more than eight pounds; for, provided the vacuum was perfect within the cylinder, the pressure of the atmosphere would be 14.2 pounds; but the condensation of the steam in the cylinder is so far incomplete, that it leaves steam or vapour within the cylinder of some density. If the steam is boiled by the injection down to 140°, it will be seen by our first table, fourth column, that it will leave the cylinder filled with a vapour of an elastic force equal to 2 lbs. 13 oz. per square inch; which force acting beneath the piston, will deduct from the pressure of the atmosphere, and reduce the next prelure on the piston to 11 lbs. 13¾ oz. per square inch, as shown by the last column. The excess of prelure beyond what is necessary to balance the weight of water is 3 lbs. per square inch, amounting, on the whole surface of the piston, to (5 x 380 =) 1740 lbs. nearly, a weight which is allowed to overcome the counter-weight which is to draw the piston up again, and the friction of the piston and pump-buckets, and make the engine move with a sufficient velocity, which will be more or less according to the state of the engine. But taking this velocity at 16 strokes per minute of six feet length each = 96 feet motion per minute, the pump of 7½ inches diameter will raise 152 gallons per minute, or 182 hogheads 13 gallons per hour. An engine of these dimensions is but a small one, yet it serves to show the superiority of Newcomen’s over Savery’s engine, in principle. Savery’s was an engine which really raised water by the force of steam; but Newcomen’s raises water entirely by the prelure of the atmosphere, steam being employed merely as the most expeditious method of producing a void, into which the athermographical prelure may impel the first mover of his machine. The elaticity of the steam is not the first mover. In the example of the engine we have just given to drain the same mine on Savery’s plan, he must have employed steam of a prelure of 55 pounds per inch, and of a temperature of 315 degrees, to raise a column of water to a height of 125 feet: the condensation of this steam would be so great on coming in contact with water of only 50 degrees, that he would have found it scarcely practicable to have thrown up any considerable quantity.

We see also the great superiority of this new machine. There is no need of steam of great and dangerous elaticity, as it operates by means of very moderate heats, and consequently with much smaller quantities of fuel; and there are no other bounds to the power of this machine, than the strength of the materials of which it is composed. How deep aoever a mine may be, a cylinder may be employed of such dimensions, that the prelure of the air on its piston may equal in appearance the weight of the column of water to be raised; and lastly, this form of the machine renders it applicable to almost every mechanical purpose, because a skilful mechanic can readily find a method of converting the reciprocating motion of the working beam into a motion of any kind which may suit its purpoze. Savery’s engine could not admit of such an immediate application, and was restricted to raising of water.

Invention of Newcomen’s Engine.—Reflecting the invention of this engine, it was no matter of original discovery, than of a combination of the inventions of others, viz. of Savery’s invention of the means of producing a vacuum by the condensation of steam, with Otto Guericke’s exhausted cylinder.

Savery made claim to the invention, and in consequence of the claim he made to the mode of condensation, as being a part of his patent, he was admitted by Newcomen and Cawley to an aocation with them in the patent which was granted in 1705, but it does not appear that they made any perfect engine until 1711.

Defagullis, in his account of the invention, makes no mention of captain Savery being associated; but says “that Thomas Newcomen, ironmonger, and John Cawley, glazier, of Dartmouth, in the county of Southampton (Baptists), made several experiments in private about the year 1710, and in the latter end of the year 1711 made propofals to drain the water of a caillery at Griffin, in Warwickshire, where the proprietors employed 500 horses at an expense of 1500l. a year; but their invention not meeting with the reception they expected, in March following, through the acquaintance of Mr. Potter of Brom Borgrove, in Worceftershire, they bargained to draw water for Mr. Back of Wolvampton; where, after a great many laborious attempts, they did make the engine work; but not being either philosophers to understand the reason, or mathematicians enough to calculate the powers and proportion of the parts, they very luckily, by accident, found what they sought for.

“ They were at a loss about the pumps, but being so near Birmingham, and having the assistance of so many admirable and ingenious workmen, they soon came to the method of making the pump-valves, clacks, and buckets, whereas they had but an imperfect notion of them before. One thing is very remarkable; as they at first were working, they were surprised to see the engine go several strokes, and very quick together, when, after a search, they found a hole in the piston, which let the cold water in to condense the steam in the inide of the cylinder, whereas before they had always done it on the outide. They used before to work with a buoy in the cylinder, includef in a pipe, which buoy rove when the steam was strong and opened the injection, and made a stroke; thereby they were capable of only giving six, eight, or ten strokes in a minute, till a boy, Humphrey Petter, who attended the engine, added (what he called foogom) a catch, that the steam always opend, and then it would go 15 or 16 strokes a minute. But this being perplexed with catches and thirings, Mr. Henry Bighton, in an engine he had built at Newcalk upon-Tyne, in 1718, took them all away, but the beam itself, and supplied them in a much better manner.” Since that time no very material alterations have been made in this species of engine, except the addition of the crank to make it turn mills.

The French authors have claimed this engine also as the invention of their countryman Papin, but without any reason: Papin had gained a knowledge of the expansive force of steam in his digester, and he invented the mode of working the pillars and cylinders by a vacuum and the prelure of the atmosphere; but he was not the first inventor of either of these. Otto Guericke and the marquis of Worescher having discovered the same things long before him; and further, he had no pretentions to claim Savery’s discovery of the condensation of steam, upon which the engine of Newcomen depends.

Papin’s Air Cylinder Engine.—Papin’s invention of the cylinders.
The first engine was for the purpose of transmuting the action of a water-wheel to a great distance, by means of air in pipes. Papin proposed this principle enigmatically, as a new way of raising water, to the Royal Society in 1685; and after many solutions had been given by the English academicians, he showed the real application and use of it, to raise water out of a mine by the power of a river at a considerable distance.

For this purpose, a water-wheel was to be placed in the river, to work the pistons of two large cylinders of pumps, from the lower ends of each of which small pipes were conducted down into the mine, to convey the air into small cisterns or receivers, which were each furnished with a furnace-pipe and a forcing-pipe, and valves to prevent the defect of the water. By the motion of the pistons of the pumps, the air was to be alternately rared and compressed in these chambers; and thus he intended to draw water into the receptacles through the furnace-pipes, and then force it up through the forcing-pipes; but he forgot that, in this method, the elasticity of the air he employed would wholly defeat his end; for when the piston of the pump was depressed, it would not compress the quantity of air contained in a long pipe sufficiently to produce any sensible condensation to force or raise water out of the receiver; nor, on the other hand, could a sufficient rarefaction of the air be produced by the ascent of the piston to obtain any efficient suction in the receivers.

Papin afterwards made some alterations to obviate the objections which were urged by Dr. Hooke and other English philosophers, and in 1688 he published another machine in the Acta Eruditorum, which is more complete, and is a most valuable invention for conveying the power of machines to a distance. Within these few years it has been employed in this country, though secretly, for a very important purpose.

In this method, the two pumps, which are worked by alternate cranks on the axle of the water-wheel, are provided with valves similar to those of an air-pump, and they draw air alternately from the conveyance-pipe which leads to the mine, so as to make a vacuum in the pipe. At the mine are placed two cylinders, with pistons fitted into them; and a rope, which is fastened to each of the pistons, is wrapped several times round an axle or horizontal shaft, which is extended over both cylinders, and is put in motion by their pistons.

Upon the middle of this axle is a large wheel, for the reception of a cord, which descends into the mine, and has at each end a bucket; therefore, by turning the axle first one way round, and then the other, the two buckets are alternately drawn up or lowered down in the mine, to draw either water or ore. The ropes from the piston of the cylinders are wrapped round the axle in opposite directions; and when one piston is pressed down, it will draw the rope and turn the axle, which winding up, the other rope will draw up the piston of the other cylinder. A single conveyance-pipe leads from both the air-pumps at the water-wheel; but when the pipe arrives in the mine it divides into two branches, one for each cylinder; and at the intersection of these branches a double-paßaged cock is placed, which will admit the air from either of the cylinders into the conveyance-pipe which leads to the air-pumps, or it will admit the atmospheric air into the cylinders; and these passages are opened alternately by the cock, so that whilst the air from one cylinder is drawing off through the conveyance-pipe by the air-pumps, the atmospheric air shall have free entrance to the other cylinder.

The consequence will be, that by the continual suction of the air-pumps a vacuum will be found under one piston, and the pressure of the atmosphere will act to press it down in its cylinder; and by the rope which is attached to it and wound round the axle of the wheel, its descent will cause the axle and wheel to turn round and draw up the cord which passes over the wheel at one side, so as to raise up one bucket in the mine and lower down the other; but during the descent of this piston, the other piston is freely at liberty to be drawn up in its cylinder, because the cock admits the atmospheric air into the same. When the piston under which the vacuum has been made is pressed down to the bottom of its cylinder, the other piston will be drawn up to the top of its cylinder, by its rope winding upon the axle. In this state the cock is turned the other way, and will then draw off the air from the cylinder in which the piston is at the top, and admit fresh air into the cylinder in which the piston is at the bottom. This will cause the axle and wheel to turn round in an opposite direction to what it did before, and draw up the opposite bucket from the mine.

In this way a constant reciprocation of the motion of the axle is kept up, and the power of the water-wheel is transmuted simply by the conveyance-pipe to any required distance, where, by using a larger or smaller cylinder, it may be made to act with any required force. The inventor proposed this method to be used to convey the power of the water-wheels in the Seine to work pumps at Verailles, instead of the cumbersome machinery employed at Marly for conveying the motion; and it is rather surprising that so simple and advantageous a method should have remained so long neglected and unknown, that even now, when its effects are publicly exhibited, the means are not known. The only improvement upon the method of Papin, which it is necessary to put in practice, is to have a receiver or air-chamber near the cylinders, to be kept exhausted by the pumps; and this being of sufficient capacity the air will rush into it, and be taken away from beneath the piston the instant the cock is opened; whereas without it, it would be drawn off more slowly by the pumps. If the conveyance-pipe is made of large dimensions, it will effect the same end most completely.

Description of the Atmospheric Engine.—Our readers being now acquainted with the principle of Newcomen's engine, we shall proceed to describe it in the state to which it was brought by Mr. Beighton, and which for more than half a century was the standard engine for raising water from mines. See the perspective view in Plate II. fig. 1, which represents the engine complete, the front wall of the house being suppressed to be removed to shew the interior.

A, the fire-place under the boiler for raising the steam, and the ash-hole below it.
B, the boiler, made of iron plates: it is filled with water about three feet above the bottom.
C, the steam-pipe, through which the steam passes from the boiler into the receiver.
D, the receiver, a close iron vessel or box, in which is the regulator or steam-cock, which opens and shuts the hole of communication with the cylinder at each stroke.
E is the communication-pipe, between the receiver and the cylinder; it rises five or six inches up in the inside of the cylinder above the bottom, to prevent the injected water from descending into the receiver.
F, the cylinder of cast-iron, about ten feet long, bored smooth in the inside; it has a broad flange in the middle, on the outside, by which it is supported when hung between the cylinder-beams, which extend across the house, and are let into the side-wall.
G, the
G, the piton, made to fit the cylinder exactly, but with liberty to slide up and down; it has a flange rising four or five inches upon its upper surface, between which and the side of the cylinder a quantity of junk or oakum is stuffed, and kept down by weights, to prevent the entrance of air or water, and the escape of steam.

II, the chain and piton-ank, by which it is connected to the working beam by an arc of a circle.

III, the working beam or lever, working on its centre, in the manner of a scale-beam; it is made of two or more large logs of timber, bent together at each end, and kept at the distance of eight or nine inches from each other in the middle, by the gudgeon or centre, as represented in the plate.

The arch-heads I, I, at the ends of the beam, are for giving a perpendicular direction to the chains of the piton and pump-rods, which are suspended at the opposite ends.

K, the pump-rod, which works in the great fucking-pump L, and draws the water from the bottom of the mine to the surface.

M, a cifer, into which the water drawn out of the pit is conducted by a trough, so as to keep it always full, and the superfluous water is carried off by another trough.

N, the jack-head pump, which is a smaller fucking-pump, wrought by a small lever or working beam, by means of a chain connected to the great beam or lever near the arch g, at the inner end; and the rod of the pump N is suspended by a chain at the outer end. This pump commonly stands near the corner of the front of the house, and raises a column of water up to the cifer O, into which it is conducted by a trough.

O, the jack-head cifer, for supplying the injection; it is always kept full by the pump N, and is fixed so high above the cylinder bottom, as to give the jet of injection a sufficient velocity into the cylinder when the cock is opened. This cifer has a waife-pipe on the opposite side for conveying away the superfluous water.

P P, the injection-pipe, of two or three inches diameter, which descends from the cifer O, to the injection-cock r, after passing which it turns up in a curve at the lower end, and enters the cylinder bottom. It has a thin plate of iron fixed upon the end d, which is within the cylinder, with three or four ajutage holes in it, to caufe the jet of water from the jack-head cifer to fly up as many steam against the under surface of the piton, and conduces the steam contained in the cylinder each stroke, when the injection-cock is open.

q, a valve upon the upper end of the injection-pipe, which is shut, to prevent waife or leakage, because the engine stands still; but before the engine is let to work, this valve must be lifted up, and kept open by a string.

f, a small pipe, which branches off from the injection-pipe, and has a cock to supply the piton with a little water to keep it air-tight.

Q, the working plug, suspended by a chain to the small arch g, of the working beam. It is usually a heavy piece of timber, with a fit vertically down its middle, and holes bored horizontally through it to receive pins, for the purpose of opening and shutting the injection and steam-cocks, as it ascends and descends by the motion of the working beam.

b, the handle of the steam-cock or regulator. It is fixed to the regulator by a spindle, which comes up through the top of the receiver. The regulator itself is a lefatorial piece of brass, shaped like a fan, which is moved horizontally by the handle b, and opens or shuts the communication at the lower end of the pipe E, within the receiver. It is represented separately in the plate by fig. 2.

ii, the spanner, which is a long rod or bar of iron, for conveying motion to the handle of the regulator, to which it is fixed by means of a pin in the latter, and some pins put through to hold it.

k, the vibrating lever, called the tumbling-bob, or the Y, having the weight k at one end, and the two forked legs at the other end, like the letter A turned. It is fixed to an horizontal axis, moveable about its centre pins, or pivots, m m, and is put in motion by means of two thronds q, p, fixed to the same axis, which are alternately raised and depressed by means of two pins in the working-plug, and the bob or weight at the top of the Y is thrown backwards and forwards; one pin on the outside, depressing the thrond k, throws the loaded end, k, of the Y from the cylinder into the position represented in the plate, and causes the leg, l, of the fork of the Y to strike against the end of the spanner, which forcing back the handle of the regulator or steam-cock opens the communication, and permits the steam to fly into the cylinder. The piton immediately rises by the weight of the pump-rod, on the admixture of the steam: the motion of the working beam, II, also raises the working plug; and another pin, which goes through the flat, raises the thrond, p, of the axis, which throws the end, k, of the Y towards the cylinder, and the leg of the fork, striking the end of the spanner, forces it forwards, and shuts the regulator or steam-cock.

q r is the lever for opening and shutting the injection-cock, called the F. It has a rack or toothed sector fixed upon its axis, which takes the teeth of a pinion, fixed on the top of the plug or key of the injection-cock.

When the working plug has ascended nearly to its greatest height, and the regulator, as above described, a pin catches the end, g, of the F, and raises it up, which opens the injection-cock, and admits a jet of cold water to fly into the cylinder, and condensed in the steam, makes a vacuum within. Then the preflure of the atmosphere, forcing down the piton into the cylinder, causes the plug-frame to descend, and another pin fixed in it catches the end of the lever, g, in its descent, and by prefling it down shuts the injection-cock; at the same time the regulator is opened to admit steam, and so on alternately; that when the regulator is shut, the injection-cock shall be open, and when the former is open, the latter shall be shut.

R, the reduction-pipe, to convey away the water which is injected into the cylinder at each stroke; its upper end is even with the cylinder bottom, and its lower end has a lid or cover, moveable on a hinge, which serves as a valve to let out the injected water, and closes each stroke of the engine, to prevent the water being forced up again when the vacuum is made.

S, the hot-well, which is a small cifer made of planks, to receive all the waife water from the cylinder, and keep it in reserve for feeding the boiler, to supply the waife occasioned by the continual evaporation of the steam.

T, the feeding-pipe, to supply the boiler with water from the hot-well. It has a cock to let in a large or small quantity of water, as occasion requires, to make up for what is evaporated: it goes nearly down to the boiler bottom, so that the lower end is always immered in water.

U, two gauge-cocks, in the upper ends of two pipes, which descend into the boiler: one is deeper than the other: their use is to try when a proper quantity of water is in the boiler, for upon opening the cocks, if one gives steam and the other water, it is right, because the intended level of the water in the boiler is between the ends of the two. If they both give water there is too much.

W is the man-hole: it is a plate which is screwed over a hole
STEAM-ENGINE.

A hole on the side of the boiler, to allow a passage into it for the convenience of cleaning or repairing.

X, the steam-clack or poppet-valve, which is a braze value at the end of the pipe opening into the boiler, to let off the steam when it is too strong. It is loaded with lead at the rate of one pound to an inch square; and when the steam is nearly strong enough to keep it open, it will do for the working of the engine.

S, the steam-valve, by which, at every act of the piston, the air is discharged from the cylinder which was admitted with the injection, and would otherwise obstruct the due operation of the engine.

T, the cylinder beams, which are strong girders going through the house, for supporting or rather keeping down the cylinder.

U, the cylinder cup of lead surrounding the top of the cylinder, to prevent the water upon the piston from flashing over when it riles too high.

W, the waste-pipe, which conducts the superfluous water from the top of the cylinder to the hot-well.

X, iron bars, called the catch-pins, fixed horizontally through each arch-head to strike the floor, and prevent the beam defending too low, in case the chains at either end should break, or if the engine makes too long a stroke.

Y, two strong wooden springs, to weaken the blow given by the catch-pins, when the stroke is too long.

Z, two friction-wheels or fectors, on which the godman, or centres of the great beam, are supported; they are the third or fourth part of a circle, and move a little each way as the beam vibrates.

Their use is to diminish the friction of the axis, which being exceedingly very large for so heavy a lever, would otherwise be very great.

Operation of the Atmospheric Engine.—When this engine is to be let to work, the boiler must be filled about two or three feet deep with water, and a large fire made under it; and when the steam is heated to be of sufficient strength to exert a preasure of about one pound beneath each square inch of the safety-valve, it will lift up the valve and escape. The water in the boiler being suffocated to be in a strong state of ebullition, and the steam issuing by the safety-valve, we will consider the machine in a state of rest, having both the steam-cock and injection-cock shut. The retorting position or attitude of the machine is such as appears in the drawing, the pump-rods, K, preponderating by their weight; and the great piston being drawn to the top of the cylinder.

The man who attends the engine depresses the handle p, so as to throw the tumbler-bob into the position of the figure; and the leg of the fork thrashing back the spanner t, opens the regulators or steam-cock, when the steam from the boiler immediately rushes in, and flies away over the cylinder, will mix with the air: much will be condensed by the cold surface of the cylinder and piston, and the water produced from it will trickle down the sides, and run off at the eduction-pipe, R, as soon as any quantity is accumulated. This condensation and waste of steam will continue, till the whole cylinder and piston are made as hot as boiling water.

When this happens, the steam will begin to open the snuffing-valve s, and illude through the pipe; at first slowly and very cloudy, being mixed with much air, the cloudy appearance of steam being always owing to its mixture with common air. The blast s will grow stronger by degrees, and more transparent, having already carried off the greatest part of the common air which filled the cylinder. We supposes, at first, that the water was boiling briskly, so that the steam was illuding by the safety-valve, which is in the top of the boiler. The opening of the steam-cock are an end to this at once, because the cold cylinder draws off the steam from the boiler with sufficient rapidity, until it becomes heated so as not to condense.

When the manager of the engine perceives that not only the blast at the snuffing-valve is strong and steady, but that the boiler is fully supplied with steam of a proper strength, which appears by the renewal of the discharge at the safety-valve, the engine is ready for starting. He now lifts up the handle s or p, till the tumbler-bob, Y, falls over the perpendicular towards the cylinder, and its leg striking the cross-pin of the spanner, t, draws it forwards, and shuts the steam-regulator; at the same instant he lifts up the handle q of the F, which opens the injection-cock. The preasure of the column of water in the injection-pipe, P, immediately forces some water through the spout d by the jets.

The cold water coming in contact with some of the pure vapour, which now fills the cylinder, condenses it, and thus makes a partial void, into which the more distent steam immediately expands; and by this very expansion its capacity for heat is increased; or, in other words, as it grows cold, it abstracts the heat more powerfully from the steam, and it immediately beyond it.

In this expansion and refrigeration the steam is itself partly condensed or converted into water, and leaves a void, into which the circumjacent steam immediately expands, and produces the same effect on the steam beyond it; and thus it happens, that the abstraction of a small quantity of heat from an insensible mafs of steam produces a condensation throughout a cylinder which is very extensive.

What remains in the cylinder no longer balances the atmospheric preasure on the surface of the water in the injection-cistern, and, therefore, the water spouts rapidly through the holes d, by the joint action of the column P, and the unbalanced preasure of the atmosphere; at the same time the snuffing-valve s, and the eduction-valve R, are shut by the external preasure of the atmosphere, and prevent the entrance of air or water into the cylinder. The velocity of the injection-water must therefore rapidly increase, and the jets dash against the bottom of the piston, and be scattered through the whole capacity of the cylinder. In a very short space of time therefrom, the condensation of the steam becomes universal, and the elasticity of what remains is very small. The whole preasure of the atmosphere, therefore, being exerted on the upper surface of the piston, while there is hardly any on its under side, if the load on the outer end of the working-beam is inferior to this preasure, it must yield to it. The piston G must descend, and the pump-piston l must ascend, bringing along with it the water of the mine; but the motion does not begin at the instant the injection is made.

The piston was kept at top by the preponderancy of the outer end of the working beam and the load of water in the pumps, and it must remain there, till the difference between the elasticity of the steam below it, and the preasure of the atmosphere, exceed this preponderancy. There must, therefore, be a small space of time between the beginning of the condensation and the beginning of the motion: this is very small, not exceeding the third or fourth part of a second; but it may be very distinctly observed by an attentive spectator, who may perceive, that the instant the injection-cock is opened, if the cylinder has the lightest yielding in its suspension, it will have upwards a little by the preasure of the air on the bottom. Its own weight is not at all equal
Steam-engine.

Equal to this prelure; and instead of its being necessary to support it by a strong floor, it must be kept down by large beams, loaded at the end with heavy walls. This heating of the cylinder flew the instantaneous commencing of the condensation; and it is not till after this has palled, that the piston is seen to start, and begins to descend.

The motion must continue till the great piston reaches the bottom of the cylinder; because it is not like the motion which would take place in a cylinder of air rarefied to the same degree. In this latter case, the impelling force would be continually diminished, because the capacity of the cylinder diminishing by the descent of the piston, the air in it would continually become more dense and elastic, until the piston would float at a certain height, where the elasticity of the included air, together with the load at K, would balance the atmospheric pressure on the piston. But when the contents of the cylinder are pure vapour, and the continued stream of injected cold water keeps down its temperature to the same pitch as at the beginning, the elasticity of the remaining steam cannot increase by the descent of the piston, nor exceed what corresponds to the temperature, according to our table. The impelling or accelerating force, therefore, remains the same; and the descent of the piston will be accelerated almost uniformly, unless there is an increase of friction, arising from the nature of the work performed by the other end of the beam. And it may be frequently observed in a good steam-engine, where every part is air-tight, that if the cylinder has been completely purged of commensurate before the steam-cock is shut, and if none has entered since, the piston will descend to the very bottom of the cylinder. It sometimes happens, by the great pump drawing air, or some part of the communication-chains giving way, that the piston descends with such violence as to beat out the bottom of the cylinder with the blow, and it is to prevent this accident that the catch-pins are applied at the end of the beam.

When the manager feels the piston as low as he thinks proper, he shuts the injection-cock, by depressing the lever q; and at the same time he opens the regulator, by forcing down the handle s, which overflies the tumbling-bob, and its leg catching the cresfs-pin of the fpanner, s, opens the regulator.

The steam has been accumulating above the water in the boiler during the whole time of the piston's descent. The moment, therefore, that the steam-cock is opened, the steam, having an elasticity of rather more than one pound per square inch greater than that of the air, rushes into the cylinder, when it immediately blows open the knifing-valve, and aflets the water which had come in by the former injection, and what arose from the condensed steam, to defend by its own weight through the eduction-pipe S, and open the valve to run out into the hot-well R.

This water is nearly boiling-hot, or at least its surface; for while lying in the bottom of the cylinder, it will condense steam till it acquires this temperature, and therefore cannot run down till it will condense no more. There is a caufe of some waste of steam at its first admissiion, in order to heat the inside of the cylinder, and the injected water, to the boiling temperature; but the space being small, and the whole being already very warm, it is very soon done; and when things are properly constructed, little more is wanted than what will warm the cylinder; for the eduction-pipe is made of large dimensions, and receives some of the injected water even during the descent of the piston, and this portion will be removed out of the way of the steam.

The first effect of the entering steam is of great service: it drives out of the cylinder the vapour which it finds there. This is seldom pure steam, or watery vapour, because all water contains a quantity of air in a state of chemical union; but the union is only feeble, and a boiling heat is sufficient for disengaging the greatest part of it, by increasing its elaticity. It may be disengaged by simply removing the external prelure of the atmosphere. This is clearly seen when we expose a glafs of water in an exhausted receiver. Therefore the small space below the piston contains watery vapour, mixed with all the air which had been disengaged from the water in the boiler by ebullition, and all that was separated from the injection-water by the diminution of external prelure, in addition to any which may enter by leakage.

Let us now consider the state of the piston, when letting out on its return; as it is evident that it will start, or begin to rife by the counter-weight, the moment the steam-cock is opened; for at that instant the excess of atmospheric prelure, by which it was kept down in opposition to the preponderancy of the outer end of the beam, is diminished. At the first instant of the return of the pump-rods, they draw up the piston with great violence, all the weight of the water in the pumps acting in addition to the counter-weight; but the falling of the lower valves in the pumps, after an inch or two of motion, arrests the further descent of the water, and bears the weight of the column of water; and after this the piston will rise gradually by the action of the counter-weight.

The action of the counter-weight is very different in the two motions of the engine; for while the engine is making a working stroke, it is lifting not only the column of water in the pump, but the absolute weight of the bucket-rods also; and while the pump-rods are descending, there is a diminution of the counter-weight, by the whole weight lost by the immersion of the rod in water. The wooden rods which are generally used being soaked in water, and joined by iron straps, are heavier, but a little heavier, than water, and they are generally about one-third of the bulk of the water in the pumps.

By this counter-weight the piston is drawn upwards; and it would even rife, although the steam which is admitted was not quite so elastic as common air.

Suppose the mercury in the barometer to stand at 30 inches, and that the preponderancy at the outer end of the beam was equal to 3th of the prelure of the air on the piston, the piston would not rife until the elasticity of the steam was equal to 30 - 2, that is, to 26 1/2 inches nearly; but if the steam was just equal to this quantity, the piston would rife as fast as the steam of that density could be supplied to the cylinder through the steam-pipe; and on this supposition, the velocity of the acfent would depend on the velocity of that supply. But this is not the case in practice, because the steam must be stronger than the air, in order to blow out and discharge the air; it will therefore enter the cylinder without any effort on the piston to draw or suck it in. At the same time, the counter-weight must not be so great as to draw up the piston with that force which will cause a fuction within the cylinder greater than the steam-pipe can supply, or it would diminish the prelure of the steam within the cylinder lower than the atmosphere, and prevent it from nistfing or blowing out the air.

In filling the cylinder with steam, it will require a much more copious supply of steam than merely to fill up the space left by the acfent of the piston; for as the descent of the piston was only to condeence of the vapour occasioned by the interior of the cylinder being sufficiently cooled to condense the steam, this cooled surface must be again preented to the steam during the rife of the piston.
piston, and must condense steam a second time. The piston cannot rise another inch, till that part of the cylinder which the piston has already quitting has been warmed up to the boiling point, and much steam must be expended in this warming; for the inner surface of the cylinder must not only be raised to the heat of boiling water while the piston rises, but must also be made perfectly dry; and the film of water left on it by the ascending piston must be completely evaporated, otherwise it will continue to condense steam.

On this account, although the counter-weight is not necessary to buck in the steam, the moving force during the ascent of the piston must be considered as resulting chiefly, if not solely, from the preponderating weight of the great pump-rods; and this force is expended partly in returning the steam-piston to the top of the cylinder, where it may be again pressed down by the air, and make another working stroke by raising the pump-rods; and partly in returning the pump-buckets into their places at the bottom of their respective working barrels, in order that they may also make another working stroke. This latter requires force independent of the friction and inertia of the moving parts; for each bucket must be pushed down through the water in the barrel, which must lift up and rise through the valves in the bucket with a velocity proportioned to the velocity of the bucket, in the same degree as the area of the pump-barrel is proportioned to the opening of the valves through which the water must pass.

From this general consideration of the ascent of the piston, we may see that the motion differs greatly from the descent; it can hardly be supposed to accelerate, even if the steam was supplied to the cylinder in ever such quantity; for the resistance to the descent of the pump-bucket is the same with the weight of the column of water, which would cause water to flow through the valves of the buckets with the velocity with which it really rises through them; and this resistance must therefore increase as the square of that velocity increases; that is, as the square of the velocity with which the bucket descends. Independent of the force of friction, and the weight of the valves, the velocity of descent through the water must soon become a maximum, and the motion will become uniform. Accordingly, any one who observes with attention the working of a steam-engine, will see that the rise of the piston and descent of the pump-rods are extremely uniform, whereas the working stroke is very sensibly accelerated.

These two motions complete the period of the operation, and the whole may be repeated by shutting the regulator, and opening the injection-cock whenever the piston has attained the proper height. For the first two or three strokes, the opening and shutting of the cocks are performed by the attendant; but when he has thus ascertained that all parts are in order, he puts pins into the holes of the pump-frame, and the motion of the engine will then actuate its own machinery, and perform its reciprocations with greater regularity than can be done by hand.

Particulars of different Parts of the Atmospheric Engine.—We shall now pay some attention to the construction of the parts of this engine, and notice some further particulars.

The furnace or fire-place should not have the grate-bars too close as to prevent the free admixture of air, nor so open as to let the coals fall through. About two inches are sufficient for the distance between the bars. The height from the bars to the bottom of the boiler in the centre should not be more than two feet, and the concavity or rife of the bottom in the centre about one foot.

The size of the furnace depends upon the size of the boiler; but in every case the ash-hole ought to be capacious, to admit the air. If the flame is conducted in a flue or chimney round the outside of the boiler, or in a pipe round the inside of it, it ought to be gradually diminished from its entrance at the furnace to its extremity at the chimney; and the section of the chimney at that place should not exceed the section of the flue or pipe, and should also be somewhat less at the chimney-top.

The boiler or vessel, in which the steam is made by the force of fire, may be formed of iron plates, or copper, or of cast-iron, the bottom being of such materials as can withstand the effects of the fire, and have sufficient strength to retain the elastic force of the steam. It may be considered as consisting of two parts; an upper part, which is exposed to the steam, and an under part, which is exposed to the fire.

The form of the latter should be such as to receive the full force of the fire in the most advantageous manner, so that a certain quantity of fuel may have the greatest possible effect in heating and evaporating the water; which is best done by making the sides cylindrical, and the bottom a little concave, and then conducting the flame by an iron flue or pipe round the inside of the boiler, beneath the surface of the water, before it reaches the chimney. For this means, after the fire in the furnace has heated the water by its effect on the bottom, the flame heats it again by the pipe being wholly included in the water, and having every part of its surface in contact with it; which is preferable to carrying it in a flue or chimney round the outside of the boiler, as a third or a half of the surface of the flame only can be in contact with the boiler, the other being spent upon the brick-work. This cylindrical lower part may be left in its diameter than the upper part, and may contain from three to five feet perpendicular height of water in it.

The upper part of the boiler is bell made hemispherical for retaining the elasticity of the steam; yet any other form may do, provided it be of sufficient strength for the purpose.

The quick going of the engine depends much upon the casioanalves of the boiler-top; for if it be too small, it requires the steam to be heated to a greater degree to increase its elastic force sufficiently to work the engine, and then the condensation on entering the cylinder will be greater. If the top is so capacious as to contain eight or ten times the quantity of steam used at each stroke, it will require no more fire to preserve its elasticity than is sufficient to keep the water in a proper state of boiling; this, therefore, is a sufficient size for the boiler-top.

It is usual to place a damper, or iron slider, in the chimney, or in the flue leading into the chimney; and this has a chain or lever, by which the attendant can regulate the aperture of the chimney, and consequently the draught of the fire, so as to keep the steam to a great regularity; for it is evident, that when the engine works slowly, it will require less steam and fuel than when working rapidly; and without the damper, the engine would be constantly exposed to an excess or deficiency in the supply of steam. The boiler is, in some engines, placed immediately beneath the cylinder, the fame as represented in Plate III.; and then the regulator is placed immediately within the boiler, and acts against the under surface of its top, in the same manner as in the first engine of captain Savery, who invented the regulator.

It was a subsequent improvement of Newcomen's engine to remove the boiler from immediately beneath the cylinder to a small flue on the outside of the engine-house; by this means the height of the building is considerably reduced; and as the wall which supports the beam-centre does not require to be carried to so great a height, it is more enabled to withstand the violent shocks to which it is constantly subjected from the working of the engine. Another and
STEAM-ENGINE.

in a long will not be necessary, both the steam-cock being movable round an upright axis Q, which is accurately fitted into a conical socket coming through the lid of the beam-box. It can be turned aside by a lever, or handle, on the upper end of this axis, so as to uncover or open the passage. The profile shows that, in the section of this plate, there is a protuberance in the middle. This rests on a strong flat spring, fixed below it, across the mouth of the beam-pipe, which spring presses it strongly towards the beam-pipe, causing it to apply very closely, and the protuberance slides along the spring, while the regulator turns to the right or left. Both the handle of the regulator, and the end of the rod or spanner in fig. 1, are pierced with several holes, and a pin is put through them, which unites them by a joint. The motion of the handle of the regulator may be increased or diminished, by choosing for the joint a hole near to the axis or remote from it, and the exact position at which the regulator is to stop on both sides is determined by pins fixed in a horizontal bar, on which the end of the handle rests.

The tumbling-bob of the Y has a long lever check-ftrap fastened to it by the middle, and the two ends of the ftrap are fastened to the beams above it in such a manner that the lump may be alternately caught, and held up to the right and left of the perpendicular. By adjusting the length of the two parts of the ftrap, the Y may be moved in any desired position. The two legs of the fork spread out from each other, and also from the line of the fknife, thus J, and they are of such length as to reach the horizontal pin, which crosses the fork or ftrap of the spanner below.

Now, suppose the pin of the spanner hanging perpendicularly beneath the axis, and the fknife of the Y also held perpendicularly, carry it a little outward from the cylinder, and then let it go, it will fall farther out of its weight, without affecting the ftrap of the fknife, till the inner leg strikes on the horizontal pin of the ftrap, and then it pulls the pin of the ftrap and the fknife towards the cylinder, and stops the regulator. It thus lets the regulator in motion with a smart jerk, which is an effective way of overcoming the cohesion and friction of the regulator against the mouth of the beam-pipe. This push is adjusted to the proper length by the check-ftrap, which stops the Y when it has gone far enough. If we now take hold of the fknife of the Y, and move it up to the perpendicular, the width between its claws is such as to permit this motion, and something more, without affecting the ftrap. But when pushed still nearer to the cylinder, it tumbles suddenly towards it by its own weight, and then the other leg of the fork strikes the pin of the ftrap of the spanner in the opposite direction, till the bob is checked by the ftrap.

The motion of the beam-pipe to the regulator is open and shut suddenly. This opening and shutting of the beam-passage are executed in the precise moment that is proper, by placing the pins in the plug-beam, which acts upon the handles o and p, at a proper height. For this reason, it is pierced through with a great number of holes, that the places of these pins may be varied at pleasure: this, and a proper curvature of the handles o and p, make the adjustment as nice as we please.

In the same manner the motions of the injection-cock are also adjusted to act at the precise moment that is proper for them. The different pins are so placed in the plug-frame, that the beam-cock may be completely shut before the injection-cock is opened. The inherent motion of the machine, or the momentum of its parts, will give a small addition to the force of the piston, without expending steam all the while, and by leaving the steam rather less elastic than before, the infrequent descent of the piston is promoted.

The injection-cock is frequently provided with a tumbling-bob, to make it open suddenly. This is an arm extending from the centre of F, or lever q, upon which the toothed sector is fixed, and having at its extremity a sufficient weight to open the cock in an instant. When this weight is lifted up to its utmost, the cock is shut, and in this position the weight is detained by a small latch, which is lifted up by a pin in the plug-frame, at the moment when the piston arrives at the top of the cylinder, and thus relieving the weight, it falls all at once, and opens the cock in an instant; but when the piston descends nearly to the bottom, another pin in the plug-frame takes the handle of the sector, and gradually closing the cock, raises the weight till the latch detains it, which happens when the piston is quite at the bottom of its motion.

The injection-cock ought to be opened suddenly; but there is much propriety in closing it gradually: for after the first dash of the cold water against the bottom of the piston, the condensation is nearly complete, and very little more water is necessary, although a continual accension of some is absolutely required for completing the condensation as the capacity of the cylinder diminishes, and the water which is already injected becomes warmer. It is the continuance of this small injection which prevents the vapour in the cylinder becoming more dense as the piston descends.

The effect of the injection in condensing the steam in the cylinder depends upon the height of the reservoir and diameter of the injection: if the engine makes a six-feet stroke, then the jack-head cistern should be at least twelve feet perpendicular above the top of the cylinder. The size of the cistern must depend upon the capacity of the cylinder, as we shall flow by a table; but if the cylinder be very large, it is common to have three or four small holes rather than one large one, in order that the jet may be dispers'd more effectually through the whole capacity of the cylinder. The injection-pipe, or pipe of conduct, should be sufficiently large to supply the injection freely with water. The injection-cistern is the common source from which all the parts of the machine receive their respective supplies of cold water. In the first place, the small branch f, which proceeds from the pipe P, immediately below the cistern, and is conducted to the top of the cylinder, has a cock at the end, which must be so adjusted, that no more water will run from it than what will keep a constant supply of a few inches of water above the piston to keep it tight. Every time the piston comes to the top of the cylinder it will bring the water along with it, and the surplus of its evaporation and leakage runs off by a waste-pipe W. This water necessarily becomes almost boiling-hot, and it was thought proper to employ a proper curvature of the handles of the boiler. This was accordingly practised for some time; but Mr. Beighton improved this economical thought by supplying the boiler from the eduction-pipe S, the water of which coming
coming from the cylinder, must be still hotter than that above the piston.

This contrivance required attention to several circumstances, which will be easily understood by considering the perspective view. The ejection-pipe comes out of the bottom of the cylinder in an inclined direction, and descends into the hot-well R, where it turns up, and is covered with a valve; in the perspective view may be observed an upright pipe T, which goes through the head of the boiler, and reaches to within a few inches of its bottom. This pipe is called the feeder, and rises about three or four feet above the surface of the water in the boiler; it is open at both ends, and has a horizontal branch from its upper end, communicating with the hot-well R. This communicating branch has a cock, by which its passage may be diminished at pleasure. Now, supposing the steam in the boiler to be very strong, it will cause the boiling water to rise in the feeding-pipe T, and palling along this branch, to rise also in the hot-well, and run over. The height of the surface of water in the hot-well, above the surface of the water in the boiler, is such, that the steam is never strong enough to produce this effect; but, on the contrary, the water in the hot-well will run off by the branch, and go down into the boiler by the feeding-pipe, as fast as the opening of the cock will admit. These things being understood, let us suppose a quantity of injected water lying at the bottom of the cylinder, it will run into the ejection-pipe S, and opening the valve in the bottom, will flow into the hot-well. By properly adjusting the cock on the branch of T, the boiler may be supplied with water as fast as the waste in steam-engine requires.

The small quantity that is necessary to supply the boiler might be immediately taken from the cold ciston, without sensibly diminishing the production of steam; for the quantity of heat necessary for raising the sensible heat of cold water to that of the boiling temperature is small, when compared with the quantity of heat that must be combined with it, in order to convert it into steam. The heat expended in boiling off a cubic foot of water, is as much as would bring six cubic feet to a boiling heat from the temperature of 55; and little difference can be observed in the performance of such engines as are fed with hot water, and those which have their boilers supplied from a brook. The hot water has, however, the advantage of being free from air; and when an engine must derive all its supplies from pit-water, the water from the ejection-pipe is far preferable to that from the top of the cylinder, because it has been in a measure boiled and diffilled.

The interior surface of the cylinder requires to be bored with great exactness; and it must have a sufficient thickness of metal to resist the pressure of the atmosphere, without bending or altering its figure. The piston is made of cast-iron, as nearly as possible to fit the inside of the cylinder, and has all round it, within two inches of the edge, a circular ledge or rim projecting upwards from it, which is both to strengthen the piston, and also to leave a space round between it and the side of the cylinder, to receive the packing or wadding which keeps the piston tight. Mr. Smeaton, who made the belt engines on Newcomen's plan, caufed the lower surface of the piston to be always planked with elm or beech, about 24 inches thick. The planking confisted of two broad planks, crofing each other at right angles, and halved into each other at the interfection, fo as to come to an equal thickness: the remaining parts or fectors between the arms of this crofs were filled up with pieces of the fame plank, well tongued and fitted together, and bolited fast to the caft-iron of the piston with one or two iron rings, let in flat under the lower surface to make it frong: the whole was surrounded with an iron hoop, a quarter of an inch less than the internal diameter of the cylinder. In this cafe, the cast-iron piston was made less than the wood which formed the bottom of the groove, to receive the wadding, which the edge of the cast-iron formed the upright fide thereof. The wooden bottom was screwed to the iron with a double thickness of flannel and tar, to exclude the air between the iron and the wood. By this means the piston was left liable to conduct heat; and the wood, being placed with the grain radiating in all directions from the centre, was not likely to expand by the heat. The flank of the piston is made with two prongs, to unite it firmly to the piston; and if the engine is large, it has four prongs, to balance it equally; and the flank must also have two or four chains upon the arch-head. But the chains, when more than one is used, must be united in pairs to the ends of a short horizontal link; and from the middle of this the flank must be suspended, by which means the train will be equally divided between the two chains. When there are four chains, they must be divided into two pairs, with horizontal links, as above; and the middle parts of these two links must be united to the ends of a longer horizontal link, from the middle of which the flank of the piston is hung: and in this way all the four chains will bear equally.

The upper ends of the chains are jointed to the ends of strong iron bars, supported on the ends of the arch-heads; and at the other ends bolted to the top of the beam, by which means they brace the arch-head.

The original method of making the great working beam was to employ a large tree, and to place the gudgeon or fulcrum under the middle of it, with proper bands to sustain it. The framed beam, represented in the view, was made by Mr. Smeaton: the two middle pieces are formed of whole balks, 12 inches square, put together with the gudgeon between them, which is five inches thick, and notched into the beams, to make it keep its place; the ends of the beams are then sprung together, and bolted fast. This being done, another pair of timbers is applied on the outside of the two former, and others on the outside of these, for the largest engines, making ten balks in the whole. When all these are firmly united, several mortises are cut through between the joints, as shewn by the small square marks in the figure; and into these, hard oak wedges are driven, so that they will be half in each beam, and prevent them from slipping or sliding upon each other in the leaf; and, in this cafe, the beams act as ties by the longitudinal strength rather than their flexibility. The great beams which furnish the cylinder, and extend across the house, are compounded of several pieces, in the same manner; and the cylinder has a projecting flanch from the middle of it, to bolt it down to the beams.

The pump-rods or spears, K, are made of wood, with iron flaps let in and bolted to them at each end, to join them together: they are made of fir, which is very good wood, as it will bear a great train endways, if the iron flaps are well fitted, and can be obtained in very long pieces. When a mine is of a confiderable depth, the pumps cannot be made to lift the whole at once; but the pit must be divided into two, three, or four lifts, and as many different pumps employed; each lifting the water into a ciston, for the supply of that which is above it. Fifty yards are as much as is proper for each lift, but in some very deep mines they are obliged to make them more. It is very difficult, in these cafes, to make all the pipes sufficiently strong to bear the pressure of the water, particularly the shock which takes place
STEAM-ENGINE.

place when the whole column of water falls upon the valves in fluctuating: the blow which they then make is like the stroke of a forge-hammer, and forms a beat every thing to pieces. The only effectual remedy is the addition of an air-reticel at the side of the pump; but in general the miner makes a hole in the suction-pipe of the pump, just below the clack, and fixes in a cock, with a small valve opening outswards: through this they admit a certain quantity of air every time the pump draws, and this air, mixing with the water in the barrel, condenses, when the valves that suddenly, and by its elasticity eases the violence of the shock. When the mine is pumped almost dry, the engine will draw a little air at every stroke, at the bottom of the pipes; and this answers the same purpose. See a description of a new pump for mining in our article Pump.

Rules for determining the Proportions of Atmospheric Engines.

—Mr. Newcomen brought forward his engine at a time when almost all the valuable mines in England were coming to a stand for want of more powerful or cheaper machines than were then known; and in consequence, in a few years his invention was put in practice at almost all the mines then existing; and new ones were opened in situations where it would have been impossible to have done it before. The first perfect engine which they erected at Griff, in Warwickshire, had only a 22-inch cylinder, and it was many years before any were made so large as 36: those which we now call small engines, were so much more powerful than any former means of draining water, that they were amply sufficient, until the mines, by growing deeper, required more power. The most obvious means of increasing the force was to change the cylinder for a larger one, and this was most frequently done one or more times; and then, when the beam and other parts would bear no greater strain, a new and larger engine was erected. In this manner they proceeded for many years, until, by gradual increase, the cylinders for common use had reached the enormous powers of 50, 60, and 72 inches diameter.

When it became impracticable to extend them much larger, engineers began to consider the means of improving their performance without increasing their dimensions: also, the consumption of fuel in these large engines was so furious an expense, as to balance the profits of many mines.

At first the fuel was not considered as an object, because the steam-engine, on the whole, was found so much cheaper than any other means of draining water. The bell engineers were those who made engines which would fulfill the task assigned to them, and, in comparison to their dimensions and expense of erection, would draw the most water, and be the most certain in the continuance of their operation. We have no accounts of the quantity of fuel consumed by any of those early engines, in proportion to the water which they raised to any given height; but the rules by which they apportioned their cylinders to the work to be performed have been preserved.

Defaguelers tells us, that Mr. Newcomen's way of finding the power of his engine, was to square the diameter of the cylinder in inches, and cut off the half figure, and then call it long hundred weights; and writing a cypher on the right hand, he called the number on that side odd pounds: this he reckoned tolerably exact at a mean, or rather when the barometer was at 30 inches, and the air heavy. The effect of cutting off the half figure from the square of the diameter, is to divide the number of superficial circular inches on the piston, into portions of cubic inches each; and as the pressure on each of these portions is estimated at a long hundred weight, or 120 lbs., the pressure will be 120 ÷ 10 = 12 lbs. per circular inch, or 15.3 lbs. per square inch: this, however, must be considered as the full pressure of the atmosphere, if the vacuum was perfect. But to compensate for imperfection, Newcomen allowed between one-third and one-fourth part, and also for what is lost in the friction of the several parts, and for accidents. If, instead of the long hundred of 120 lbs., Newcomen had taken the common hundred of 112 lbs., he would have had 112 ÷ 10 = 11.2 lbs. per circular inch, or 14.4 lbs. per square inch, which is still nearer the medium pressure of the atmosphere.

Defaguelers says this rule will agree pretty well with the work at Griff engine, there being lifted at every stroke between two-thirds and three-fourths of the weight of the atmospheric column precluding on the piston; i.e., between 10 and 11½ lbs. on each square inch. To give the estimation in round numbers, the diameter of the cylinder of Griff engine will be 32 inches; this squared is 1024; cut off the half figure, and we have 48 cwt. 40 lbs. for the preasure of the atmosphere. The column of water in the pumps weighs about 27½ cwt. to which adding the weight of 75 yards of iron rods, equal about 9 cwt., the weight lifted at the end of the beam would be 36½ cwt.; from which we must subtract about 4 cwt. for the piston, and the other weight at that end of the beam, reducing the load to 32½ cwt.: so that the weight of the atmosphere being 48 cwt. 40 lbs. raises a weight of 32½ cwt. with a velocity of six feet in two seconds, confidering only the descending stroke of the piston. This requires an effective pressure on the piston of nearly 11 lbs. per square inch, including friction and counter-weight; but to balance the weight of the water in the pump, demands a pressure of only 8 lbs. per square inch of the piston.

In calculating the powers of the steam-engine, it has been a common mistake with engineers to take into the account no other circumstances than the diameter of the cylinder, and the perpendicular height and diameter of the pumps; from which they calculate only what burthen is laid upon each square inch of the cylinder or piston area, supposing the piston to be at rest, but without paying any regard to the velocity of the engine's motions under such burthen, or the number of strokes per minute. Without taking these particulars into the account, it is impossible to calculate the quantity of water raised to a given height, which is the only means of obtaining the exact power or acting force of an engine; it would be like attempting to measure the contents of a solid body by only two dimensions. Steam-engines have at different times been calculated to carry a load varying from 5 lbs. to upwards of 10 lbs. to the square inch; but when working with the light preasure of 5 lbs. to the inch, they are expected to go with double the velocity; that is, the piston to move through double the space in the same time that it would with a preasure of 10 lbs. In this case the same quantity of water would be raised to a given height, in the same space of time. In the steam-engine, as well as in other machines, there is a maximum, which cannot be exceeded without applying some new principle; and though by bad workmanship an engine may fall short of what it should do, the best workmanship can only produce a certain effect.

In estimating the power or effect of engines in this manner by the pounds per inch in the area of the piston, it must be considered as the clear product of the engine in the column of water it will raise, abstracted of all deductions for friction, counter-weight, &c. For, by attending to the different lifts of pumps in the engine, that of a coal or a copper mine, we find that we must, beside the altitudes and the diameters, take into the account the friction of the buckets, and of the water on the sides of the pumps; the opening
STEAM-ENGINE.

opening of strong double-leathered valves, together with the dones and gravel that enter at the foot of the pump; the inertia of the pump-rods, the chains, the massive lever placed between the cylinder and the pumps, all to be overcome by the pressure on the piston, in addition to the 7 or 8 lbs. per square inch. These additions to the power required for the mere raising of the water are so considerable, as to be at least equal to half what is required for the work performed: this will raise the real acting pressure of the atmosphere to 105 or 115 lbs. per square inch. When this is the case, the vapor which remains in the cylinder must be equal in pressure to 4 or 5 lbs. per square inch; and this, by our first table of expansion, will indicate a temperature of from 155° to 160° Fahrenheit.

In general, the water in the hot-well indicates a lower temperature than this; but although we have but little information concerning the state of the water in the atmospheric engines, when working in their usual state, it must be considerably more perfect than has been suggested by the idea of a pressure of 8 lbs. per inch: for an engine carrying a load of 7½ lbs. on the square inch of the piston, together with the friction and inertia, even in large engines, cannot be less than 11½ lbs. on the inch. Mr. Horblower informs us that he tried the vacuum of several engines in the county of Cornwall; and in one, which was reckoned the least, the vacuum in the cylinder brought the barometer-gauge to 23, and sometimes 24 inches, instead of 30 inches, at which it would have stood if the vacuum was perfect. If we take the extreme of these observations, it will be 11.6 lbs. on each square inch.

Mr. Henry Beighton seems to have been the first who reduced the steam-engine to any degree of certainty in its operations, and laid down the rules for calculating its powers. Beighton was a mathematician as well as an engineer, and conducted the Ladies Diary from 1714 to 1744. For several years he lived at Griff, and had constant opportunities of trying experiments on engines.

We have before noticed his invention of the working-gear, or mechanism, by which the regulator and steam-cock are alternately opened and shut. In 1717, Mr. Beighton published the following table of the necessary proportions of the cylinders of engines to the pumps, when drawing water at different depths, from 15 to 100 yards, in different quantities, from 48 to 480 hogheads per hour.

This table is formed on the foundation of the ale-gallon, (containing 282 cubic inches,) which, when filled with pure running water, weighs 10 lbs. 7 oz. avoirdupois; and a superficial inch, on a vacuum, takes in about 14 lbs. 13 oz. of the atmosphere, when the mercury stands at a medium in the barometer.

But allowing for several frictions, and to give a considerable velocity to the engine, experience has taught us to allow but little more than 8 lbs. to an inch in the cylinder's base, that it may make about 16 strokes in a minute, at about fix feet each.

An Example for the Use of this Table.—Suppose it was required to draw 150 hogheads per hour, at 90 yards deep; in the seventh column, I seek the nearest number, viz. 149 hogheads, and against it, in the first column, I find a pump of seven-inch bore; then under 90, the depth on the right hand in the same line, I have 27 inches, the diameter of the cylinder fit for that purpose, and go for any other. Henry Beighton.

This estimation of 8 lbs. pressure for each square inch continued for many years to be the rule with engineers who constructed their engines according to this proportion; and if the engines were of a better or worse construction, they would move with a greater or less velocity, because all the excels of pressure which could be obtained above the 8 lbs. was appropriated to overcome the friction and the inertia of the machine; and also to raise the counter-weight; if, therefore, this additional quantity was greater or less, the engine would move quicker, and raise a greater quantity of water.
STEAM-ENGINE.

Mr. Brighton expected his engine to move 16 strokes per minute, of fix feet each, or 96 feet of motion per minute; but succeeding engineers found them seldom to do so, and then began to diminish the burthen to 7 lbs. per square inch, and even 6 lbs., in order to obtain a greater velocity of motion.

The celebrated engineer Mr. John Smeaton carried the engine of Newcomen to perpacs as great a degree of perfection as its principle admitted. Having constant occasion to employ large steam-engines in the great works he executed, he turned his attention to consider the means of improving their effect, and diminishing the consumption of fuel. In calculating the proportions for an engine for the New River Company, in 1767, he considered that the stoppage of the water at every stroke, as well as putting the lever-beam, piston, heavy rods, and chains, from a state of rest into motion, twice at every stroke, was a great loss of power; he therefore determined to work the engine slower, and with larger pumps, and put upon the piston all the load it would bear. To reduce the velocity of the column of water still more, he would place the fulcrum of the beam out of the center, and make the stroke of the piston nine feet, while the pump which lifted 36 feet should work with only a fix feet stroke. This arrangement obliged him to employ a long narrow cylinder, of only 18 inches diameter, and from this he also expected to obtain other advantages; viz. that every part of the steam, being nearer the surface of the cylinder, would be more readily condensed; and, in consequence, that a less quantity of injection-water would serve the cylinder, which would itself be more heated. Under all these appearances of advantage, he ventured to burden the piston with a presure of 10.4 lbs. per inch. Thus, area of piston (18 inches diameter) 25.4; weight of the column of water 36 feet in the pumps, 18 inches diameter, 3960 lbs., of which take 3 lbs for the difference of the length of stroke, and it gives 2640 lbs. for the weight to be lifted by the piston; and dividing 2640 by 254, the area of the piston, gives 10.4 lbs. pressure per inch. Having once seen a common engine struggle under this burden, I thought myself (says this ingenious engineer) quite secure under these advantages; but how great was my surprize and mortification, to find that, instead of requiring less injection-water than common, although the injection-pump was calculated to afford as much injection-water as usual, in proportion to the area of the cylinder, with a sufficient overplus to answer all imaginated wants, it was unable to support the engine with injection; and that two men were obliged to assist to raise the injection-water quicker by hand, to keep the engine in motion: at the same time that the cylinder was so cold, I could keep my hand upon any part of it, and bear it for a length of time in the hot-well. By good fortune, the engine performed the work it was appointed to do, as to the raising of water; but the coals by no means answer'd my calculation. The injection-pump being enlarged, the engine was in a state of doing business, and I tried many smaller experiments, but without any good effect, till I altered the fulcrum of the beam so much, as reduced the load upon the piston from 105 lbs. to 83 lbs. per inch. Under this load, though it shortened the stroke at the pump-end, the engine went so much quicker, as not only to raise more water, but consume less coals, took less injection-water, the cylinder became hot, and the injection-water came out at 180° of Fahrenheit; and the engine in every respect not only did its work better, but went more pleasantly. This at once convinced me that a considerable degree of condenfation of the steam took place in entering the cylinder, and that I had lost more this way by the coldness of the cylinder, than I had gained by the increase of load. In short, this single alteration seemed to have unfettered the engine; but in what degree this condensation took place under different circumstances, and whether it is upon the medium, so as upon the whole to do work, was still unknown to me. But resolving, if possible, to make myself master of the subject, I immediately began to build a small fire-engine at home, that I could easily convert into different shapes for experiments, and which engine was very near ready to set to work in the winter of 1769.  

With this experimental engine, which is represented in Plate III. Steam-Engine, Mr. Smeaton made a multitude of experiments, which he noted down with great care in tables, and from their results deduced rules for the proportions of the parts of his engines; he afterwards erected many engines of the largest dimensions, which fully verified his experiments: the first of these was at Long Benton colliery, in 1774, which had a 52-inch cylinder, and afterwards a 72-inch, for the empress of Ruffia, at Cronstafft.

Mr. Smeaton's Experimental Engine.—Plate III. contains an elevation of this engine, showing all its parts at one view; and, after the minute description which we have given of Mr. Newcomen's engine in Plate II., it is not necessary to enlarge on the particulars of the present. A, B, are the walls of the building; C, ground-fills, extending from the wall B, to the wall of the boiler or furnace F; D are strong upright timbers, to support the cross-beam a, on which the centre of the beam is joined; E are the cylinder-beams, framed into the upright D, and the walls A, B; and the cylinder G is hung between them by thick cross-planks g, g.

M M the great beam, rattling on its centre, and formed to arcs of circles at the ends, to which are suspended the chains b for the piston, and the chain of the main-pump fpear H. It has also attached to it the plug-frame Q, and, at the other end an iron rod K, which works the injection or jack-head pump, I, by means of a counter lever a a, which brings the rod, f, of the pump to a convenient place, near the main-pump O O. The proper distance for the motion of the beam is limited by two iron fiddles or pins h, h, which reach out from each side of the arch-heads, and stop on pieces of wood, supported by the beams S, called the spring-beams. These beams also, which support the upper floor of the house, are let into the walls A, B, at the ends, and rest in the middle on the cross-beam d, and are firmly bolted down, as shewn in the drawing.

N is the injection-pipe, 13 the injection-cock, and X the piston water-cock, branching off from the injection-pipe N. L is the injection-cillem, placed in the highest part of the house; k k is the pipe from the injection-pump I, by which it is supplied; and T is the white pipe, at which the excess of water runs off. The pipe T leads down to the small cillem n, which will always be kept full, and the overflow will run down the waste-pipe l l, and escape out of doors.

f is the fire-door, and the ash-pit is beneath it; the fire circulates round the boiler, and then pails into the chimney; x is a small door at the bottom of the chimney, to clear the foot, and there is also a damper to regulate the draft: z is the boiler, and its figure below is shewn by the dotted lines: v is a pipe rising from it, which has the safety-valve at the top of it, contained in a box or trough, which carries the steam through the wall at w: n is the steam-cylinder, and the white piston, which contains mercury, and shews the pressure of the steam. The cylinder C, besides the bored part in which the piston works, has a bottom W, screwed on by a flange at the lower part, and from this bottom part defends the steam-pipe S. The short pipe, 12, joins to the lower end of the injection-pipe NN; and opposite
STEAM-ENGINE.

opposite to this is a similar short pipe, for the exciting-valve. Also from the bottom of the cylinder there descends the sink, or ejection-pipe, which enters the hot-well R, and then is covered with a valve. S is the waste-pipe, from which the excess of hot water in the hot-well is carried off into the well E E.

As the hot-well is placed so low that the boiler cannot be supplied from it, a small feed-pipe, P, proceeds from the lower part of the cylinder, and enters the boiler, having a cock, R, to regulate the quantity which shall pass through, and a valve to prevent the water being drawn up from the boiler into the cylinder. In the top of the boiler is the regulator-plate, 7, to the under surface of which the regulator is fitted; the handle or lever of the regulator is also seen, and the spanner or rod, 5, by which it is alternately moved backwards or forwards by the arms 3 and 4 of the 1. When its weight or bob, 3, falls over on either side of the perpendicular, it is checked by the stop 9; and 2 are the arms or handles by which the 4 is moved when the pins in the plug-beam, Q, act upon them, and 6 is a weight to balance the weight of the handles.

10, 11 is the F, or lever of the injection-cock; it is connected with the handle of the cock, 13, by a fork, which cannot be seen; and the end, 11, is loaded with a sufficient weight to cause its descent, and open the cock, except when it is elevated, by pressing down the end 10; and when it is held up by the hook 12, the cock will then be shut; but when the plug-frame rises to its highest, it draws the wire 14, and lifts the catch 12, so as to let fall the weight 11, and opens the cock in an instant.

The action of this engine is apparent after the explanation which we have given of the former engine, and it is only necessary to explain a small machine which is contained in the cistern V, called the cataract: it was very commonly used in the engines for the mines in Cornwall, to regulate the motion of the engine to any given number per minute, so that the defcribed quantity of water could be drawn, without waiting the steam in drawing more.

The cataract is nothing more than a small tumbling-bob, moving on a centre within the box V, in the same manner as the A; but instead of the weight or bob at the top, it has a small box or cup, which is filled with water by a small stream dropping continually from the small cistern z, through a cock. The lever, on which the cup is fixed, has a second lever and counter-weight applied to it, which makes it always assume the vertical position, or nearly so, except when the cup is full, and then it is of sufficient weight to make the cataract-tumbler fall over, and in that position the cup inclines to such a magnitude, that it discharges its contents, and the counter-weight causes its immediate return. The cataract, when it falls over, strikes a piece which is connected with a wire 15, and this by a lever, 16, and the second wire, 17, draws up the catch 12.

When the engine works with the cataract, the wire 14, before mentioned, is detached; and in this state we will suppose the regulator open, the injection-cock shut, and the piston to have just arrived at the top of the cylinder. A pin in the plug-beam, Q, feizes the handle 1, overthrows the tumbling-bob, 3, of the 4 towards the cylinder, and the prong, 5, of the fork of the 4 draws the rod 5, and shuts the regulator. In this situation the engine will remain, until the steam, which flows from the cistern z, through the cock, fills the cup at the top of the cataract, and causes it to fall over; it then strikes suddenly on the piece of the wire 15, and by the lever 16, and wire 17, it raises the hook-catch 12. This lets fall the weight 11, and opens the injection-cock, to throw a jet in the cylinder, which condenses the steam therein, making the piston to descend; and when it arrives at the bottom, the pin in the plug Q depresses 10, which shuts the injection, and then, by depressing 2, overthrows the tumbling-bob, and opens the regulator. This admits steam again into the cylinder, and the counter-weight makes the piston return. The cataract returned the piston that its cup inclined so much as to throw out its water, and the cup then began to fill again; but it will not again act, or discharge the injection-cock, until it is quite filled; and the injection-cock will not open till this happens; so that the engine waits at the top of the stroke till the cataract is ready; and this time of waiting can be regulated, by diminishing or increasing the steam which drops down the cock, so as to draw up exactly as much water as drains into the mine.

In 1765, Mr. Smeaton made a portable steam-engine for draining foundations, or other temporary works. It had a pulley or wheel, to receive the chain which communicated motion from the piston to the pump-rod, instead of a beam; and the whole machine being supported in one frame of wood, it had no connection with the building in which it was placed, or it could work all together in the open air. The frame was shaped like the letter A, and the vertex supported the pivots of the wheel, whilst the cylinder and pump were bolted down to the ground-fills, on which the A was erected. The engine in its action was the same as others; the boiler required no setting in brick-work, but was in the shape of a large tea-kettle, and the fire-place was in the centre of it, surrounded on all sides by the water. On one side was an opening for the fire-door, and a large tube or pipe led through the water to a hollow sphere of cast-iron, in which the fire was made, upon a grate; and from the grate another large tube or ash-pit descended perpendicularly through the bottom of the boiler, and was open below to supply air to the fire; also opposite the fire-door was a third large tube or chimney, leading from the sphere through the side of the boiler, and it then turned up in the manner of the spout of a tea-kettle, to carry off the smoke into a tall chimney of brick or of iron-plate.

From Mr. Smeaton's manuscript papers (now in possession of Sir Joseph Banks) we gain much practical as well as philosophical information on the atmospheric engines; and as these engines are still used very extensively at coal-mines, we think the publication of the particulars will be of service.

Mr. Smeaton's experiments with his experimental engine were very numerous, and so diversified, as to afford all the information which can be derived upon Newcomen's engine. It would exceed our limits to transcribe many of these experiments; but we think it will be serviceable to give the table of proportions, which he settled from the results of all his experiments, and after which table, between the years 1774 and 1782, he erected no less than eight first rate engines, with cylinders of five and six feet diameters, and many others of smaller dimensions. A full description, with drawings, of one of these engines, is given in the publication of Mr. Smeaton's Reports, 3 vols. 4to. London, 1811.
Mr. Smeaton's Table for the Proportions of the Parts of Newcomen's Engines, deduced from actual Experiments.

**STEAM-ENGINE.**
The different columns of this table explain themselves, except the great product per minute. This is the effect of the engine expressed in a convenient manner, to separate it from all considerations of the diameter of the pump, or of the number of strokes which the engine makes in a minute; being the multiple of all these, and is thus obtained. Multiply the square of the diameter of the cylinder in inches, by the pressure on each square inch of the piston, not expressed in pounds weight, but in the height of a column of water in feet; and this again is multiplied by the velocity of the motion of the piston per minute. For example, a 26-inch cylinder: square of diameter, \( (67.6) \times 18 \) feet, the pressure per square inch in feet of water, \( = 12168 \times 76.21 \) feet, the journey per minute, \( = 927323 \), the great product per minute, as per table.

The table is calculated upon the proposition that the pressure upon each square inch of the piston is 8 lbs. avoirdupois, or 18 feet column of water.

The last column, or effect per minute of one bushel per hour, is a comparative view of the effect of different fixed engines, shewing the advantages of large engines in respect to small, in the quantity of work they will effect in proportion to the coals they consume.

To find the number of bushels of coals which any of the engines will consume per hour, calculate the internal surface of the cylinder in square inches, and add to this three times the square of the diameter, to allow for the piston bottom, cylinder bottom, and the surface of the pipes which are within the cylinder. Next calculate the solid content of the cylinder in cubic inches, and find the proportion between the superficial and the solid measure of the cylinder; according to the number of this proportion, find a number in the following table for a divisor.

</table>

Lately, cut off three places of figures from the great product per minute, and dividing by the divisor, the quotient will be the effect of one bushel per minute.

For example, a 72-inch cylinder: its circumference will be 22.63, which, multiplied by 135 inches, the length, gives 30650 square inches; and adding there to 15552, which is three times the square of the diameter, we have 46102 superficial inches; and the content of the cylinder is 549652 cubic inches, which is 11.9 times the number of the superficial inches. By seeking in the last table for 11.9 or 12, we find the number 572 for the divisor of the great product, after cutting off its three last figures, viz., 7558 = 572 = 13 bushels per hour.

By this way of finding the proportion between the surface and the content of the cylinder, an allowance is made for the loss of steam which takes place from condensation, when it enters into the cylinder at every stroke, after it has been cooled by the injection thrown into it.

The quantity is very considerable, and forms the greatest objection to this form of the steam-engine. An attentive observation to the action of an engine will shew that there is a waste, but not the quantity in which it takes place. The moment the regulator is opened, when the piston is at the bottom of the stroke, the steam may be perceived to issue from the lifting-valve with a strong puff, because the steam is more elastic than air by one or two pounds per square inch; but as the piston rises, this steam diminishes, and soon ceases, and no more steam will issue during the whole rise of the piston.

To ascertain the quantity of this loss by condensation, it becomes first necessary to know what degree water is expanded, when converted into steam, at the pressure of the atmosphere; and compare this with the degree of expansion which it requires to convert the water, which the boiler consumes in a given time, into such a quantity of steam as will fill the cylinder the requisite number of times in the same period.

Mr. Beighton made an experiment at Griff engine, in Warwickshire, on the degree of rarity of water when converted into steam, but without determining the temperature. The pressure of the steam was just one pound upon the square inch, as he determined by the feel of his yard of the safety-valve; and by our second table, we find this to denote a temperature of about 216°. The cylinder of the engine contained 113 gallons of steam at every stroke, which, at 16 strokes per minute, is equal to \( 1868 \) ale-gallons, or \( 1808 \times 8 = 14464 \) pints of steam per minute. He found that the necessary supply of fresh water for the boiler, under these circumstances, was about five pints per minute, to keep the surface of the water at a constant level; therefore, the relative bulk of the steam of one pound per inch pressure, and the water from which it was produced, were as \( 5 : 14464 \), or as \( 1 : 2803 \) nearly. By an unaccountable mistake, Defaguliers, who relates the above experiment, deduces from the same data, that the expansion is \( 13388 \), a number which has been frequently quoted by other writers. Mr. Beighton's experiment cannot be admitted as conclusive, because the cylinder being cooled by the condensing water at every stroke, the steam would be condensed, and lose much of its bulk in entering into the cold cylinder. But without making any allowance for that loss, Mr. Beighton's experiment makes a greater degree of expansion than has been found by others; and we should not have mentioned this experiment at all, had it not been so frequently quoted after Defaguliers with his enormous error, even by Belidor, Prony, and other foreign writers.

Mr. Smeaton made some experiments by weighing a Florence flask of four inches diameter, first when it was perfectly dry and empty, and afterwards when it was full of water; then pouring out all the water, except a small quantity, he put the globe on the fire, and made it boil througly, till the last drop of water disappeared, and at that instant he stopped up the mouth to retain the steam which was within it. The flask being now weighed, gave the difference of weight between the flask filled with water and with steam of an elastic force equal to that of atmospheric air; and deducting the weight of the empty flask from each of these experiments,
experiments, it gave the proportion of the bulk of the steam to that of the water; this, by a mean of six different experiments, he determined to be as $\frac{1}{7}$ : 1. But supposing that some air was contained in the flask along with the steam, he inverted the mouth of it in water when it was filled with the hot steam, and found it to draw up the water in the same manner as described by captain Savery; but it was not quite filled with water, for a small bubble of air remained in the flask, and this he estimated to be such a portion of the whole content, as induced him to reduce his estimate of the expansion from 2459 times to 1800 times; and this number, the same number that Mr. Watt had determined, he used in his calculations.

His investigation of the quantity of steam destroyed by a given surface of the cold cylinder was as follows. The cylinder of the experimental engine was 9.5 inches diameter and 50 inches long; making the requisite additions to its bottom and piston, the internal surface was 2242 square inches, and the solid content was 3940 cubic inches. The quantity of water necessary to supply the boiler at each stroke was found to be 8.5 cubic inches: therefore, $3940 \div 8.5 = 463$ times, which the 8.5 cubic inches of water must have expanded to fill the cylinder at each stroke. But supposing the water to have expanded 1800 times, the 8.5 inches $\times 1800 = 15300$ cubic inches of steam produced, which is 3.88 times the quantity employed to fill the cylinder. The difference of these numbers, viz. 15300 - 3940 = 11360 inches of steam condensed and lost. This, divided by the number of superficial inches on the surface of the cylinder, gives 4.96 cubic inches condensed by every square inch of surface.

It will be readily seen, that the proportion between the quantity of steam which must be produced, and the quantity which will be employed, will be less in large cylinders than in small ones; hence the above is the extreme case; and in a similar trial of a 52-inch cylinder, he found the waste to be only 2.7 cubic inches for each inch of surface. Hence we see the reason for Mr. Smeaton's rule of making the proportion of the surface of the cylinder to its capacity the ground-work for the calculation of the quantity of coal.

In common engines, which are loaded to leven or eight pounds upon the inch, and are of a middle size, the quantity of steam which is condensed in retorting to the cylinder the heat which it had lost, is equal to the full contents of the cylinder, besides what it really required to fill it; so that twice the contents of the cylinder are employed to make it raise a column of water equal to about seven or eight pounds for each square inch of the piston; or to take it more simply, a cubic foot of steam makes a sufficient vacuum to raise a cubic foot of water about eighteen feet high, besides overcoming the friction of the engine, and the resistance of the water to motion.

In all Mr. Smeaton's experiments he observed the quantity of water which was evaporated in proportion to the coals, and found by a mean of a great number of experiments, that a bushel of coals evaporated 1700 cubic inches of water, or 7.35 cubic feet; and estimating the expansion at 1800 times, the bushel of coals will produce 13230 cubic feet of steam, of little more in elasticity than the atmosphere, and about 21.4° of Fahrenheit's thermometer.

The work actually performed by atmospheric engines in proportion to the coals.—We shall next give the results of the performance of some old engines, according to Mr. Smeaton, before he began his improvements. The engine at Long Benton colliery, which was considered as one of the best in the neighbourhood of Newcasttle, was tried by Mr. Smeaton in 1772; it was of the following dimensions. Cylinder 52 inches diameter, stroke 7 feet. The pump was 12 inches diameter, and drew the water 61 fathoms high; and also an injection-pump 8 inches diameter, and 5 feet 3 inches stroke, which raised water 58 feet. This engine consumed 8 bolls (of 2 cwt. 1 qr. 211bs. each) of coals, such as are generally used for engines, in two hours and two minutes, when working at the rate of from 7½ to 8 strokes per minute, or 7½ per minute at the medium.

The computations from these data are first to ascertain the real weight of water in the pumps: the main pump being 12 inches diameter, and the injection-pump 8, the proportion of the areas of the two will be as the squares of their diameters, and their load in proportion to their height of column; therefore, as 144 : 64 :: 58 feet high : 25.7 feet; that is, the whole load of the injection-pump will be equal to 25.7 feet of the main column of 12 inches diameter; but this is, provided that the length of stroke was the same in both.

To reduce them to one, say as 7-feet stroke, or 84 inches, $\frac{75.7}{21} = \frac{67.5}{21}$ in. :: 25.7 ft. :: 20.7 feet of the column of the main pumps, say 21 feet.

Hence, the whole load consists of the main column of 12 inches diameter, and 61 fathoms or 366 feet, and the injection-pump equal to 21 feet thereof, 366 + 21 feet = 387 feet.

To obtain what Mr. Smeaton calls the great product, by which the powers of different engines can be compared, multiply the figure of the pump's diameter 144 inches $\times$ 387 feet lift = 55728, which multiplied by a 7-feet stroke = 39296, and again by 7.75 strokes per minute = 3023244, the whole product or effect of the engine, without regard to coals, or without any allowance for the weight of the pump rods, and the counterpoise of the engine.

The quantity of coals was 2 cwt. 1 qr. 211/2 lbs. = 2753 lbs. $\times$ 8 bolls = 2188 lbs. which divided by 88 lbs., the weight of a London bushel, gives 24.86 bushels consumed in the whole time of the experiment, viz. two hours and two minutes, or 122 minutes.

To find the coals for one hour's work, say as 122 minutes : 60 min. :: 24.86 bushels :: 12.2 bushels per hour.

Lastly, the whole product 3023244, divided by 12.2, gives 2474601 for the produce or effect of one bushel of coals per hour.

This engine was rebuilt according to Mr. Smeaton's plan, with the same cylinder of 52 inches and 7-feet stroke, but the pumps were enlarged to 12.2 inches diameter, and lifted in two columns each 24 fathoms 4 feet high. The injection-pump was 7 inches diameter, 5 feet 6 inches stroke, and lifted 70 feet 7 inches high.

In 1774 Mr. Smeaton tried the experiment, and found that when this new engine was working at the rate of twelve strokes per minute, 2 cwt. 1 qr. 16 lbs. of the common engine coals supplied it 22 minutes.

From this he made a similar computation to those for the former engine. Square of 12.2 inches the diameter of the main pumps 148.84; square of 7 inches the diameter of injection-pump 49; its lift 70 feet. Then say as 148.84 :: 49 :: 703 :: 23.21 feet of the main column, if the lengths of the strokes were equal; but as they are not, say as the long stroke 84 in. :: 66 in. :: 23.21 ft. :: 18.2; therefore the load of the injection-pump is equal to the load of 18.2 feet of height of the main column.

The total load then is equal to a barrel 12.2 inches diameter, twice 24 fathoms 4 feet, or 296 feet + 18 feet, viz. 314 feet lift.

To obtain the great product, multiply the square of the pump's diameter 148.84 by 314 feet; the height lifted $=$ 75.7. 46735.76,
STEAM-ENGINE.

The pump, kept in a London waterway, has 3.05 buhles of fluid in 22 minutes, during which time it worked 12 strokes per minute; it is therefore 164 strokes; then say, as 3.05 buhles : 1 buh : 86.5, the number of strokes which the engine will make for each buhle it consumes.

At every stroke the engine raises a cylinder of water, 12.2 inches diameter, 7 feet long, and weighing 354.8 lbs. 314 feet high. Multiply this 354.8 lbs. by the 86.5 strokes which the engine makes for each buhle of coals, and we have 365955, the number of pounds of water lifted 314 feet by each buhle of coals. And lastly, 365955 x 314 = 9,636,660 lbs. of water lifted one foot high with each buhle of coals.

Mr. Smeaton's Directions for making Engines. — Mr. Smeaton made his engines with a wooden bottom to the pilon, as we have before noticed. This was because wood communicates heat much less rapidly than metals. The pilon is kept much cooler than any other part to which the steam has direct access, not only from the water which is poured upon it to keep it tight, and prevent the leakage of air into the cylinder, but also because it receives the first and mott direct action of the cold injection-water; and as the steam in entering the cylinder through the pipe-plant first meets the cold surface of the pilon, it is thereby condensed in a greater degree than by an equal portion of the internal surface of the cylinder. By covering the bottom of the pilon with wood, it will receive or conduct less heat from the steam; and for the same reason, the cold water, when it is thrown upon against the pilon, will be less heated by the contact of it, the wood acting as a neutral body on the fluids, which alternately act against it.

The injection-cap, or jet, according to Mr. Smeaton, should be a square hole through a brafs plate, and rounded from the under side, that it may throw up a full bore. The middle of the jet should not be directed to strike the centre of the pilon bottom, but it should rise perpendicularly, so as to strike the pilon bottom at right angles. That part of the injection-pipe which is within the cylinder should be made of wood, or of metal, wrapped round with tarred marline, or small rope, to separate the metal of the pipe from the contact of the steam, or hot water, which not only saves the condensation of some steam, but by preventing the pipe becoming hot, that portion of injection-water which is contained in the pipe is kept cool, and the steam which afterwards flows through the pipe will enter in its coolest state. The injection-cylinder should be placed as high as the building will admit, so as to give a smartness to the jet. A pipe should be applied beyond the fitting-valve, with a cock in it, which being partially closed, the asting can be regulated, if it should be found too great, so as to emit more steam than is requisite. Mr. Smeaton also placed a small air-cock on the upper part of the education-pipe, or some other part having free communication with the cylinder, for the largest engine. This was to be only of the size of a small common beer-cock; and when the steam was properly regulated, this cock was to be opened as much as it could be, to allow the pilon to come fully down into the cylinder. We suppose this air-cock must have been found practically beneficial, or such an experimental engineer as Mr. Smeaton would have discontinued to recommend it; but we do not know on what principles the admission of air could be serviceable, unless it was to diminish the defending power of the pilon when it arrived near the bottom of the cylinder, and thus diminish that acceleration of the pilon, of which we
we have before spoken in the description of the action of the engine.

Lastly, in adjusting the engine to its work, to determine the proper degree of counter-weight, it was to be put together, and the pumps filled with water, but the buckets without the leathers, and the piston without any packing. In this state, a weight, equal to about 1 1/2 lbs. per square inch, being laid upon the piston, the engine was ballasted at either end of the beam, as it might require, until it was found in exact balance. Then, when the piston was relieved from its weight, it would have a counter-weight tending to draw it up with a force equal to 1 1/2 lbs. per square inch. This was for engines of the largest dimensions; but as the proportion of loss by friction of the piston and buckets is greater in smaller cylinders and pumps, smaller engines must have 1 lb., and the smallest engines 2 lbs. per inch. When it is not convenient to fill the pumps with water up to the top, allowance must be made for the difference of the pump-rods not being immersed.

Mr. Smeaton expected his engines, which were calculated to be loaded with a neat burden of 8 lbs. per square inch, would, with the counter-weight as above, make their returning stroke rather quicker than the working stroke, and this he preferred.

The proper proportion of the counter-weight has been a matter of much mathematical investigation by writers on the engine, particularly M. Boffut; but it depends upon so many contingent circumstances, that it would be impossible to apply any theorem to practice, even if the theory were established; and the adjutment is easily ascertained by experiment.

The design of the engineer in giving or allowing a preponderancy to the outer end of the beam, is simply that the buckets may descend, and that the piston may rise and allow the steam to fill the cylinder, without any further combination of apparatus being employed for that purpose. Now let us observe its operation, and the manner of adjusting its quantity in an engine's first fitting to work. Supply the water already up to the top of the pump; the steam being admitted into the cylinder till it has driven out the air, the operator shuts the steam-cock, without supplying any injection; and the engine will make its first stroke, though very quietly, by the external condensation from the surface of the cylinder: he then allows steam again to enter the cylinder, and according to the piston's tendency to rise, he suits his judgment to the degree of counter-weight necessary: if it rises too fast, he puts iron or other ballast upon the pump-end of the beam; and if it rises too quick, he places these weights on the piston-end. We have then two important circumstances to attend to in this regulation. First, that the pump-bucket shall descend as quick as it can, but without such force as shall occasion a violent shock to stop the motion at the end of the strokes; and secondly, that the piston shall not be drawn up faster than the steam-regulator (with the degree of opening that is given to it) can supply steam; for that would impede the discharging functions of the engine, or getting rid of the air and condensing water; and unless there are performed punctually, the engine soon ceases to work. Now neither the air nor the water can be discharged instantaneous from the cylinder, but require a certain time, in proportion to the quantity of each, and the degree of strength in the steam; and therefore the piston must not rise so quick as to prevent the steam acting on the air and condensing water, which it will do if the engine has too great a counter-weight, and the steam is low; for if the piston ascends faster than the boiler supplies steam, there can be no discharge, and after a stroke or two the engine will stop.

But this is on the supposition that the engine is working with its full intended velocity. When an engine is erected on a mine or pit which is sinking, the quantity of water to be lifted by the pump being small, the engine must work slowly, and the counter-weight must be in proportion; the beam will nevertheless require an extra counterpoise at the pump-end, because of the lightness of the pump-rods; but as the mine or pit becomes of greater depth, and successively lengths of rods are applied for the different lifts of pumps, the weight must be diminished, and at length transferred to the piston-end of the beam, in such quantity as to keep the engine under command; for as the velocity of the returning stroke depends upon the quantity of counter-weight, this must be regulated according to the quantity of water which this engine has to draw, or rather to the number of strokes the engine is to make in a minute. As this velocity is to be increased when the quantity of water increases, a greater counter-weight must be added; but it is not until the engine works at its intended load, that the counter-weight must be brought to the degree we have mentioned.

While an engine is working, as we have suppos'd, with a small portion of its full load, the injection must be very sparingly applied, so as to condense imperfectly within the cylinder, or the piston will descend with such velocity, and stroke upon the spring-beams with such violence, as to beat every thing to pieces.

When a mine is going down, and the engine-shaft receives all the water from the different parts of the mine, the quickness of the engine's stroke must depend upon the uniform influx of the water, and the engine must be accurately regulated to this quantity of water, as to stop it up at every stroke. Now if this supposing up is violent, the air will be driven into the pumps at the conclusion of every stroke, and cause the engine to work irregularly; and, on the other hand, if the strokes of the engine are not quick enough, the water will gain on the miners and prevent their working. The velocity, as we have before stated, must be regulated by the quantity of injection which will determine the motion of the stroke, and the counter-weight will regulate the time of the returning stroke: but a much better regulation of the velocity of the engine can be attained by the counterpoise, which we have before described.

Even when the engine continues to work with its full load and counter-weight, and when a proper injection is allowed to condense fully, the engine-man can retard or accelerate the returning strokes of the engine, in some degree, by the regulation of the fire; for if the engine should return too quick, he lets down the damper in the flue of the chimney; or if it is too slow, he raises the damper. By these means he can vary the action of the beam, on the lower side of the piston, from one to two pounds on the inch, greater than the pressure of the atmosphere, which in a sixty-inch cylinder will amount to 2800 pounds, and is a sufficient latitude to make the engine return very quick or very slow, but does not alter the period of the working of the stroke.

Other Improvements on Newcomen's Engine.—Mr. Smeaton's improvements on the engine, as we have flown, consisted only in proportioning its parts, but without altering anything in its principle.

In 1759, Mr. James Brindley, the engineer who designed and executed the duke of Bridgewater's canal, obtained a patent for improvements in the machinery of the fire-engine. The boiler he proposed to be made of wood and iron, with a cast-iron flue or fire-place within of it, and surrounded...

STEAM-ENGINE.
STEAM-ENGINE.

rounded on all sides, so as to give its heat to the water. The chimney was an iron pipe or tube, also immersed in the water of the boiler. This plan he expected would save a considerable portion of the fuel. The feeding-pipe for the boiler was to be made with a slack, to be opened and shut by a float upon the surface of the water in the boiler, so as to supply it with water always to the same level, without any care on the part of the engine-man. The great chains for the arches of the beam were to be of wood, and his pumps were also to be made of wooden flaves hooped together. These are all the improvements mentioned in the specification of his patent: but in the new edition of the Biographia Britannica, we are informed that, in 1756, Mr. Brindley undertook to erect a steam-engine near Newcastle-under-Lyne upon a new plan. The boiler of it was made with brick and stone, instead of iron plates, and the water was heated by internal iron flues of a peculiar construction, by which conveyances the consumption of fuel necessary for working a steam-engine was reduced one-half. He introduced also into his engine water cylinders, made in the manner of cooper's ware, instead of iron ones, the former being cheaper and more easily managed in the shafts; and he likewise substituted wood for iron in the chains which worked at the end of the beam. He had formed designs of introducing other improvements into the construction of this useful engine, but was discouraged by obstacles that were thrown in his way.

The most important improvement in the atmospheric engine was the application of it, by means of a crank and fly-wheel, to the purpose of turning mills. This was not much invention to any one who had considered the action of a foot-lathe; but it does not appear to have been put in practice till a late period, or brought into any extensive use till after Mr. Watt invented his engine. Mr. Jonathan Hulks had a patent in 1736, for working rowing-wheels at the side or head of a boat by the force of Newcomen's engine, and we believe he proposed to employ a crank, to produce the rotatory motion of his wheels.

In 1759, Mr. Keane Fitzgerald propounded, in the Philosophical Transactions, a contrivance to work the ventilator by the fire-engine, for the benefit of those who work in mines, where it is employed to draw off the air. He considered the lever of the fire-engine, which works up and down, and performs at a medium about twelve strokes in a minute, is made to turn a wheel constantly one way, and the number of strokes is also increased to fifty or sixty in a minute. The machine is described by three figures annexed to the memoir, and is considered as ingenious. It is flated that it may easily be made to turn a mill to grind corn, or a wheel to raile coals.

It is related in the Encyclopaedia Britannica, that Mr. Fitzgerald took out a patent for communicating a rotative motion from the steam-engine, but we believe this is a mistake. In the Edinburgh Review it is stated, that an atmospheric engine was employed at Hartley colliery, in Northumberland, as early as 1768, to draw coals out of a pit. It had a toothed fecker on the end of the working beam, working into a trundle, which, by means of two pinions with ratchet-wheels, produced a rotative motion in the same direction, by both the ascending and descending stroke of the arch; and by shifting the ratchet, the motion could be reversed at pleasure. This engine had no fly-wheel, and went happily and irregularly. Who the inventor was is not mentioned.

A patent was taken out in 1769 by a gentleman of the name of Stewart, for applying a steam-engine to the purpose of rotative motion, by a chain going round a pulley, and also round two bars furnished with ratchet-wheels, with a weight suspended to the free end of the chain, which served to continue the motion during the return of the engine. About the year 1778, Mr. Matthew Walbrough, of Bristol, also obtained a patent for communicating a rotative motion from the steam-engine, by a method which was virtually the same as that at Hartley's only he added a fly-wheel, which we believe was then, for the first time, employed in the steam-engine. Two or three of these engines were erected, one at his own works, for turning lathes, &c. and also one at Southampton, at Mr. Taylor's works, besides two or three for grinding corn; but, owing to the defective mode of communicating the motion, they were subject to such irregularities as rendered them of little use.

The crank, which is now the universal method of communicating the motion of the engine to machinery, was, we believe, first applied to an engine at Birmingham. This method of converting the reciprocating motion into a continuous rotatory motion, was by employing the great beam to work a crank or train of wheelwork. As the real action of the engine was confined to its working stroke, it was soon found advantageous to equalize, as nearly as could be, the power of the working and returning strokes. For this purpose, the rod which extended from the beam to the crank, and connected the engine and the mill together, and which is called the connecting rod, was made equal in weight to half the power of the engine, being made of cast-iron of large dimensions, and when the weight was not in the rod, it was placed on the beam at that end.

Suppose that by this means the engine is made to exert an equal force to turn round the crank in the ascent and descent of the connecting rod, it will remain to find some force which shall continue the motion in the interval of its change from ascending to descending, and vice versa. To accomplish this, it is necessary to connect with the crank or wheel-work a very large and heavy fly, which shall accumulate in itself the whole force of the engine during its time of action; and therefore continue the motion, and urge forward the working machinery, while the steam-engine is going through its inactive period of changing the stroke. This will be the case, provided that the refulence exerted by the machine during the whole of the working stroke of the steam-engine, under the influence of the friction of both, does not exceed the whole preulence exerted by the steam-engine during its periods of action upon the crank; and provided the momentum of the fly, arising from its weight and velocity, be sufficiently great; so that the refulence of the work, during the changing of the stroke of the steam-engine, will not make any very sensible diminution of the velocity of the fly. This is evidently possible and easy, for the fly may be made of any magnitude; and being exactly balanced round its axis, it will soon acquire any velocity conformant with the motion of the steam-engine.

During the working stroke of the engine, it is uniformly accelerated; and by its acquired momentum, it produces the movement of the mill until the engine changes, and makes its returning stroke; but in doing this, its momentum is shared with the inert matter of the steam-engine, and consequently its velocity diminished, but not entirely taken away. The weight of the connecting rod, therefore, by pressing on the crank aright during the returning stroke, increases the remaining velocity in the fly, by a quantity equal to the whole that it lost during the inactivity of the engine. This must be acknowledged to be a very important addition to the engine; and though sufficiently obvious, it is ingenious, and requires considerable rotative skill and address to make it effective.

Mr. John Steed, in 1781, had a patent for applying the crank to a steam-engine; and in the same year, the abbc
STEAM-ENGINE.

Arnal Canon of Alais, in Languedoc, entertained a thought of the same kind, and proposed it for working lighters in the inland navigations, a scheme which is now successfully practiced in America, and in this country. His brother, a major of engineers in the Austrian service, carried the proposal much farther, and applied it to manufactur- 

es; and the Austrian chamber of mines at Vienna patented the project. (See Journal Encyclopédique, 1781.) But these schemes are long posterior to Mr. Hull's patent, or to Mr. Fitzgerald's proposals, and are even later than the erection of several machines driven by steam-engines by Mefirs. Watt and Boulton.

When the more improved engines of Mr. Watt came into use, many persons tried to improve the atmospheric engines by adopting some of Mr. Watt's ideas: one of these was to employ valves to close and fill perpendicularly into a conical seat, for the alternate admission of steam and cold water into the cylinder, instead of the sliding regulator and injection- cock. Mr. George Burr, who published his Practical Coal- 

Viewers, or Engine-Builders Companion, in 1796, at Sheff 

cfield, gives drawings of such an engine, and tables for the proportions of all the parts, from which, as they contain information not given before, we have extracted the following particulars.

Mr. Curr's Table of Proportions for the Parts of Atmospheric Steam-Engines.

</table>

In all these engines, he supposes the length of the stroke to be nine feet, and that they work 8 1/2 feet stroke in common work.

In 1793, Mr. Francis Thompson had a patent for making the atmospheric engine work a double stroke, for the convenience of turning machinery by a crank; this he effected by employing two cylinders, one inverted over the other, and the piston of both connected by one rod, which passed through the bottom, or rather the top of the inverted cylinder, and was connected with the beam; by this means the cylinder acted alternately to make an up and down stroke. This never came into use, for the engine was as complicated as Mr. Watt's, without any of his advantages.

Mr. Watt's Steam-Engines.—The principle of this valuable invention will be best explained by a statement of the manner in which it originated, and the steps by which it attained its present degree of perfection.

Mr. James Watt was, in 1763, a maker of mathematical instruments at Glasgow, and being a man of a truly philosophical mind, and well conversant with all branches of science, he was in habits of associating with the most celebrated scientific men at that time in Scotland, particularly with Dr. Black, Dr. Robbuck, and Dr. Robbison, then a young philosopher. About this time he undertook to repair a working model of a steam-engine belonging to the university of Glasgow, and during this employment, observed the great loss of steam from the condensation of the cold surface of the cylinder, which we have before explained in Mr. Smeeaton's investigations, though the latter were not made till after Mr. Watt's. He observed that a great quantity of heat is contained in a very minute quantity of water, in the form of elastic steam; for when a quantity of water is heated several degrees above the boiling point in a close digester, if a hole be opened, the steam rushes out with great violence, and in three or four seconds, the heat of the remaining water is reduced to the boiling heat. If the steam be condensed, the whole of it will afford only a few drops of water; yet this small quantity, in the state of steam, carried off with it all the exced of heat from the water of the digester. Mr. Watt reasoned, that if so great a quantity of heat is contained in a certain quantity of steam, the economical use of the steam was a matter of the first importance in the improvement of the engine, more than the construction of the furnace, which had been the chief object of former efforts to improve the engine, the improvement of the application of the steam having been much neglected after it was first settled by Bighton.

The cylinder of the little model was heated when the steam was in it, so that it could not be touched by the hand; but before a vacuum could be made, it required to be cooled by the injection, and was then to be heated again by the re-entrance of the steam; this, he saw, could not happen, unless the heat was abstracted from the steam, which must occasion the condensation and waft of a considerable portion. His first enquiry was, what portion of the steam was thus wasted; but to very few experiments had been made, even upon the most essential part of the subject, that the real bulk of water, when converted into steam of a given heat, remained unknown, until he determined it by new experiments in the year 1764. The opinions which had been entertained concerning its bulk before that time were much beyond the truth, and could by no means be deduced from the very inaccurate experiments which were said to have been made. Thus
STEAM-ENGINE.

Thus furnished with data, he was enabled to ascertain that the loss of steam, in alternately heating and cooling the cylinder, was not less than three or four times as much as would fill the cylinder and work the engine. The boiling of water in an exhausted receiver at low heats, which had been discovered, we believe, by M. Coulomb, was about this time communicated to Mr. Watt; but it was neither known what these heats were, nor what progression they observed under various pressures, before he made his experiments on that subject. These experiments pointed out another defect of the common steam-engine, viz. that the injection-water thrown into the cylinder to condense the steam becoming hot, and being in a vessel exhausted of air, it produces a steam or vapour, which in part refills the preflure of the atmosphere upon the piston, and lessens the power of the engine; this might be remedied by throwing in as much water as would cool the whole vessel below the point at which water boils in vacuo; but then it would increase the fill-mentioned inconvenience, which is the destruction of steam that unavoidably happens upon attempting to fill a cold cylinder with that fluid. Others, who had constructed steam-engines, found, that as they made their exhaustion more perfect by making the cylinder colder, they increased the condensation of steam in a greater proportion than they gained power. Though it appears they were ignorant of the cause, they were so capable of the effect, that they contented themselves with causing the engine to raise a load equal to seven pounds upon the square inch of the area of the piston; whereas the preflure of the atmosphere would have raised much more, if the cylinder had been perfectly exhausted.

Mr. Watt's first attempt at the improvement of the engine was by employing a wooden cylinder, which would transmit the heat more slowly; this had some effect, but did not answer in other respects, and he was obliged to abandon it, as well as Mr. Brindley, who had before tried the same thing. He then caused his metal cylinders in a wooden case with light wood-albes; by this, and using no more injection than was absolutely necessary for the condensation, he reduced the waste almost one-half. But by using so small a quantity of cold water, the inside of the cylinder was hardly brought below the boiling temperature, and there consequently remained in it a steam of very considerable elasticity, which robbed the engine of a proportionable part of the atmospheric preflure.

It was not until the next year (1762) that Mr. Watt made his great invention of performing the condensation in a separate vessel from the cylinder. He conceived, that if a vessel, which he afterwards called the condenser, was made to communicate with the cylinder by a pipe, and filled with steam at the same time, an injection being thrown into the latter vessel would condense the steam therein, and cause a vacuum. Under these circumstances, the elasticity of the steam in the cylinder would cause it to rush into the vessel to restore the equilibrium; but this steam being condensed immediately it entered the vessel by the continuance of the injection, the vacuum would still remain, and draw off the remaining steam from the cylinder until none was left. Here then was the vacuum in the cylinder produced, without any necessity for diminishing the temperature below the boiling point. Having thus obtained the vacuum to cause the descent of the piston, the subsequent re-afcent could be obtained by cutting off the communication between the cylinder and the condenser, and admitting steam into the engine. The boiling of water in an exhausted receiver at low heats, which had been discovered, was about this time communicated to Mr. Watt; but it was not necessary to admit any fresh steam from the boiler to the condenser, as the vacuum produced therein still continued, and it would be ready to receive and condense the steam from the cylinder, as soon as the piston arrived at the top of it, ready to make another stroke.

The first difficulty which opposed itself to this beautiful chain of reasoning was, how to continue the action, and prevent the separate condensing vessel from filling with the injection-water, and also how to get rid of the air. To snift by blowing steam into the vessel, in the manner of the former engine, would have caused him as great a waste of steam from condensation, as he would have by all his discovery. He then thought of condensing without injection, simply by the application of cold water to the outside of the condenser, on Savery's first plan; and to get rid of the small quantity of water produced by the condensation of the steam, he intended to carry a pipe down from the condenser to a depth of 34 feet, from the end of which the water would run off by its gravity. But the air which is carried over by the steam would also accumulate by degrees, and could not be so easily evaporated; a small pump must then be applied to draw it off, and keep the condenser empty.

Mr. Watt at the same time conceived, that it would be very advantageous to employ the preflure or expansive force of the steam to actuate the piston in its descent, instead of the preflure of the atmosphere, as it would be more manageable than the other in its intensity. Thus was the whole discovery made in a day, and it only remained to invent the details of the mechanism to carry it into effect, and to establish by experiment the requisite proportions of the parts.

Mr. Watt's first experiment on these new ideas was to try the effect of the separate condenser; but before he had made the apparatus for the experiment, he resolved to extract the condensed water from his condenser by means of the same pump which should draw off the air, as this method would be applicable in all situations.

The first apparatus was a cylindrical vessel, fitted with a piston, which could be drawn up in it to exhaust the air therefrom. This vessel was made to communicate, by means of a long pipe half an inch in diameter, with the cylinder of the engine, which was two inches in diameter, and ten inches long. The pipe had a stop-cock, to cut off the communication at pleasure; and the cylindrical vessel, which was made of thin tin-plate, was immersed in cold water. The piston of the cylindrical vessel being pressed to the bottom to displace the contained air, was then drawn up to leave a vacuum there, and the cylinder of the engine, having its piston at the top, was filled with steam. The cock in the communicating pipe being then opened, the piston descended with a velocity, which showed that the vacuum in the cylinder was almost perfect; and he found, that when he used water in the boiler purged of air by long boiling, nothing that was very feebly inferior to the preflure of the atmosphere on the piston could hinder its coming quite down to the bottom of the cylinder. This alone was gaining a great deal; for in most engines, the remaining elasticity of the steam arising from the heated injection-water was not less than one eighth of the atmospheric preflure, and therefore took away one-eighth of the power of the engine.

Mr. Watt was so much occupied in other business, that it took him much time to complete his machine, and bring the whole to bear, so that he did not apply for his first patent until 1768, which bears date 12th Jan. 1769, and is for his method of lessening the consumption of steam and fuel in fire-engines. The specification contains the following principles.
STEAM-ENGINE.

"First. That the vessel in which the powers of steam are to be employed to work the engine, which is called the cylinder in common fire-engines, and which I call the steam-vessel, must, during the whole period that the engine is at work, be kept as hot as the steam that enters it; first, by enclosing it in a case of wood, or any other material that transmits heat slowly; secondly, by surrounding it with steam, or other heated bodies; and thirdly, by suffering neither water, nor any other substance colder than steam, to enter or touch it during that time.

"Secondly. In engines that are to be worked wholly or partially by condensation of steam, the steam is to be condensed in vessels distinct from the steam-vessels or cylinders, although occasionally communicating with them. These vessels I call condensers; and while the engines are working, these condensers ought at least to be kept as cold as the air in the neighbourhood of the engines, by applications of water, or other cold bodies.

"Thirdly. Whatever air, or other elastic vapour, is not condensed by the cold of the condenser, and may impede the working of the engine, is to be drawn out of the steam-vessels or condensers by means of pumps, wrought by the engines themselves, or otherwise.

"Fourthly. I intend, in many cases, to employ the expansive force of steam to press on the pistons, or whatever may be used instead of them, in the same manner as the prelure of the atmosphere is now employed in common fire-engines. In cases where cold water cannot be had in plenty, the engines may be wrought by the force of steam only, by discharging the steam into the open air after it has done its office.

N. B. This should not be understood to extend to any engine where the water to be raised enters the steam-vessel itself, or any vessels having an open communication with it.

"Fifthly. Where motions round an axis are required, I make the steam-vessels in form of hollow rings, or circular channels, with proper inlets and outlets for the steam, mounted on horizontal axes, like the wheels of water-mills. Within them are placed a number of valves, which suffice bodies to go round the channels in one direction only. In these steam-vessels are placed weights, so fitted to them as entirely to fill up a part or portion of their channels, yet rendered capable of moving freely in them by the means hereinafter mentioned or specified. When the steam is admitted into these vessels, between the weights and the valves, it acts equally on both, so as to raise the weights to one side of the wheel, and by the action on the valves, successively to give a circular motion to the wheel; the valves opening in the direction in which the weights are preffed, but not in the contrary one, as the steam-vessel which moves round it is supplied with steam from the boiler, and that which has performed its office may either be discharged by means of condensers, or into the open air.

"Sixthly. I intend, in some cases, to apply a degree of cold, not capable of reducing the steam to water, but of contracting it considerably, so that the engines shall be worked by the alternate expansion and contraction of the steam.

"Lastly. Instead of using water to render the piston or other parts of the engines air and steam-tight, I employ oils, wax, resinous bodies, fat of animals, quicksilver, and other metals, in their fluid state, as described.

Soon after his patent, Mr. Watt became associated with Dr. Roebuck, who established the Carron iron-works. They proposed establishing an extensive manufactury for such engines under the patent; and Mr. Watt began his first real engine of 18 inches cylinder, at Kinneil, near Borrowstounness. This was a sort of experimental engine, and was successively altered and improved till it was brought to considerable perfection. In the details of its construction, the greatest difficulty of all was in the packing of the piston, so as to be steam-tight; because Mr. Watt's principle did not admit of water being kept upon the piston to prevent the leakage, as in the old engines. He found great difficulties in procuring a cylinder sufficiently accurate, until a new method was introduced at Brunam foundry, by Mr. John Wilkinson. In the old method of boring, the instrument which performs the part of cutting the metal was guided in its progress only by the incorrect form given to the cylinder by the moulder; and though it inferred that every part of the cylinder should be circular, it gave no certainty that the cylinder would be straight. This was quite sufficient for the old engines, but Mr. Watt's engines required greater precision. Wilkinson's machine, which is described in our article CYLINDER, infures all the accuracy the subject is capable of; and if the cylinder should be cast ever so crooked, the machine will bore it straight and true.

Dr. Roebuck becoming embarrassed, from the failure of his vail undertaking in the Borrowstounness coal and salt works, was unable to prosecute the manufactury of steam-engines, and, in 1774, disposed of his interest in Mr. Watt's patent to Mr. Matthew Boulton, whose establishment at Soho, near Birmingham, was then the most complete in England, and conducted with the most spirit. A portion of the works was allotted to Mr. Watt, who erected a foundery, and the necessary works to carry his invention into effect, on a grand scale.

In consequence of the great loss of time, and the enormous expense necessary for bringing the engine to perfection, Mr. Watt was not able to produce any large engines, as specimens of his invention, until 1774; and found, from the difficulty of introducing them, that the term of his patent was likely to pass away before he should be reimbursed: he, therefore, applied to parliament for a prolongation of his term, which was granted for 21 years, by an act passed in 1775. With this encouragement, and with the advantage of Mr. Boulton's assistance in systematizing the manufacture of the parts, Mr. Watt soon produced many capital engines, which were erected in Staffordshire, Shropshire, and Warwickshire, and a small one at Stratford near London. He found it necessary to admit a small jet of injection into the condenser, and to employ an air-pump of sufficient dimensions to extract both the condensed steam and injection-water, as well as the air; for the condensation, by the application of external cold, was not sufficiently rapid, and the engine was so much improved as to afford ample for the power requisite to work the air-pump.

The condensing of the steam, by injection into the education-pipe, was an idea as early as the other kinds of condensers, and was tried in the very first engine built at Kinneil; but the other imperfections of that machine, owing to its leaks and bad workmanship, made a bad vacuum; and this being attributed to the air which came in with the injection-water, Mr. Watt diffused the injection into the condenser, until the size and expense of the tubulared condenser for large engines, made him resolve to facilitate a part of the power of the engine to convenience, and to employ larger air-pumps. In an engine at Bedworth, three air-pumps were used, two below, which were side by side, and worked by chains from each side of the beam, and a third above these two, and between them in the middle: this third one received the hot water lifted up by the other two; and by levelling the surface exposed to the prelure of the atmosphere, extracted the water with
STEAM-ENGINE.

with greater ease. In 1778 he only employed two air-pumps for the largest engine, one being double the area of the other, and in succeeding engines used only one, as a preface, which is the air-pump of Smeaton.

A sketch of one of these first engines is given in Plate IV.

Steam-Engines, fig. 4. The cylinder, and great beam, with its arch-heads and the pumps, stood in the same position as the former engines; but the cylinder, A, was smaller in proportion to the load than those before used, as it was generally loaded to 12½ pounds on the square inch. The cylinder was very accurately bored withinside, to make it straight and cylindrical, and externally it was surrounded by a second cylinder, or jacket B B, leaving a small space, G, all round between the bored or internal cylinder, and the outer jacket B.

This space, G, communicated by a large pipe, F, with the boiler, and always remained full of steam, so as to keep the cylinder, A, at the same heat with the steam, and thereby prevent any condensation within it, which would have been a much greater loss than an equal condensation from the external surface of the jacket B. The jacket, B, was furnished with a lid, C, which had a hole in the centre for the piston-rod, a, to pass through. The rod was made truly cylindrical, so that the hole could be kept steam-tight by a collar of oakum screwed round it at E. The inner cylinder, A, had a close bottom, and the jacket, B, joined to the fame, the cylinder being fitted with the piston H H, as usual; but the top of the internal cylinder, A, did not reach quite up to the lid of the jacket B, or outer cylinder; by which means the steam had always free access to the top of the piston, H, from the space, G, between the cylinders, and consequently from the boilers through F. At the bottom part of the inner cylinder there were two regulating valves, O and K, one of which, O, either admitted the steam to pass from the interface, G, between the jacket and the cylinder, through a passage, I, into the space of the interior cylinder below the piston, or shut out the steam from that space at pleasure; the other valve, K, opened or shut the end of the ejection-pipe M, which conducted to the condenser L. The condenser, L, was a close vessel, made of tin, and furnished with an air-pump N. The air-pump had valves, and a bucket, d, for exhausting the air, and drawing off the water which was produced by the condensation of the steam, along with the air which is extracted from the water in boiling, and rises with the steam. The air-pump was constructed nearly the same as a common pump, except that it had a lid or cover on the top of the barrel, to keep the pressure of the atmosphere from bearing constantly upon the bucket. The rod, d, of the bucket passed through a flapping-box in the lid, and was suspended by a chain from the great working beam of the engine. The condenser L, together with the air-pump N, were placed in a large cistern of cold water, X, situated generally under the floor of the engine-house, between the cylinder and the wall on which the beam rested, and supplied constantly with fresh cold water from a small pump worked by the engine, or the cistern was placed outside of the wall, between the wall and the pit of the pump.

The action of this engine is as follows: Suppose steam from the boiler to enter at F, and fill the space, G, between the jacket and the cylinder, and also the upper part of the cylinder above the piston. The condenser L, is exhausted of its air, by opening both valves, O and K, in the bottom of the cylinder, and allowing the steam from the space, G, to blow through it, and through the valves of the air-pump; both valves are then shut, and the external cold condenses it so as to leave a vacuum in the condenser, whilst the cylinder, A, is all the while full of steam, from the space G, both above and below the piston H: the steam-valve, O, being shut, cuts off all communication with the under side of the piston from the steam in G, or in the boiler, and at the same time the exhausting-valve, K, from the condenser is opened, when the steam rushes from the space of the cylinder A, below the piston, through the ejection-pipe M, into the vacuum of the condenser, with great violence, till it comes in contact with the cold sides of the condenser L, which is made of thin metal, and immersed in cold water. Under these circumstances the steam is immediately deprived of its heat, and reduced into water; more steam immediately rushes in from the cylinder, until it is exhausted, and makes a vacuum beneath the piston H. The steam which is above the piston ceasing to be counteracted by the steam which was below it, pretexts between the top of the piston and the bottom of the lid, C, with its whole elastic force, and causes the piston to descend to the bottom of the cylinder, carrying along with it the beam, and raising the pump-buckets at the other end. The exhausting-valve, K, is then shut, and the steam-valve, O, opened, which, allowing the steam to enter below the piston, leaves it at liberty to rise; in which case, the superior weight of the pump-rods raises the piston to the top of the cylinder, ready to commence another stroke.

The advantages that arise from this construction are:

1. The cylinder, being surrounded with the steam from the boiler, is always kept uniformly as hot as the steam itself, and is, therefore, incapable of destroying any part of the steam which should fill it, as the common engines do.

2. The condenser being kept always as cold as water can be procured, and colder than the point at which it boils in vacuo, the steam is perfectly condensed, and does not oppose the descent of the piston; it is, therefore, forced down by the full power of the steam from the boiler, which is somewhat greater than that of the atmosphere.

3. The efficacy of the steam being employed to press down the piston, instead of the prelude of the atmosphere, the air does not enter the cylinder, or cool its interior surface; and the engine is not conformed, as in the former engine, to work with its whole force, but it is only to administer steam of a proper elasticity, and we can vary the force of the engine very considerably, without losing any more fuel than that for which we obtain an effect.

When an engine of the old form is to be erected, the engineer must make an accurate estimate of the work to be performed, and must proportion his engine accordingly. He must be careful that it be fully able to execute its task; but its power must not exceed its load in any extravagant degree. This would produce a motion which is too rapid, and which, being alternately in opposite directions, would occasion jolts, which no building or machinery could withstand. Many engines have been shattered by the pump's drawing air, or a pump-rod breaking; by which accidents, the steam-piston descends with such force and rapidity, that every thing must give way. But in most operations of mining, the task of the engine increases, and it must be so constructed, at first, as to be able to bear this addition. It is very difficult to manage a common engine when it is much superior to its task; the only mode is, as we have described, by the supply of a scanty injection; and that only during a few hours each day, allowing the pit-water to accumulate during its repose. This increases the first cost of the erection, and wastes fuel; the miners are also much accommodated with water during the inaction of the engine. Mr. Watt's engine can, at all times, be exactly fitted, during the working stroke, to the load of work that then happens to be on it; it is only necessary to administer steam of a proper elasticity. At the first erection of the engine,
engine, it may be calculated equal to twice its task, supposing that the steam admitted above the piston is to be three or four pounds per square inch more elastic than the atmosphere; but when the engine is first set to work, it may be made to act with a small portion of its force, by using weaker steam; for when once the ebullition in the boiler is fairly commenced, and the whole air is expelled from all parts of the apparatus, it is evident that, by damping the fire, steam of half this elasticity may be continually supplied, and the water will continue boiling, although its temperature does not exceed 185° of Fahrenheit's thermometer. This appears, by inspecting our first table of vaporous dilution.

The method now proposed has one inconvenience; for, while the steam is weaker than the atmosphere, there is an external force tending to squeeze in the sides and bottom of the boiler, which could not be refilled in a large boiler, if the difference were considerable, and common air would rush in through every crevice of the joints of the engine. The regulation of the velocity of the engine may be produced by diminishing the passage for the steam into and out of the cylinder; for this purpose, the exhaustion-valve K, by which the steam passes away from the cylinder, may be so constructed, that its mechanism will lift it more or less high from the conical seat in which it is lodged, and consequently the passage can be enlarged or contracted at pleasure, by the distance to which the valve is drawn up. The degree of opening given to the exhaustion-valve would determine the rate at which the steam would flow off from the lower part of the cylinder to the condenser, and consequently the velocity of the descent of the piston; also the degree of opening of the other, or steam-valve, O, would determine the rate of ascent of the piston, by regulating the rate at which the steam could pass from the boiler into the lower part of the cylinder.

But to save the trouble of making the adjustment for the degree of opening of the working valves, it is better to place a separate valve in some part of the steam-pipe F, which brings the steam from the boiler to the jacket of the cylinder; then if this valve, which is called the throttle-valve, and is solely for the purpose of regulation, be partially closed, so that it will not admit steam into the jacket as fast as the descent of the piston makes room for it in the cylinder, it is evident that the steam in the top of the cylinder, and in the space of the jacket, must expand itself to fill a greater space, and thereby become more rare than before, and pref upon the piston with less force. And this mode of regulation, by diminishing the quantity of the supply of steam, rather than diminishing the elasticity in the boiler, that is, a very considerable increase of the load of the engine cannot stop its motion, although it may retard it, because the closing of the throttle-valve only diminishes the velocity of the motion, not the force which the engine is capable of exerting when moving under a still less velocity. Suppose the load is so increased as to make the engine move very slowly, it will flow through the valve into the jacket, and top of the cylinder faster than the descent of the piston will make room for it, and in consequence it will accumulate, until it has acquired the same pressure as within the boiler, or a sufficient pre pressure to overcome the resistance to the piston, and make it descend. The form of the engine represented in fig. 4, was that which Mr. Watt first employed in his single engines for pumping; and, in some cases, where atmospheric engines were altered to this plan, the old cylinder, being inverted, served for the jacket, or external cylinder, the new cylinder being little more than half the area of the old one. He afterwards adopted another form for the arrangement of the parts, in which the steam for the supply of the cylinder does not pass through the jacket, but enters from the steam-pipe through a valve immediately into the top of the cylinder; and though the jacket has a communication with the boiler, the steam admitted within it is only for the purpose of keeping up the heat, and preventing any condensation of the steam within the cylinder. In this way the jacket becomes less essential to the engine; and about the year 1778, Messrs. Boulton and Watt began to make the jackets of wrought-iron plate, about 1½ inch from the cylinder all round; and, in some cases, they laid the jacket aside, but found this an ill-judged economy, and returned to it again, as they perceived that it made a difference in the fuel.

This engine is represented in Plate IV. fig. 5. The cylinder, A A, like the former, is closed at top by the lid or cover C; but this lid is screwed to the top flange of the cylinder itself, instead of the top of the jacket, which may be omitted or not in this form, because the current of steam from the boiler, for the supply of the cylinder, does not flow through it, as in the former engine. The steam is brought from the boiler to the cylinder by the pipe F, which appears like a circle, being cut across in the direction of its length: j is the regulating or throttle-valve in that pipe, and d the communicating passage into the top of the cylinder, immediately beneath the valve, so that through this the steam has always entry into the top of the cylinder to press upon the piston, in such quantity as the opening of the regulating-valve, f, will allow. W is the steam-pipe, which defends to the bottom of the cylinder, for the purpose of establishing a communication between the top and bottom of it, when the piston is to ascend; and O is the steam-valve, which opens or shuts that communication at pleasure. F is the exhausting-valve, which being opened when the steam-valve, O, is shut, allows the steam to pass off to the condenser, which may be considered as the same which we have before described.

Suppose the piston at the top of its cylinder, and all the parts (except the exudation-pipe M, and condenser, which are vacuous) full of steam; if the valve O be shut, the exhausting-valve K, being opened, will permit the steam contained in the lower part of the cylinder to pass by its elasticity, and rush into the vacuum of the exudation-pipe and condenser; and being there condensed, the rest will follow till none remain; then the steam, flowing through the throttle-valve, and passage d, into the top of the cylinder, presses down the piston into the vacuum cylinder, until it arrives at the bottom; the exhausting-valve, K, is then shut, and at the same time the steam-valve, O, is opened by the plug-frame: this suffers the steam from the boiler to rush in and occupy that small portion of the bottom of the cylinder beneath the piston, which being filled with steam of an equal density to that above it, there will be an equal pressure on both sides of the piston; and the opening of the valve, O, having made a free communication between the top and bottom of the cylinder, the piston is at full liberty to rise by the action of its counter-weight, until it arrives at the top of the cylinder, and then the steam-valve, O, is shut, and the exhausting-valve, K, opened, to make another stroke, as before.

The sketch in fig. 2, was taken from an engine Messrs. Boulton and Watt erected at Hull, in 1779; and this, with some slight variations in the manner of its action, which we shall afterwards describe, is the present standard engine for pumping water: the variation is, that the regulating-valve, F, is made to open and shut at every stroke, and for regulation, another valve is applied in the steam-pipe just before it arrives at F.

In the two engines which we have described, the piston defends in consequence of the preasure of the steam being made...
made to act upon it whilst there is a vacuum beneath; and the ascent is made, when the piston is placed in equilibrio, by an open communication being made between the upper and lower parts of the cylinder; and this will always be an exact equilibrium, not imperfect, as in the old engine, where the varying preface of the steam and of the atmosphere always renders the circumstances in which the piston rises uncertain.

It is evident that the ascent of the piston may be as well performed in vacuo; provided the vacuum is made at the same time both above and below the piston. This form of the engine is represented in fig. 3, in which, as the same letters of reference are used, it is needless to repeat the description of the cylinder and piston. F is the valve which admits the steam to the top of the cylinder, to press upon the piston: this valve is shut when the engine makes its return or upstroke. K is the exhaust-valve, placed close beneath the steam-valve F, instead of being at the bottom of the pipe W, which descends to the condenser, and gives off a branch, I, to the bottom of the cylinder: by this pipe the steam is always drawn off from the bottom of the cylinder, to keep a constant vacuum therein. Suppose the exhausting-valve, K, open, the steam in the top of the cylinder will also pass off into the condenser through the pipe W, and leave a vacuum in the whole cylinder: in this case the piston rises freely by the counter-weight to the top of the cylinder; and being arrived there, the exhausting-valve, K, is shut, and the steam-valve, F, opened. The steam from the boiler entering into the top of the cylinder, and prefilling between the lid and the top of the piston, presses down the latter to the bottom of the cylinder, where being arrived, the steam-valve, F, is shut, to prevent the farther admission of steam from the boiler; and at the same instant, the exhausting-valve, K, being opened, the steam from the top of the cylinder presses off to the condenser, and this makes a vacuum above the piston, the fame as was before made beneath it: in consequence, the piston is left at full liberty to rise by the action of the counter-weight, until it arrives at the top; the exhausting-valve, K, is then shut, and the steam-valve, F, opened, to make a fresh descent. The advantage of this contrivance is, that the whole time of the ascent of the piston is allowed for making the condensation; but this is found of little importance in practice, because the vacuum takes place almost instantaneously, when the exhausting valve is opened, to allow the steam to pass off to the condenser.

Mr. Watt's Expansion-Engine.—This was a most important improvement, of which Mr. Watt had the first idea in 1769, but did not fully put it in practice until 1778. It consists in shutting off the farther entrance of steam from the boiler, when the piston has been pressed down in the cylinder for a certain proportion of its total descent, and then leaving the remainder of the descent to be accomplished by the expansive force of that steam which is already introduced into the cylinder. This gives the means of regulating the acting force of the engine, because the pins of the plug-frame can be placed in such a manner, as that the steam-valve shall be shut when the piston has descended one-half, one-third, one-fourth, or any other proportion; and so far the cylinder will be occupied with steam of the same elacticity as that in the boiler, which is usually about the same as the atmosphere. In order to press the piston farther down, the steam must expand; and though its elacticity will diminish, it will be enough to complete the stroke. It is plain that this can be done in any degree at pleasure, as the adjustment of the pins in the plug-frame can be varied in an instant; and according as the engine requires more or less power, to allow the steam to act with its full force upon the piston for a greater or less portion of its total descent. If this method of working an engine had no other advantage than the regulation of the power, it would not effect the end better than the throttle-valve; but by the expansive principle a great saving of steam is made. We have before observed, in describing the action of Newcomen's engine, that the motion of the piston is accelerated in its descent by the continued action of the preface of the atmosphere whilst the load is constant, or even greater at the first, considering the vis inertiae. Mr. Watt's engine is the same, but in a less degree, when it has a throttle-valve, because the steam cannot then come to the piston, except in a limited quantity; but when the top of the cylinder is opened to the boiler, or the throttle-valve fully open, the effect is the same as if the atmospheric air had free entrance into the top of the cylinder. Now by flooding the further entrance of the steam at a certain portion of the descent, the piston can be made to descend with an uniform velocity, by the expenditure of only a portion of that quantity of steam which would be required, if steam of its full density was employed to press it down to the bottom with an accelerated velocity.

But when the steam is shut off at a portion of the descent, the preface on the piston is continually diminishing as the steam becomes more and more rare; and, consequently, the accelerating force which works the engine diminishes. The motion of the descent, therefore, will no longer be uniformly accelerated; it will approach much faster to uniformity; or it may even be retarded; because, although the preface on the piston at the beginning of the stroke may exceed the refusance of the load, yet when the piston is near the bottom, diminution of the preface may occasion the refusance to exceed the preface; in this case the motion can only be continued by the momentum of the moving parts. Whatever may be the law by which the preface on the piston varies, it is possible to contrive the connecting machinery in such a way, that the chains or rods at the outer end of the beam shall continually exert the same preface to lift the pump-rods, or that the machinery shall vary its force according to any law which is found most convenient. This may be done on the same principle that the watch-maker, by the form of the fuste, transmits an equal preface to the wheel-work, from a very unequal action of the main-spring. In like manner, by making the communication from the piston to the pump-rods by means of chains, which wind upon arch-heads, formed to portions of a proper spiral instead of a circle, the force of the piston upon the beam and pump-rods can be regulated at pleasure, so as to produce an uniform effect.

This was the subject of Mr. Watt's patent, March 12, 1782, for certain improvements upon steam-engines, and certain new pieces of mechanism to be added to them. The specification of this patent, which is lodged in the Rolls chapel, states the invention to consist in shutting off the steam at a portion of the descent, as we have described, and applying and combining levers, or other contrivances, so that the unequal or decreasing action of the steam upon the piston shall produce an uniform effect in raising the water in the pump-barrels.

The action of the expansion of the steam on the piston is thus explained. Suppose the whole descent of the piston decimally divided, viz. into ten parts, and each subdivided, the varying preface of the expanding steam on the surface of the piston at each division will be according to the following table,
applied to its fullest extent, would, we think, be impracticable: we mean, when steam of great caloric preasure is employed, and when the stoppage of the supply is made to take place at a very small portion of the defcent. In this cafe, the ftrain upon the centres of the fnaifs or levers, sufficiently oblique to equalize the action, would be beyond all bounds. Lord Stanhope has applied the principle of Mr. Watt's levers, in the most judicious manner, to the printing-prefs. (See Printing.) But in fo small a machine, worked only by the strength of one man, the long call-iron frame of the press has been frequently broken.

We fuppofe it is for fuch reafons, that Meffrs. Boul- ton and Watt have not, that we know of, applied these contrivances to any of their engines, but have contented themselves with employing steam a little more than the prefire of the atmosphere, and stopping the supply at one-fourth or one-third of the defcent, according to the circumftances under which the engine works. In this cafe, the decafing prefire in a large engine is not much greater than to counteract the acceleration, and aided by the moment of the heavy working beam, pump-rods, and rifing column of water, produces nearly uniform motion. Mr. Hornfley, about 1781, had a patent for a method of applying the expafive principle of Mr. Watt in two fuccefive cylinders in fuch a manner, as to approach more nearly to an equality of force, by which item of great prefire can be employed to act by its expansion. This kind of engine, of which a defcription is to be found in Mr. Watt's Specifica- tion of 1782, has since been brought to a great degree of perfection by Mr. Woolf, as we fhall notice.

Description of Meffrs. Watt and Boulton's complete Single Engine. — Plate III. fig. 1, is taken from the engine at Chefses water-works, for pumping water for the supply of London; it was erected in 1804, and is estimated at fifty horfes' power. — We have hitherto confidered Mr. Watt's engine as being fett up with the great woofen beam, and arch-heads, chains, and pumps, the fame as the old engine. This was the form of the engine for fome years; but from 1784, when Mr. Watt invented the parallel motion for his double acting engine for turning mills, that ingenious contrivance has been applied to the pumping engines, instead of the arch-head and chains, as being more correct in its action. Also, for about fifteen years past, they have employed call-iron working beams instead of wood. A B C is the beam, which is made of call-iron instead of wood, and is composed of two large plates, of the fhape represented in the figure, put together at twelve inches dis- tance from each other, leaving a space between them, the centre or axis B paffing through the middle of both plates. The axis lies on the floor D, which is fupported by the wall E, built beneath the centre. Q is the cylinder, contained within a fteam-jacket, composed of segments frewed to- gether. F is the fteam-pipe coming from the boiler G. a b is the pilfon-rod, connected with the end, C, of the beam by links C, 6; and whilft the upper ends of the links move in the arc of a circle, with the end of the beam, the lower ends, b, are made to accommofate themselves to the vertical motion of the pilfon-rod a, by means of the rods, c, extenfing to the smaller links, d, which form a parallelogram. The motion of the parallelogram is governed by the bridge-rods, which move about a fixed centre m. The action of this contrivance is fully explained under the article Parallel Motion; and it is enough for our prefent purpofe to un- derftand, that the lower ends, b, of the links, b, C, will afcend and defend in a perpendicular right line. A similar motion, but of half the quantity, is given to the rod, R, which works the air-pump, N, of the engine at the lower end, and the middle part of the rod has the plug-beam, R, attached to it, which has pins, or chocks, lrcwed on to it to actuate the handles, x, y, and z, of the mechanifm for the valves, which mechanifm is very different from that employed in the old engines, and even from that of the first engines of Mr. Watt. But to define all the varieties which have been adopted, would occupy a volume, and afford information of but little value.

The pump-rod, p, is fuspended at the end, A, of the beam by another parallel motion, and the upper part, S, of the rod is made of call-iron, and very malleive, to have a fufficient weight in itself to draw up the pilfon, and make the return stroke. The real pump-rod, p, is joined to the heavy counter-weight S, and is polished, like the pilfon-rod a, that it may slide through a collar of leathers in the head of the pump Y, because the pump is of that kind called lifting force-pumps; its bucket rafes the water in ascen- ding, but it forces it through the air-well T, and pipe X, which leads to a refervoir two miles diftant, in Hyde Park, and elevated 150 feet above the level of the water in the well where the pump draws from. This well has a communica- tion with the river.

The cylinder, Q, is kept down by the weight of a pier of mafonry, on which it is placed, and large iron bolts, m, defcend from the lower flanch to the groundfills, upon which the mafonry is built. Immediately before the pier is the condening ciftern, M, which contains the air-pump N, the condener L, partly concealed, and hot-well g, and is kept fuppiled with cold water by the cold-water pump I, worked by the beam at the outer end, and the waftes runs oft again into the well, so as to keep the water in the ciftern always cold.

The valves, which muft be opened and shut to produce the action of the engine at four in number viz. the upper fream-valve at F, the lower fream-valve O, and the exhauffion-valve K, fig. 2, and a small valve K', beneath the water in the ciftern M, to admit the injection into the condener; but these parts are better explained in fig. 2, which is a fection of the cylinder, air-pump, and condener on a double fcale.

A, the fection of the cylinder, in which the pilfon X, moves; F, the fream-pipe coming from the hoiler; L, the condener; N, the air or difcharging-pump; m, a pallage or pipe from the pump L, to the condener N, in which the fream is an occafional communication by a hanging-valve at m, which muts towards the condener; f is the injection-valve, to be lifted by the engine at every stroke, for the purpofe of condening the fream in the condener L; c, q, and the fuffing or blowing-valve, placed outside the condening ciftern (of which M M is a fection, on purpofe to fhew the contents); the injection-valve, c, communicates with the condener by a pipe paffing through the fide of the ciftern M, and is inferted at the fide of the condener; K is the exhauffion-valve, to be lifted by the engine, and open a communication between the cylinder A and the condener L; O is the fream-valve, to be lifted by the engine, and open a communication between the lower part of the cylinder, and upper part thereof, through the fream-pipe r, which is the upper fream-valve of the fame kind, opening a pallage from the boiler to the top of the cylinder; and thence by the pipe r, and valves O, K, to all parts of the engine.

We muft now attend to the mechanifm by which the engine is made to feed itfelf, and perform its reciprocations. The valves are lifted by means of a lever applied to each, within the iron box in which it is contained, entering into an open- ing in the ftem of the valve; and afecond lever is fixed on the axis of the lever, on the outside of the box, to be connected with
with the levers and handles \(x, y, z\), which open and shut the valves. There are three separate axles, or spindles, placed parallel and above one another, and each has a handle or spindle \(x, y, z\), by which it is moved, either by the hand, to start the engine, or by the clock-s on the plug-beam \(R\), when the engine is in action. The two upper spindles, \(x\) and \(y\), have short levers projecting from them towards the cylinder; and from each of these levers a rod is suspended, with a sufficient weight, \(n\), at the lower end to turn round the spindle, each upon its axis, in that direction which will cause the handles, \(x\) and \(y\), to fly upwards. Also the lower spindle has a lever projecting from it, away from the cylinder, with a heavy weight, \(n\), fixed at the end; but this being applied, on the opposite side, to the weights of the two upper handles \(x, y\), the weight \(n\), causes the handle, \(z\), to descend. Both the axles of the lower handles, \(x, y\), have small levers, or catches, \(t\) and \(u\), which act in the hooks of a double latch, or detent, \(t, v\), which is moveable upon a centre-pin situated between the two axles. The hooks of this detent are to detain the catches of the spindles, and prevent the handles, \(y, z\), from moving by the action of their respective weights, until the detent is moved on its centre, so as to release the catches of the levers from its hooks \(t, v\). But it is evident, from fig. A, that when only one catch, \(z\), is hooked by the lower hook, \(v\), of the detent, and consequently the weight of its spindle is held up, if the other catch, \(y\), is moved by depressing its handle, \(y\), so as to raise its weight in the act of entering the hook, \(t\), of the detent, it will press the end, \(u\), of the detent forwards upon its centre, and this at the same time pressing back the hook, \(v\), at the opposite end of the detent, releases the catch, \(z\), of the lower handle, \(z\), therefrom, and the weight, \(n\), on that spindle immediately falls.

The spindle of the upper handle, \(x\), is devoted to opening and shutting the upper steam-valve \(F\), having a lever which communicates by a rod, 2, with the lever, 3, of that valve; so that by depressing down the handle \(x\), it will shut the valve \(F\). The weight \(o\), which is applied to the upper spindle, tends to lift up the handle \(x\), and open the valve \(F\); and when the upper handle, \(x\), is depressed, the valve will be shut; or when the handle is suffered to fly up by the action of its weight, it will open the valve.

The second spindle, \(y\), has a lever communicating with the lever of the exhausting-valve \(K\), by a rod 4. The weight \(o\), applied to this like the former, tends to lift up the handle \(y\), and draw open the valve; but when the handle \(y\), is depressed, the valve is shut, and in this position the catch, \(t\), is held down by the hook, \(u\), of the detent before explained, and retains the valve shut.

Lastly, the lower spindle, \(z\), is for the lower steam-valve \(O\), which is opened by the rod 14, when the handle, \(z\), is suffered to fall down, and shut when the flame is up, being held by the catch 2, and hook 3. In all these the weight tends to open the valve; but when the valve is to be kept shut, the detent holds the weight up. Now, by removing the detent, the weight falls and opens the valve in an instant.

The upper spindle has no detent to detain it; but what is equivalent is a rod, 5, jointed to that lever of the middle axis which has its weight and rod, 6, suspended from it.

The upper end of the rod, 5, is made with a loop, or long flat pin, which works a pin at the end of a lever, 6, projecting from the upper end of the axis. The consequence of this is, that while the middle axis is detained by its catch, and detent 4, to keep the exhausting-valve \(K\), shut; the lever, 6, of the upper spindle will be borne up by its pin resting in the bottom of the loop of the rod, 5, so as to keep the weight from opening the upper steam-valve \(F\), as long as the exhausting-valve is kept shut; but when the catch 4, of the middle axis is discharged, and its weight has opened the exhausting-valve, the looped rod, 5, will no longer support the lever, 6, of the upper axis, but allows its weight to descend and open the upper steam-valve; but at the same time the upper steam-valve, \(F\), is not confined to be always open when the exhausting-valve, \(K\), is open; for the upper steam-valve may be shut by depressing the upper handle \(x\), without affecting the exhausting-valve at all, because the flat, or loop, in the top of the rod, 5, allows that motion. This property must be attended to, because the action of the engine, by expansion, depends upon it. We have not before noticed the injection-valve, from which a long wire ascends, and is attached to a strap, 9, which winds upon the middle axis; therefore, when the middle handle, \(y\), flies up by its weight, it winds the strap, and opens the injection-valve at the same instant that the exhausting-valve is opened.

The injection-valve, 7, is placed to close the orifice at the end of a short curved pipe, which enters into the condenser and turns up; and the pipe has a cock in it, between the valve and the condenser, to cut off the communication, or to regulate the supply of injection when the valve is opened. This cock must be always shut when the engine is not at work, to prevent the condenser filling with water.

**Operation of the Engine.**—We will now consider the action of the engine. Suppose the fire lighted beneath the boiler \(G\); all the valves are kept shut by depressing down the two upper handles \(x\) and \(y\), and lifting up the lower one, their respective catches detaining them in those positions, until the steam is sufficiently heated, and the engine is ready to work. In the quiescent position of the engine, when it is at rest, the counter-weight always draws the piston fully at the top of its cylinder, as in the figure; the air-pump bucket will also be at the top of its barrel.

In order to prepare for setting the engine to work, all the three valves must be opened at once. This is done by relieving the spindles from their several catches, when the weights immediately open the valves. The steam enters through the valve \(F\), into the top of the cylinder, and by the pipe \(r\), through the lower steam-valve \(O\), into the bottom of the cylinder; also through the exhausting-valve \(K\), into the condenser \(L\), driving before it some air, which passes out at the snuffing-valve \(w\). At first, the coldness of the parts condenses all the steam which enters; and it is not until all the iron, with which the steam comes in contact, is heated to the temperature of boiling water, that the steam ceases to flow from the boiler in a steam, and be condensed as it arrives at the cylinder and condenser; but after this, the steam acquires the same force in the cylinder and pipes that it has in the boiler: it then occupies every cavity and crevice of the engine, and in a little while displaces all the air in the cylinder, condenser, and pipes, which passes out, and is discharged at the snuffing-valve \(w\). This valve is always covered with water in a small cistern attached to the side of the large one, to ensure its tightness. Through this valve the air is discharged by the steam, not at every stroke, as in Newcomen's engine, but only at first setting the engine to work, and this operation is called the blowing through. It is known when the cylinder and other vessels are properly heated, and the air discharged by a very smart crackling noise at that valve, like a violent decimation of guilt in the fire; this noise being occasioned by the water in the small cistern producing a sudden and rapid condensation of the suffling steam when the air is all gone.
STEAM-ENGINE.

It being known by this sign that all parts of the engine are cleared of air, all the three valves are to be shut, by pressing and holding down the two upper handles $x, y$, and lifting up the lower handle $z$, in which situation its catch, 2, will retain it. This cuts off the further supply of steam from the boiler, and also intercepts the passage of the steam from the cylinder to the condenser; and as the cold surface of the condenser still continues to condense a considerable portion of steam, there will soon be none left, and a vacuum will be formed in the condenser, while the cylinder both above and below the piston is full of steam. The vacuum in the condenser will soon become perfect from the external cold alone, though more slowly than when an injection is made.

In this state the engine is prepared for starting at a moment's notice, by the engine-man letting the two upper handles, $x$ and $y$, rise up, by their respective weights: this opens the upper steam-valve, and the exhausting and injection-valves; the former admits the steam into the top of the cylinder, to press upon the piston; while the latter allows the steam, already in the lower part of the cylinder, to flow into the vacuous condenser; and at the same instant that it opens the injection-valve, the valve is lifted at the same time with the exhausting-valve; this admits a jet of cold water into the condenser, and condenses the steam as fast as it arrives from the cylinder, so that in an instant all the steam in the lower part of the cylinder will be drawn off and condensed. The pressure of the steam on the piston being now balanced by any thing beneath the piston, it descends and draws up the pump-buckets, and columns of water in the pumps, with a velocity proportioned to the pressure of the steam, and the diameter of the piston, compared with the height of the column of water in the pumps, and the diameter of the bucket: but the piston having defended about one-third of its stroke, a check of the plug-frame, $R$, meets the upper handle $x$, and pressing it down, shuts off the steam from the boiler. That part of the handle on which the check acts becomes perpendicular when the valve is shut, the handle being bent for that purpose; and the check can therefore defend farther, and slide against the perpendicular part of the handle, which is straight, without producing any farther depression of the handle, at the same time that it keeps it down to the same point, fo as to hold the valve shut. The piston, therefore, continues its descent by the further expansion of the quantity of steam at full jet into the cylinder; but having arrived at the bottom of its stroke, a check on the opposite side of the plug-beam, $R$, seizes the middle handle, $y$, and presses it down, which pushes the rod, 4, until it shuts the exhausting-valve $K$, and also shuts the injection-valve by the stop and rod 9. When the catch, 1, of this handle, $y$, presses on the upper hook, $i$, of the detent $r$, it relieves the catch, 2, of the lower axle $z$, and then the weight, $n$, causes the handle, $z$, to fall, and pulling the rod 14, opens the lower steam-valve $O$. Let us now consider the position of the engine; the middle handle, $y$, will be held down by its catch, 1, holding in the upper hook, $i$, of the detent, $r$, as to keep the exhausting-valve, $K$, shut; and the upper steam-valve, $F$, is also kept shut, by the same means which keep it shut during the latter two-thirds of the descent of the piston.

Under these circumstances the piston is at liberty to rise by the action of the counter-weight $S$, because the opening of the lower steam-valve, $O$, has established a free communication between the top and bottom of the cylinder, and the steam in the top of the cylinder can flow through the pipe $x$, and enter the bottom of the cylinder, as far as the piston rises, by the action of the counter-weight.

When the piston has returned to within one-third of the top of the cylinder, the check of the plug-frame quits the upper handle $x$; but this handle cannot yet be thrown up by its weight to open the upper valve, because the rod, 5, from the lever of the middle axis bears up the shorter lever, 6, of the upper axis $x$; and thus the motion continues, till the piston arrives very nearly at the top of the cylinder: in this state the plug-frame then seizes the lower handle $z$, and lifting it up, shuts the lower steam-valve; and the catch, 2, of the lower axis pulling the lower hook, $d$, of the detent, moves it on its centre, so as to release the catch, 1, of the middle axis, $i$, of the detent. This being the case, the longer axis of the middle axis causes its handle, $y$, to fly up, and by the rod, 4, it opens the exhausting-valve; and by drawing the stop and rod, 9, it opens the injection-valve; at the same time the upper axis, $x$, losing the support of the rod 5, which kept it up, its weight carries up the upper handle $x$, and by pulling the rod, 2, it opens the upper steam-valve $F$.

The steam from the boiler is now admitted to press upon the upper surface of the piston, while the steam from the lower part of the cylinder beneath the piston rushes into the condenser, where being met by the cold injection, it is condensed, and makes a vacuum in the lower part of the cylinder, which brings down the piston to make another stroke.

At one-third of the descent, the plug-frame, as before, presses and holds down the upper handle $x$, to keep the upper steam-valve shut; and when the piston has arrived at the bottom, the plug-frame presses down the middle handle $y$, to shut the injection and the exhausting-valves; and in catching, this discharges the lower axis, and the weight thereof opens the lower steam-valve. The piston then rises by the counter-weight, and when at the top of its stroke, the plug-frame lifts the lower handle $z$, and shuts the lower steam-valve; and in catching, discharges the other two handles, which open the upper steam-valve, the exhausting-valve, and the injection-valve, and this produces the descent of the piston, as before.

If the air has been fully discharged from all parts of the engine by blowing through, the action of the air-pump does not begin until the injection-water and the air, which are extricated from the water in the boiler, have accumulated in some quantity in the condenser; then at every descent of the bucket, $d$, of the air-pump, it dips into the water contained in the bottom of the barrel $N$, and the water passes through the valves in the bucket; these valves shut when the bucket is drawn up, lifting all that water which is above them up to the top of the barrel, and there it is forced out through the hanging-valve $g$, into the hot-water $g$. The drawing up of the bucket at the same time makes a vacuum in the pump-barrel beneath it; and if this vacuum is more perfect than that in the condenser, with which it will be, if the condenser contains either air or steam, it will press by its elasticity upon the surface of the water in the lower part of the condenser, and force it through the hanging-valve at $m$, into the lower part of the barrel, $N$, of the air-pump; and when all the water is gone from the condenser, the air or elastic vapour which is in the condenser will follow and enter into the pump, until the space of the barrel beneath the bucket is filled equally with the condenser.

This takes place while the pump-bucket is at the top or its barrel; and on the descent of the bucket, the space beneath it is diminished, until it compresses this rarefied vapour so much, that its elasticity will be sufficient to close the hanging-valve $m$, and to lift the valves in the bucket $d$, and pass through them into the space of the barrel above the bucket; and when the bucket has descended to the very lowest, the water contained in the bottom of the barrel, not being able to escape through $m$, must pass up through the valves, and reft upon the bucket $d$. When the bucket ascends, it carries before
STEAM-ENGINE.

before it this water and air, and as it rises the space of the barrel above the bucket diminishes, and the rare vapour or air in it condenses by being crowded into less space, until at last it becomes equally dense with the atmospheric air, and then the water following it, drives it through the valve, \( g \), into the open air.

The acent of the bucket, \( d \), left a vacuum beneath it, as before, and this drew a portion of the air or vapour from the condenser into it, ready to be extracted by the next stroke. As soon as the bucket begins to return, the discharge-valve \( g \), fluids, and prevents the atmospheric air from entering into the pump. By this we see, that if the vapour in the condenser is so rare that the whole contents of the barrel of the pump will only make a few cubic inches, when reduced to become equal to the pressure of the atmosphere, this small quantity will be effectively evacuated through the discharge-valve \( g \), because the water retreating upon the bucket follows the air, and will chase every particle of it from the top of the pump, and then follow itself.

The air-pump of Mr. Watt's engine requires to be of large dimensions, and the condenser is generally of the same size, by which means the rarefaction of any elastic vapour contained in the condenser will be equal to half at every stroke; that is, the air-pump will extract half the quantity of the elastic vapour every time; because, supposing the vacuous space which the bucket of the pump leaves behind it, when it is drawn up, to be equal to the capacity of the condenser, then the vapour in the condenser must expand itself to fill a double space, by which one half of it will enter into the pump, and be drawn out by the succeeding stroke, while the other half will remain in the condenser.

The cylinder at Chelsea is four feet diameter, and eight feet stroke, and the air-pump two feet diameter, and four feet stroke: thus, their areas respectively are as one to four, and their capacities as one to eight. But it must not be considered that this large pump, full of air, is to be drawn out of the condenser at every stroke; for, as we have flated before, the vapour with which it is filled reduces itself to a small quantity before it comes to the density of atmospheric air. At first sight we should be led to conclude, that the pump affects the power of the engine, as a deduction, of as much power as the pressure of the air upon the surface of its bucket; but if we consider its construction, having a valve at \( g \) to keep off the pressire of the atmosphere, it is certain its bucket can have little weight upon the engine, until the bucket is near the highest limits of the stroke; and taking the sum of the retreat, from the commencement of the stroke to its termination, it will be found to be very little in comparison with the power of the cylinder.

An air-pump of one-eighth the capacity of the cylinder is sufficient to keep the condenser empty when it is a single engine. If a smaller air-pump were employed, it must be in action to lift out the air and water, for a greater portion of its stroke.

In fact, whatever the size of the air-pump may be, it will occasion little more resistence to the engine than from the friction of its bucket, except during the time that it has actually opened the valve, \( g \), to discharge the air or water which it contains: before that period, the resistence is only that of compressing the vapour; an operation which begins at nothing, but increases by an ascending proportion referre to that of the decrease of the pressure of the steam, when acting in the cylinder by expansion, as we have before explained.

In Mr. Watt's early engines, the air-pump and condensing eilter were placed at the outer end of the beam; and there are some reasons to prefer that mode of construction, where the building will admit of it. In this case, the pump-bucket being drawn up by the descent of the piston, the engine requires a less counter-weight than in the form just described, in which the air-pump must be wholly worked by the counter-weight. Also, it is during the descent of the piston that the action of the air-pump is most necessary; and it is possible that an engine, having the pump worked by the outer end of the beam, may make a better vacuum than when it is worked by the inner end, because there may be some, though a very slight impulse given to the remaining air of the last stroke, by the rush of steam into the condenser at the instant the steam-piston begins to descend, and the air-pump to rise; for no sooner is the exhausting-valve opened, than the steam rushes towards the condenser, and giving a momentary tendency to a plenum therein, may give a push to the air through the hanging-valve, between the pump and the condenser; and hence it is reasonable to conclude, that more air will enter the pump by this means, than if it were left to its own expansion.

It is necessary that the parts appropriated to the condensation of steam should be kept as cold as possible; and those intended for the operation, or passage of the steam, as hot as possible; hence the air or discharging pump and condenser are placed in the cylinder of cold water, which is kept constantly full by the cold-water pump, and a little running away into the well, to carry off the excess of heat; and if the injection-valve is placed low in this cylinder, it will take the water in the coldest state. The injection-valve and cock are seen in fig. 2.

As the condensing apparatus is immered in water, to be kept cold, the cylinder should, if possible, be immersed in steam, to be kept hot; for which purpose, Mr. Watt from the first used a casing or jacket round the cylinder, and also at the top and bottom: this was attended with very beneficial effects, although it enlarged the steam surface, and exposed the external jacket to a more rapid condensation than would have taken place from the surface of the cylinder itself. But to have the vacuum as perfect as possible, it is necessary that the cylinder be kept up to such a temperature, as to prevent the least condensation of the steam upon the internal surface, either above or below the piston; because, if the sides of the cylinder were to be wet, as in the common atmospheric engine, the vacuum would be vitiated, as there would be occasioned by this wetness a moisture gradually forming to steam, which the outside casing prevents, when filled with steam from the boiler, and the heat which escapes from the surface of the jacket does not impair the operation of the engine; but if it were possible to cover this outward case again, with any sort of substance which would entirely prevent the transformation of heat from the casing, it would supercede the use of the jacket altogether, and would apply with more advantage to the cylinder itself; but we do not know of any substance which will not admit this transformation more or less. Some of Messrs. Watt and Boulton's best engines we have seen surrounded by a case of polished copper, we believe outside of the jacket.

In small engines, it is common to place the cylinder within the boiler, and it must then be kept fully as hot as the steam which enters it; but this is not practicable in a large engine, nor is it advisable in any case, because the frequent repairs which the boiler requires must derange all parts of the engine.

When the jacket is used, a small copper pipe is conducted from the steam-pipe to keep it full. As the jacket of a large cylinder must be exposed to be heated or cooled less than the metal cylinder to which it is attached, the unequal expansion might break the joints; to avoid this, the jacket is made in two halves, put together in the middle of the
the length, without any other attachment than that of entering into each other for three or four inches, with a cup which is packed with hemp and tallow. The steam-pipe has a similar joint at b, fig. 2, which unites it to the box of the exhausting-valve K, and will admit of drawing out a little. 

Description of other Parts of Mr. Watt's Engine.—In the drawing (fig. 1) in our plate, the condenser is represented at one side of the air-pump, in which situation it partly conceals the pump. In fig. 2, they are put into a different position for explanation, the condenser being represented beneath the cylinder. The ejection-pipe is carried sideways from the box in which the ejection-valve is situated, so that the condenser can be placed in any situation which is convenient.

13, 13, are the catch-pins, which are firmly fixed to each end of the beam, and limit the motion of the engine by coming down to strike upon the beams of the floor D, if the engine makes too long a stroke; and pieces of cork are laid on the floor to soften the blow with which it would otherwise strike. It once happened to this engine, that the valve of the pump-bucket breaking, the engine suddenly lost its load, or resistance, which occasioned the piston to descend, and strike on the spring-beams, or floor D, for two or three successive strokes, with such violence as to break one of the beams; and at last the piston striking the bottom of the cylinder, the momentum of the beam forced down upon the rod so violently, as to bend the great piston-rod quite crooked. To prevent similar accidents, a smaller steam-pipe was added at the side of the vertical steam-pipe, communicating with the passage into the bottom of the cylinder: this pipe is kept closed by a valve; but if the engine descends so low as to strike on the spring-beam D, the catch-pin, 13, of the beam strikes a small lever 10, and by the communication wire, 11, opens the valve, and lets the steam into the lower part of the cylinder, beneath the piston, and this destroys the vacuum, so as to prevent the farther descent of the piston.

There is also a small spring-catch or detent, which tends to spring under the lever of the upper steam-valve, and prevent it from descending. This catch is held back by a second catch, which is relieved when the catch-pin strikes the lever 10, and then the first-mentioned detent, by retaining the steam-valve from being opened, prevents any danger of the engine making a repetition of the stroke while it has no load.

Boiler.—The boiler of the engine we have not mentioned before, it is set in a furnace, so as to receive the heat of the fire, and the flame passes through a long flue, which goes twice round the bottom part of the boiler, to give as much as possible of its heat to the water before it enters into the chimney. The steam-pipe, F, has a throttle-valve in it at 30, which regulates the supply of steam to the cylinder. This valve is not a conical spindle-valve, the same as the other valves of the engine, but is a circular plate of metal, made to fit the bore of the pipe, and is moveable upon an axis, which passes diametrically across the plate; and the end of the axis, where it comes to the outside, has a lever fixed on it to communicate motion to the valve, which being turned edgways in the pipe, prevents any resistance to the passage of the steam; but when turned flat across the pipe, it flows its bore; and although it is not fitted with any extraordinary care, it is sufficient to regulate the steam. This kind of throttle-valve is preferable, because it can be moved by a very slight force.

Regulator.—There is a contrivance to regulate the velocity of the engine, by a small pipe proceeding from the air-vessel of the pump; it conveys water to the lower part of a small vertical cylinder, into which a piston is fitted, and loaded with a heavy weight; then if the engine works too fast, so as to force more water into the air-vessel than the main pipes, X, will carry off, it must make a greater preflure and condensation of the air in the air-vessel, until the water is forced to run quicker through the main-pipe, and this preflure being also communicated by the small pipe to the regulating cylinder before-mentioned, causes its piston to lift the weight and rise up, and this motion is communicated by a wire to the throttle-valve, so as to close it and diminish the supply of steam; or, on the other hand, if the engine works too slow, the preflure in the air-vessel must diminish, and then the loaded piston will sink and open the throttle-valve a small quantity, to admit more steam.

It should have been mentioned before, that the weight with which the piston of this regulating cylinder is loaded, is so contrived, that it will increase in force as the piston ascends, and diminish as it descends. There are many ways of doing this, but the one adopted, in this case, is to load the piston with a very heavy cast-iron chain, some of the links of which fall upon the ground as it descends, and relieves the piston from its weight; but as it ascends, it lifts other links off the ground, and becomes more loaded, until it finds itself a place where the load will balance the preflure of the water in the air-vessel.

It is evident that, by this contrivance, the motion of the engine will at all times be so regulated, as to supply just the quantity of water desired; but this quantity can be made greater or less, by applying a greater or less weight to the piston, so that it will sink more or less into its cylinder, before it will come to an equilibrium with the preflure in the air-vessel, and will thus open the throttle-valve more or less. But when the adjustment is once made, it will keep the engine working with regularity at that velocity.

In some of the latest engines erected by M'Fers, Watt and Boulton, they have, by an ingenious movement, made the motion of this regulating piston communicate with a long screw, attached to the plug-beam, which regulates the check that flows the upper steam-valve at any required portion of the descent of the piston. By this means, although the screw is in constant motion with the plug-beam, the screw is turned so as to regulate the check on the plug, and measure out the quantity of steam which the engine shall have introduced into the cylinder at each stroke, to enable it to fulfil its task.

One of the main properties of the engine, by which it regulates itself, and provides for all its wants, that the great beauties of the invention consist. M. Behord, 80 years ago, speaking of the old engine, says: "It must be acknowledged, that this is the most wonderful of all machines, and that nothing of the works of man approaches so near to animal life. Heat is the principle of its movement: there is in its tubes a circulation, like that of the blood in the veins of animals; having valves which open and shut in proper periods, it feeds itself, evacuates such portions of its food as are useles, and draws from its own labours all which is necessary to its own sufficiency." To purify the idea, we may now say of the more perfect machine, that it has what approaches the appetite of animals, in taking that kind and quantity of food which its exigencies require, and in rejecting that which is unnecessary. But we must explain these self-regulators more fully.

Apparatus connected with the Boiler.—In order to know the exact height of the water in the boiler, two gauge-cocks are employed, one of which reaches to within a little of the height or level at which the water should stand, and another reaches a little below that level. If the water stands at the
defied height, the first-mentioned cock, being opened, will give out steam; and the other cock will emit water, in consequence of the pressure of the supercumbent steam on the surface of the water. But if water should issue from both cocks, it will be too high in the boiler; and if steam issues from both, it will be too low. This is the same contrivance which was used by Newcomen's engine; but Mr. Watt applied in his first engines a small vertical glass tube, which has a communication with the boiler by a copper pipe cemented to each end: one pipe, from the top of the glass tube, enters the boiler above the intended level of the water; and the other pipe, from the bottom of the glass tube, enters the boiler below the surface of the water. In this way, it is evident that the glass tube will always be filled with water to the same level as the water in the boiler, and may be graduated with inches, to inform the engineer when the boiler requires a supply.

Another contrivance is a pipe defending beneath the surface of the water in the boiler, when at its intended level; and in the upper end of the pipe at the top of the hole a whistle or mouth-piece is formed: then, if the water in the boiler sinks too low, the steam will issue from the pipe, and, passing through the whistle, will make such a noise as to call the engine-man to his duty, even if he should have fallen asleep. This contrivance is rendered unnecessary by a subsequent one, by which the boiler will always feed itself, exactly as fast as its evaporation of steam requires.

The boiler is kept constantly supplied with water, to repair the wane of evaporation, by means of a small pump 20, which draws hot water from the hot-well 8, and raises it to such a height, that the water will run through a pipe, shown by the dotted lines, into the cistern 14, placed over the top of the boiler, at an elevation of some feet. From this cistern a tube, 18, descends into the boiler, and terminates beneath the surface of the water therein, so as to feed the boiler with water. But as it is necessary that the water in the boiler should always be preferred at the same level, this feed-pipe is closed by a valve in the bottom of the cistern 14, which prevents the water running down into the boiler, until the level of the water subside, and shews that it requires replenishing. A crooked arm, which is attached to the side of the small cistern 14, supports the short lever 15, 16, which moves upon a centre-pin. The extremity, 16, of this lever suspends, by means of the wire 16, a flone or piece of metal, which hangs just below the surface of the water in the boiler. The wire passes through a small flussing-box in the top of the boiler, to prevent leakage. The other extremity, 15, of the lever is connected by a wire with a valve at the bottom of the cistern 14, which covers the top of the pipe 18; and this end of the lever is loaded with a sufficient weight to balance the flone in the boiler. Now it is a maxim in hydrostatics, that when a heavy body is suspended in a fluid, it looses as much of its weight as equals that of the quantity of fluid which it displaces. When the water in the boiler, therefore, is diminished, by the conveyance of part of it into steam, the upper surface of the flone will be above the fluid, and its weight will consequently be increased in proportion to the quantity of its mass that is not immersed. By this addition to its weight, the flone will overcome the balance-weight on the end, 15, of the lever, causing the extremity, 16, of the lever to descend, and in consequence, by elevating the opposite arm 15, will open the valve at the top of the pipe 18, and thus gradually introduce a quantity of water into the boiler equal to that which is carried off by evaporation. This process is continually going on, while the water is converting into steam; and it is evident that too much water can never be introduced, for as soon as the surface of the water coincides with the surface of the flone, it recovers its former weight, and the valve at the bottom of the cistern, 14, shuts the top of the pipe 18, and prevents any more water entering the boiler, until the float or body, 21, descends by the diminution of the water therein.

When the engine is flexibly at work, the flone subsides until it opens the valve to admit a regular stream of water, which will just equal the waste by evaporation; and then the operation will go on regularly, without any action of the float, until something is altered.

We have before stated, that the steam in the boiler is no stronger than the atmosphere; but there would still be great danger of the boiler's bursting, if the steam should accidentally become too strong: the boiler is, therefore, furnished with a safety-valve, which is so loaded, that its weight, added to that of the atmosphere, may exceed the pressure of the interior steam, when of a sufficient strength. As soon as the expansive force so far increases as to become dangerous to the boiler, its pressure preponderates over the pressure of the atmosphere, and the safety-valve is opened, when the steam escapes from the boiler, till its strength is sufficiently diminished; and the safety-valve shuts again, by the predominance of its pressure over that of the interior steam. By opening the safety-valve, the engine may be flopped at pleasure, and to effect this, a small rectangular lever, with equal arms, is fixed upon the float of the valve, and connected with its top. To one of these arms a chain is attached, which is conducted into the engine-house, and passes over a pulley from a horizontal to a vertical direction, so that it hangs like a bell-pull. By pulling it, the valve is opened, and the machine is flopped.

There is also another valve of safety, for the receiver of the object of the first-mentioned safety-valve: it opens internally, and is balanced by a small lever, and a sufficient weight to keep it shut, until the pressure of the steam within the boiler becomes much less than the external air, which then forces open the valve, and enters into the boiler, till the equilibrium is restored. It is evident that this valve can never be necessary so long as the engine is at work; but its use is to prevent the fuses of the boiler being crushed in by the weight of the air, when it has done work, and the steam within it cools and condenses.

Self-adjusting Damper.—By another ingenious contrivance, the boiler is made to regulate the heat of its furnace, in proportion to the quantity of steam which the cylinder draws off from it. For this purpose, a damper or iron sliding-door is fitted into the flue, just where it enters the chimney; and a chain is conducted from it, over pulleys, to any convenient situation, where the engine-man can pull it like a bell-pull, to draw up or lower down the damper, and by that means regulate the draught of air through the furnace, and the heat of the boiler.

To make the damper self-regulating, a large pipe of six or eight inches bore is fixed vertically through the top of the boiler: it is open at top and bottom, but the lower end descends nearly to the bottom of the boiler, so as to be always immersed beneath the surface of the water. Now the steam prefling on the surface of the water in the boiler, and the atmosphere prefling on the surface of the water in the open pipe, it is evident that the relative levels of the water in both will be at all times in exact proportion to the relative elasticity of the air and the steam: and if at any time the preflure of steam diminishes, by the heat of the furnace growing less, or by the engine drawing off more steam, the surface of the water in the open pipe will subside; and as there is a flone-float in this pipe, balanced in the same man
ner as the feeding-float before described, the defcent of the
flone is made to operate upon the chain of the damper, and
draw it up so as to increase the draught of the furnace, until,
by the accession of heat, the flone recovers the intended
premure, and restores the damper to its place. On the
other hand, when the premure of the flone is on the in-
crease, either from the engine being retarded or stopped,
or from the furnace burning too fast, the premure of the flone
on the surface of the water in the boiler rarifies the water in
the open pipe; and the flone-float, then rising by its balance-
weight, closes the damper, and diminishes the draught, till
the flone subsides to its deifined force. By this means, the
flone is always preferred to the flame intensity; a circum-
stance very necessary to the regularity of the motion of the
engine.

Steam-Gauge.—To ascertain the premure of flone with
a greater degree of exactitude than by the load on the sur-
face of the safety-valve, which is liable to many uncertain-
ties, Mr. Watt employs a steam-gauge, consisting of an inverted
fiphon, or bent tube, of glass or iron; one leg of which is
jointed to the steam-pipe, and the other is open to the at-
mosphere. A quantity of mercury being poured into the
tube, it will occupy the bent part which joins the two legs;
and the surface of the mercury in one leg being ex-
posed to the premure of the flone, while the external air
acts upon the other, it is evident that the difference of level
of the two surfaces will express the premure of the flone in
the height of a column of mercury.

When the tube is of glafs, this difference of level may be
seen and measured on a scale; but when an iron tube is used,
a small light wooden rod is made to float on the surface of the
mercury in the open leg, and point out the height on a
scale of inches, fixed above the tube. But in this case the divi-
sions, which are numbered for inches, must be only half
inches; because, as the mercury descends in one leg as much
as it rises in the other, the scale reads double, to shew the
difference of level.

Barometer-Gauge.—Mr. Watt has also adapted a gauge,
called a barometer, to indicate the degree of vauum in his
engines, an addition which is of important consequence to
the good performance of the engine, to the profit of the
proprietors, and the credit of the engineer; yet in many en-
gines in London, we fee this important instrument either
out of repair, or wholly laid aside.

The form of this barometer can be uniplowed without a
figure: it is a tube of glass 30 inches long, filled with mer-
curry, and applied to a scale of inches, the lower end being
immersed in a cup, in the fame manner as the common baro-
meter, or weather-glass; it is, in fact, the fame thing as a
barometer in every refept, except that the vacuum is not
made in the top of the tube, in the Torricean manner,
but by the engine. For this purpofe, a small copper tube is
conducted from the condenser, and connected to the top of the
glass tube, by which means the surface of the mercury in the
tube is relieved from the premure of the atmosphere; and
the weight of the atmosphere, which preffes upon the surface of
the mercury in the bafon, will caufe it to mount up in the
tube to a greater or lefs height, according as the vacuum is
more or lefs perfect, or as the atmosphere is more or lefs
heavy; which will be shown by a common barometer placed
at the fide of the engine barometer.

The pipe which lead from the condenser to the top of the
barometer tube must be provided with a cock, which fhould
be fhut when the engine is blowing through, to prevent the
flone entering the tube, and blowing the mercury out of it;
but the bafon for the mercury must be made large enough
to contain all the mercury, because, when the engine is not
at work, the air will leak in, and allow the mercury to de-
scend into the bafon.

It has been proposed to make the barometer in the form
of an inverted fiphon, jufi the fame as the common steam-
gauge, one leg being made to communicate with the
condenser, and the other left open to the air. In this
way, the rife of the mercury in one leg produces a corre-
sponding fall of the mercury in the other; but on this ac-
count, if the scale is applied to one leg, the divifions muft
be only half inches, that is, provided the two legs are of the
fame bore; but if they are of different bores, the scale muft
not be half, but of a proper proportion, to shew always the
difference between the level of the surface of the mercury in
the two legs.

The flone tubes may be made of glafs; but if the quickfilver
is not very pure, the alloy with which the venders of this
article adulterate it is by constant action brought to
the surface, and, together with the vapour, make the tube
fo foul, that no precision can be obtained. Iron is the best
material for both parts of the tube, which fhould be cor-
rectly of one diameter, or else the result will be erroneous,
as we have before remarked; for it is difficult to graduate a
scale by experiment in an iron tube, where the difference of
level of the mercury in the legs cannot be seen. This tube
must communicate with the condenser by a small copper pipe,
and a flop-cock be placed between the gauge and condenser.
The index in this instrument is the fame as in the steam-gauge,
that is, a light deal rod, which is put into the shorter tube; and
quickfilver being poured into it within three inches of the
end, the rod is put into the tube, and floats on the quick-
filver. It is almoft needless to remark, that the graduation
on this inftrument must be inverted with regard to that of a
fingle tube.

The barometer fhews the perfection of the vacuum, or
the premure of the atmoilphere to enter into the condenser,
whilft the steam-gauge fhews the premure of the flone to
ecape into the air. By adding the height of these two co-
 lumns together, we have the premure of the flone upon the
pifton, provided the throttle-valve is fully open, fo that
there is no obftacle to the entrance of the flone from the
boiler into the cylinder. It would be interefling to have a
fingle gauge made to express this in one: nothing would be
more easy than to have a long glafs tube bent to an inverted
fiphon, and one of the legs being connected with the steam-
pipe, and the other with the condenser, the difference of level
between the tow surfaces would at all times express the pre-
ferve on the pifton.

Counter.—In many of Mr. Watt's engines, a little ap-
paratus is attached to the beam, to afcerfin the number of
frokes the engine makes in any given time: this contrivance is
called the counter, and is a train of wheel-work, working like
clock-work, commonly attached to the beam in such a manner,
that every froke made by the engine moves one tooth, fo that
the index tells how many frokes have been made since last ex-
aminced. This is fuch that in a box, that no perfon can gain
access to it but the one entrusted with the key. When the
box is attached to the beam, the inclination of the beam caufe
the pendulum to vibrate every time the engine makes a froke,
and thus moves the counter round one tooth for every froke.
In other cafes, the box containing the counter is fixed to
the spring-beam floor, and at every froke the beam frikes a
fmall detent, and moves the counter one tooth. It was
by the account of this inftrument that Morfes, Bolton and
Watt charged their portion of the favings for working their
engines during the term of Mr. Watt's patent.

Conftitution of the Valve.—The flone and eduction-
valves are of that kind called button or conical fplindle-
valves.
STEAM-ENGINE.

values. Mr. Watt, in his first essays, employed cocks, and also lifting-valves, such as the regulator or 'steam-value' of the old engine. But he found them always lose their tightness, after a short time. This is not surprising, when we consider that they are always perfectly dry, and almost burning hot. He was therefore obliged to change them all for spindle-valve, which being truly ground, and neatly fitted in their motions at first, are not found to get out of order by any length of time. Other engineers now use them commonly in the old form of the steam-engine; where, however, there is left need for them.

The manner of constructing these valves is as follows. 

Fig. 3, represents a valve, with its seat and box; suppose it one of the steam-valves; the box is at the end of the pipe which introduces the steam, and b b is the upper part of the pipe, which communicates with the lower part of the cylinder, or with the condenser. At e e may be observed a part more faintly shaded than the surrounding parts. This is the seat of the valve, and is a brass or bell-metal ring, turned conical on the outside, so as to fit exactly into a conical part, bored out in cold iron, of the pipe b b. This ring or seat is fitted in by cement; and the cone being of a long taper, the ring fits firmly in it, especially after having been there for some time, and united by ruff. The valve itself is a strong brass plate, D D, turned conical on the edge, so as to fit the conical or inner edge of the seat. These two cones are very nicely ground into each other with emery. This conical joining is much more obtuse than the outer side of the ring e e, so that although the joint is air-tight, the two pieces do not stick closely together. The valve has a spindle or round tail, D e, which is freely moveable up and down in the hole of a cross-piece extended beneath the ring or seat e e; and on the upper side of the valve is a strong piece of metal, D G, firmly joined to it, one side of which is female, and the other side of which is inserted into a toothed rack.

A is the section of an iron axle, which turns in holes in the opposite sides of the valve-box: and one of these, where it passes quite through the side of the box, is nicely fitted by grinding, so as to be air-tight; and a stuffing of hemp, well soaked in melted tallow and rosin, is made to surround the outside of the hole, to prevent all ingress of air. The end of this axis projects a good way without the box, and carries a spanner or handle 3, which is connected by a rod with a lever, moved by the plug-frame. 

To the axis, A, is fixed a strong piece of metal, or sector, the edge of which is formed into an arc of a circle, having the axis, A, in its centre, and is cut into teeth, which work in the teeth of the rack, D G, on the valve, and lift the valve when the sector is moved. K K is a cover, which is fixed by screws to the top of the box F, and may be taken off, in order to get at the valve when it needs repairs. From this description it is easy to see, that by turning the handle 3, which is on the axis A, the sector must lift up the valve by means of its toothed rack D G, till the upper end of the rack touches the top or cover K; and turning the handle, 3, in the opposite direction, brings the valve down again to its seat.

The force requisite to lift up a large valve from its seat is very great, the valve being kept down by a pressure of the steam upon its upper surface while there is a vacuum beneath it. The valves of the Chelsea engine are nine inches diameter, and therefore contain (9 x 9 = 81 x .7854 =) 62½ square inches, and each being pressed by at least 15 lbs., makes 82½ lbs. weight to keep the valve down; and this should, if possible, be lifted in an instant, to admit the steam to pass off without delay. One method of balancing this weight is by means of a small piston, applied beneath the valve. Thus, the lower part of the pipe or box in which the valve is contained, is bored out to a short cylinder, and a piston is truly fitted therein, as shewn beneath K, fig. 2: a cover or bottom is fixed on to clothe the lower end of the short cylinder; and there is a small copper pipe from the jacket, which admits steam into the space of the short cylinder beneath its piston, while there is a vacuum in the box in which the valve is contained, and which is open to the upper surface of the piston. The axis of the valve being connected with the piston, it is evident that the action of the piston to ascend will counteract that of the valve to descend; and therefore, by apportioning the area of the piston to that of the valve, it may be made to lift with the slightest force.

Even without this contrivance, which is only applied beneath the exhausting-valve, as is seen in the section, fig. 2, Mr. Watt invented a very simple and effectual method of raising up the valves by levers. The force which holds down the valve is quite momentary; and the instant the valve is detached from its seat the pressure is over, although it has not run more than a tenth of an inch; the force is, therefore, no impediment to the engine, but would be an inconvenient labour to the man who starts and stops it.

By Mr. Watt's contrivance, the lever is put in such a position that when it begins to raise the valve, that its mechanical energy is almost infinitely great. Let fig. 3, represent the valve flint, which is supposed to have been just closed by the chock on the plug-beam in its deficient coming in contact with the handle x, and depressing it, which is moveable with the axis X: on this same axis is another arm, X 2, connected by a joint with the leading rod 2 3, which is connected also by a joint with the lever 3 A, fixed on the axis, A, of the sector, contained within the valve-box. Therefore, when the chock of the plug-beam depresses the handle x, and turns the arm, X 2, round upon its centre, it pushes up the lever, 3 A, by means of the connecting rod, until the valve is closed, as shewn in fig. 3. At that time, the rod 2 3, and the arm, X 2, of the lever, are in one straight line, while the lever 3 A, (on the axis of the sector,) is at right angles to rod 2 3, which moves it; consequently the rod is acting with its greatest power to turn the axis A, upon which the fector is fixed. In this situation the valve is kept closed by the catch or detent before explained, which holds down the handle x, until it is wanted to be opened; the plug-beam then, by lifting the lower handle, releases the catch, and the weight, x, applied to the axis turns it round into the position of the dotted lines, and the lever, X 2, draws the rod 2 3, and, by depressing the lever 3 A, as before the valve.

From this arrangement, the intelligent mechanic will perceive that, in this position, the force exerted by lever X 2 is extremely great to pull down the rod 2 3; and, at the same time, another great advantage arises from this disposition of the levers, which is, that any prehure, however strong, applied upon the valve to open it, would be ineffectual, as that force would be exerted to turn the lever X 2 endways, in the direction of the axis X, instead of turning it round, as shewn by the figure, which represents the valve flint, and retained in that position by the lever X 2.

Construction of the Piston.—In Mr. Watt's first attempt, the greatest difficulty which he encountered was to make the great piston tight. The old and effectual method, by water lying on it, was inadmissible. He was therefore obliged to have his cylinders most nicely bored, perfectly cylindrical, and finely polished; and he made numberless trials of different soft substances for packing his piston, which should be tight without enormous friction, and long remain so, in a situation perfectly dry, and hot almost to burning.

After many trials, he settled the form of the packing which is now universally employed. The piston has a projecting rim at
STEAM-ENGINE.

at bottom, which is fitted as accurately to the cylinder as it can be, to leave it at full liberty to rise and fall through the whole length. The part of the piston immediately above this is about two inches less all round than the cylinder, to leave a circular groove or channel, into which the hemp, or soft rope which is called gasket, is rammed, to form the packing; then, to keep the packing in its place, a lid or cover is put over the top of the piston, with a ring or projecting part, which enters into the circular groove for the packing, and pressing upon it, the plate is forced down by screws. The lower part of the groove round the piston being made rounding, with a curve, this prelude on the packing forces it against the inside forlace of the cylinder. The piston must be kept supplied with melted grease; for which purpose a funnel is fixed on the top of the cylinder, with a cock and pipe to let the grease down. The stuffing-box in the top of the cylinder, round the piston-rod, is packed with hemp in a similar manner, a collar, with a hole through it for the passage of the rod, being screwed down, to confine the packing in its place.

After all that has been done in this respect, it is probable that the greatest part of the waste of steam which we still perceive in engines, arises from the unavoidable escape by the fides of the piston during its deficient. If the piston is packed too tight as totally to prevent the loss, the friction is so increased as to fully outweigh the saving. But it is a fortunate circumstance, that the performance of Mr. Watt's engine is not immediately destroyed, nor, indeed, sensibly diminished, by a small want of tightness in the piston. In the atmospheric engine, if air enters in this way, it immediately puts at ftrap to the work; but in the new engine, although even a considerable quantity of steam escape past the piston during its deficient, the rapidity of condensation is such, that the diminution of pressure is not considerable, and the waste of steam is the greatest inconvenience.

A great many schemes have been since tried to make better methods of packing a piston, but none of them have been brought into use, except the metallic expanding piston, which was proposed by Mr. Cartwright, as we shall notice in describing his engine. Something of the same kind, but not for steam-engines, is to be found in Leopold's Theatrum Machinarum Hydraulicum, 1724.

The actual Performance of Mr. Watt's Engine with respect to Coals.—At the first establishment of their engines, Meflrs. Boulton and Watt charged their profits in proportion to the saving of fuel which their engine made, when compared with a common engine burning the same kind of coals. They had one-third of these savings paid them annually, or the payment was redeemed at ten years' purchase. It should be observed, that Mr. Smeaton's improvements were introduced about the same time as Mr. Watt's, and therefore the comparison was not with his engines, but with the former ones. It was Mr. Smeaton's rule, judging from some experiments made before him on some of Mr. Watt's early engines, to ellimate Mr. Watt's engine at one-half the consumption of fuel as his own for the same work, in large engines, or a full greater proportion in small engines, because the waste of steam is greater, and he reckoned his own at only one-half of the common engines, as he found them; therefore, Mr. Watt's will be four times as great in effect as the common engines.

As early as 1776, when Mr. Watt first established his engine, we find his proposals, deduced from experiment, whole length, 500,000 cubic feet of water one foot high with one cwt. of coals. He afterwards adopted the denomination of the number of pounds of water which could be lifted one foot high by a bushel of coals as the scale for engines; if we reduce this to the latter term, it will be 24½ millions. Thus, 500,000 cubic feet × 62.5 lbs. the weight of a cubic foot of water, = 31,250,000 lbs. of water raised by 112 lbs. of coal. They say, as 112 lbs. : 31,250,000 lbs. :: 88 lbs. the weight of a bushel of coals, to 24,553,571, the number of pounds of water which will be lifted one foot high with one bushel of coals. Mr. Watt was at that time in expectation of making a great improvement by adopting his expansive method.

Mr. Smeaton, who was defirous of promoting Mr. Watt's discovery, made an experiment in 1778, on an engine on the Birmingham canal, for returning into the refervoir the water let down by the passage of boats through the locks.

The working cylinder was 20 inches, and the pump also 20 inches, lifting 27 feet, at the rate of 11 strokes per minute, of 5 feet 9 inches length each. It worked for an hour with 65 lbs. of Wednesbury coals.

When reduced, this experiment gives about 18 millions lifted one foot by a bushel of coals. Thus, the area of the pump is (20 × 20 = 400 × 7.854 = ) 314 square inches, X .434 lbs. = 136.27 lbs. weight for every foot in height, X 27 feet = 3679 lbs. the total weight of the column. The motion per minute is 634 feet (11 strokes of 5 ft. 9 in. each), or 379 feet per hour, X 3679 lbs. = 13,601,805 lbs. raised 1 foot high per hour. The coals consumed in the hour was 65 lbs.; therefore say, as 65 lbs.; 13,601,805 lbs. :: 88 lbs.; 18,903,156 lbs. raised one foot high with each bushel of coals of 88 lbs.; load on the piston 27 ft. of water, or (27 ÷ 400) = .0678 lbs. per square inch.

When the engines were made to work with the expansion, they were enabled to raise as much as 30,000,000 lbs., but this is when the engines are of the belt construction, and working under every advantage of the parts being tight and in the belt order; for these circumstances, when neglected, as they usually are by the engine-keepers, make a most material difference in the result.

In the great scale of practical operations this nicety of management cannot be expected; and accordingly, from reports on the engines now working on the mines in Cornwall, which, with the exception of a few of Woolf's engines, are all on Mr. Watt's principle, and most of them constructed by Meflrs. Boulton and Watt, taking the average of nine engines, haul, good, and indifferent together, they were found in August, 1811, to raise only 13,500,000 lbs. one foot high for each bushel of coals which they consumed.

But when it was known by the engine-keepers that their engines were under examination, they took so much pains to improve the effects, that by gradual increase, the engines, in 1815, lifted 21,500,000 lbs. taking the average of 33 engines. This information we obtain from the monthly reports of the engines which are working for draining the mines; these were began in the year 1811, by the agreement of a number of respectable proprietors of the valuable tin and copper mines in Cornwall, who resolved to have ascertained the real work which their respective steam-engines were performing, as it was suspected some of them were not doing duey adequate to the consumption of fuel; and for the greater certainty of attaining their object, it was agreed that a counter should be attached to each engine, and all the engines be put under the superintendence of some respectable and competent engineer, who should report monthly the following particulars in columns viz. the name of the mine; the size of the working cylinder; whether working single or double; the load per square inch upon the piston; length of the stroke in the cylinder; the number of pump-lifts; the depth in fathoms of each lift; diameter of pumps in inches; time during which they worked; consumption of coals in bushels during that time; number of strokes during the time; length of stroke in the pump; load upon the whole area of the piston in pounds; pounds lifted
STEAM-ENGINE.

I employ the steam after it has acted in the first vessel to operate a second time in the other, by permitting it to expand itself, which I do by connecting the vessels together, and forming proper channels and apertures, whereby the steam shall occasionally go in and out of the said vessels. Thirdly: I condense the steam, by causing it to pass in contact with metallic surfaces, while water is applied to the opposite side. Fourthly: To discharge the engine of the water used to condense the steam, I suspend a column of water in a tube or vessel constructed for that purpose, on the principles of the barometer, the upper end having open communication with the steam-vessels, and the lower end being immered in a vessel of water. Fifthly: To discharge the air which enters the steam-vessels with the condensing water or otherwise, I introduce it into a separate vessel, whence it is protruded by the admission of steam. Sixthly: That the condensed vapour shall not remain in the steam-vessel in which the steam is condensed, I collect it into another vessel, which has open communication with the steam-vessels, and the water in the mine, resort, or river.

"Lastly, in cases where the atmosphere is to be employed to act on the piston, I use a piston so constructed as to admit steam round its periphery, and in contact with the sides of the steam-vessel, thereby to prevent the external air from entering in between the piston and the sides of the steam-vessel.

The following is a description of this engine by the inventor, as it was published in the Encyclopaedia Britannica. Let A and B (Plate V, fig. 1) represent two cylinders, of which A is the largest; a piston moves in each, having their rods, C and D, moving through collars at E and F. These cylinders may be supplied with steam from the boiler by means of the square pipe G, which has a flange to connect it with the rest of the steam-pipe. This square part is represented as branching off to both cylinders: c and d are two cocks, which have handles and tumblers as usual, worked by the plug-beam W. On the fore-side of the cylinders (that is the side next the eye) is represented another communicating pipe, whose section is also square, or rectangular, having also two cocks a, b. The pipe Y immediately under the cock b, establishes a communication between the upper and lower parts of the small cylinder B, by opening the cock b. There is a similar pipe on the other side of the cylinder A, immediately under the cock d.

When the cocks c and a are open, and the cocks b and d are shut, the steam from the boiler has free admission into the upper part of the small cylinder B, and the steam from the lower part of B has free admission into the upper part of the great cylinder A, but the upper part of each cylinder has no communication with its lower part.

From the bottom of the great cylinder proceeds the education-pipe K, having a valve at its opening into the cylinder; it then bends downward, and is connected with the conical condenser L. The condenser is fixed on a hollow box M, on which stand the pumps N and O, for extracting the air and water, which last runs along the trough T, into a cistern U, from which it is raised by the pump V, for re-cranking the boiler, being already nearly boiling hot. Immediately under the condenser there is a spigot-valve, at S, over which is a small jet-pipe, reaching to the bend of the education-pipe K. The whole of the condensing apparatus is contained in a cistern, R, of cold water; a small pipe, P, comes from the side of the condenser, and terminates on the bottom of the trough T, and is there covered with a valve, Q, which is kept tight by the water that is always running over it.

M.

Lately,
STEAM-ENGINE.

Lastly, the pump-rods, X, cause the outer end of the beam to preponderate, so that the quiescent portion of the beam is represented in the figure, the piftons being at the top of the cylinders.

Suppose all the cocks open, and steam coming in copiously from the boiler, and no condensation going on. L., the beam must drive out all the air, and at last follow it through the valve Q. Now shut the cocks b and d, and open the valve, S, of the condenser; the condensation will immediately commence, and draw off the steam from the lower part of the great cylinder. There is now no pressure on the under side of the piston of the great cylinder A, and it immediately descends. The communication, Y, between the lower part of the small cylinder B, and the upper part of the great cylinder A, being open, the steam will go from the lower part of B, into the space left by the descent of the piston of A. It must, therefore, expand, and its elasticity must diminish, and will no longer balance the pressure of the steam coming from the boiler, and preffing above the piston of B.

This piston, therefore, if not withheld by the beam, would descend till it came in equilibrio, from having steam of equal density above and below it. But it cannot descend so far; for the cylinder A is larger than B, and the arch of the beam, at which the great piston is suspeded, is no longer than the arm which supports the piston of B; therefore, when the piston of B has descended as far as the beam will permit it, the steam between the two piftons occupies a larger space than it did when both pistons were at the top of their cylinders, and its density diminishes as its bulk increases. The steam beneath the small piston is, therefore, not a balance for the steam on the upper side of the frame, and the piston B will act to depress the beam with all the difference of these pressures.

The flightest view of the subject must shew the reader, that as the pistons descend, the steam that is between them will grow continually rarer and less elastic, and that both pistons will draw the beam downwards. Suppose now, that each one had reached the bottom of its cylinder, shut the cock a, and the eduction-valve at the bottom of A; the condensation will again operate, and cause the piftons to descend; and thus the operation may be repeated as long as steam is supplied; and once full of the cylinder B, of ordinary steam, is expended during each working stroke.

The piftons of this engine are composed of two flat circular plates, ground very true to each other, and one of them turns round on a pin through their centres; each is pierced with three fectorial apertures, exactly corresponding with each other, and occupying a little less than one-half of their surfaces. By turning the moveable plate so that the apertures coincide, a large passage is opened for the steam; and by turning it so that the solid part of the one covers the aperture of the other, the cock is shut. Such regulators are now very common in the cast-iron boxes for warning rooms.

Mr. Hornblower's contrivance for making the collars for the piston-rods air-tight, is this; the collar is in fact two, placed at a small distance from each other; and a small pipe, branching off from the steam-pipe, communicates with the space between the collars. This steam being a little stronger than the atmosphere, effectually prevents the air from penetrating through the upper collar; and though a little steam should get through the lower collar into the cylinder A, it can do no harm. The manner of making this stuffing-box is as follows: on the top of the cylinder is a box to contain something soft, yet pretty close, to embrace the piston-rod in its motion up and down; and this is usually a fort of plated rope of white yarn, nicely laid in, and rammed down gently, occupying about a third of its depth; upon that is placed a fort of tripod, having a flat ring of brass for its upper, and another for its lower part; and these rings are in breadth equal to the space between the piston-rod and the side of the box. This compound ring, being put on over the end of the piston-rod, another quantity of this rope is to be put upon it, and gently rammed as before; then there is a hollow space left between these two packings, and that space is to be supplied with strong steam from the boiler. Thus is the packing about the piston-rod kept in such a state as to prevent the air from entering the cylinder when at any time there may be a partial vacuum above the piston.

Mr. Hornblower's description of this engine was followed by a mathematical investigation of the principles of its action, by the ingenious professor Robison, which demonstrates that it is the same thing in effect as Mr. Watt's expansion-engine; but though this is true, there is a considerable difference in the slips by which the effect is attained, which gives an important advantage when it is reduced to practice. We shall give an investigation in a more popular form, using only common arithmetic. Mr. Hornblower assumed, that the power or preffure of steam is invariably as the space into which the steam is expanded; this is the case with air, and for the present we shall grant it to be so with steam, and reason from the same data as the ingenious inventor gives us.

To explain clearly what passes in the two cylinders, we must deviate from the precise form of the engine, and divest ourselves of one complication of ideas, by reducing both cylinders to the fame stroke; therefore, suppose the engine to be made like fig. 2, which represents the two cylinders placed one upon the other, the lower one being double the capacity of the upper one, and both pistons being attached to the same rod, which may be applied to the end of the beam, so that the descent of the pistons must draw up the load at the opposite end of the beam.

Then, if we suppose the small piston to be 10 inches in diameter, the great piston must be 14.14 inches; and to avoid all difficulties of the ratio of the expansion, and the preffure of steam, we will suppose the engine to be worked by the preffure of atmospheric air instead of steam; and for the convenience of round numbers in our calculation, we will consider the preffure at only 10 lbs. per circular inch on the surface of the piston.

The area of the small piston will be 100 circular inches, and being assumed to move without friction, the preffure upon it will be 10 x 100 = 1000 lbs. The area of the great piston is twice as much, or 200 circular inches, and the preffure 2000 lbs. Suppose both pistons to be at the top of their respective cylinders; let the atmospheric air be admitted to press freely upon the upper surface of the small piston; and suppose
pose the space between the two pistons filled with air of the same density, while there is a perfect vacuum made in the lower part of the great cylinder, beneath its piston.

Under these circumstances, the two pistons will begin to descend with something less than 2000 lbs. of load upon the outer end of the beam, because there are 2000 lbs. of preface on the great piston by the air contained in the space between the two pistons, bearing on the 200 inches of surface with a weight of 10 lbs. per inch; and beneath this piston there is nothing to counteract the preface. At the same time, the small piston, having air of equal density above and below it, is in equilibrium.

This force would balance a load of 2000 lbs.; but suppose we diminish the load to 1900 lbs., then the pistons will immediately begin to descend; but they will soon flop, because the air between the two pistons must expand itself, to fill the increasing space occasioned by the equal descent of both pistons in the cylinders, one of which is twice the area of the other; and as the air becomes rarer, its preface on the great piston must diminish. Now as this same diminution occasions the small piston to have a power of descent, we will first consider the pistons separately, and then conjointly, in their power of descent, with which they draw down the beam.

STEAM-ENGINE.

Now let us consider how Mr. Watt's principle of expansion would operate in the same circumstances; that is, in a cylinder of 14.14 inches diameter; which is to be supplied with air of 10 lbs. pressure per circular inch, until it has completed one-half of its deficit, and leaving the remainder of the deficit to be accomplished by the expansion of the air already contained in the upper half of the cylinder.

\[
\begin{align*}
\text{At the beginning, the power of deficient will be} & \quad 2000 \\
\text{At one-fourth, the power will fill be} & \quad - \\
\text{At one-half, the power will be} & \quad - \\
\text{At three-fourths of the deficient, the power will be} & \quad \{1333\} \\
\text{diminished to} & \quad - \\
\text{Because the air must occupy one-fourth of the length of} & \\
\text{the cylinder, in addition to that half of the cylinder which} & \quad \text{it occupied before the expansion began; therefore the} \\
\text{space is one and a half times the former, or as three to} & \quad \text{two, and the preffure will be two-thirds of 2000}. \\
\text{At the bottom the preffure will be} & \quad -1000 \\
\text{Because the air is expanded to occupy twice the space it} & \quad \text{filled before.} \\
\text{fills} & \quad 833.3 \\
\end{align*}
\]

The sum total is very nearly the same as the former, but both are greater than they should be, from the imperfect manner in which we have been obliged to make our calculation, so as to express it in common arithmetic, without having recourse to fluxions, which is the only method of treating quantities that are constantly increasing or decreasing by any given law.

The source of the inaccuracy is easily explained: at first we let out with the preffure at 2000 lbs. in Mr. Hornblower's engine, and did not take into the account that it decreases at all, until the piston has descended to one-fourth, but reasoned as though it diminished all at once at that place; whereas it began to diminish from the very first Starting. Here then we have taken a small quantity too much. In the same manner, our process takes no notice of the diminution which happens between one-fourth and one-half of the deficient, or between the other points at which we have chosen to examine it; the result is, as if the diminution took place suddenly at each of those points. The remedy for this would have been to have taken the account at a greater number of places, as it is by fluxions alone that we can take an infinite number, so as to obtain a true result. Now in the second calculation of Mr. Watt's expansion-engine, we have taken a still less number of steps for the consideration of the expansion, because, although there are four steps in the process, two of them are before the expansion begins.

This is the reason of the apparent difference; for in reality there is none in the sum total of the varying powers exerted through the whole stroke, as will appear to any person who will take the trouble to read professor Robison's investigation. But if we consider the difference of the manner in which the whole power is expended during the stroke, we shall see great reason to prefer Mr. Hornblower's method, from the much greater uniformity of the action; it begins at 2000, and ends at 1500; whilst Mr. Watt's begins at 2000, and ends at 1000: hence the necessity of those ingenious contrivances for equalizing the action in Mr. Watt's patent of 1782.

Mr. Hornblower's is not uniform, but approaches uniformity more nearly, so that he could have carried the effect of the expansive principle much farther, in employing stronger steam, than we believe he ever proposed to do.

We have been thus full upon this subject, because the gaining more power by the expansion of air or steam acting in double cylinders, has been a favourite idea with many, and there are no less than five different patents for it, but several of these have been upon mistaken notions; neither Mr. Watt's nor Mr. Hornblower's can have any advantage from flattening off the air, or from a double cylinder, when air is used to press the piston nor could they gain any advantage from the expansion of steam in their engines, if the preffure of it was inversely as the space it occupies.

The advantage of the expansive principle arises wholly from a peculiar property of steam, by which, when suffered to expand itself to fill a greater space, it decreases in preffure or elastic force by a certain law, which is not fully laid down; that is, the relation between its expansive force and the space which it occupies is not clearly decided: but Mr. Woolf has found that, by applying these properties in their fullest extent to the double cylinder engine, he can make most important improvements in the effects which can be obtained from any given quantity of fuel. Steam is a fluid to different from air, as to have no one property in common with it, except elasticity. This elasticity is wholly derived from the quantity of heat which it contains, and its force increases and diminishes with the quantity of heat; but by what law it increases or diminishes we are uncertain, because we have no measure of the actual quantity of heat which is contained in steam of any given elastic force. All we know with certainty is what is stated in our table of expansion, viz. that water, being converted into steam, and condensed in a close vessel, when heated until the thermometer indicates a certain temperature, will have a certain preffure or elastic force. But here we must observe, that the thermometer indicates only the intensity of the heat, without affording a direct measure of its quantity. When steam is suffered to expand itself into any given space, the quantity of rarefied water which will be found to be contained in any given bulk of steam, in its expanded state, must be undoubtedly proportioned to the quantity of water contained in the same bulk of steam, before the expansion took place, in the inverse ratio of the space which it originally occupied, and that space which it fills when expanded; but we cannot say that this is the case with heat; and it is the quantity of heat alone which determines the elastic force.

We believe that in practice Mr. Hornblower was not able to obtain any greater effect from the application of the expansive action in two cylinders, than Mr. Watt did in one cylinder. In 1791-2, he erected an engine in Cornwall, at Tin-Croft mine, of which the large cylinder was 27 inches diameter, and worked with a stroke of eight feet long, and the small cylinder 21 inches diameter, working with a six-feet stroke. The only account we have been able to obtain of the performance of this engine, is from a pamphlet published by Thomas Wilson, an agent of Melfiae. Boulton and Watt, professedly with a view to prevent the introduction of Mr. Hornblower's engines into that country, in which he makes it appear, that it raised only 14,222,120 lbs. of water one foot high with each bushel of coal.

In Mr. Hornblower's own account of his engine, in Gregory's Mechanics, he informs us, that "an engine was erected in the vicinity of Bath, some years since, on this principle, and under very disadvantageous circumstances. The engine had its cylinders 19 inches and 24 inches diametar, with lengths of stroke in each suitable to the occasion: viz. 6 feet and 8 feet respectively. The condensing apparatus was very bad, through a fear of infringement on Mr. Watt's patent; and the greatest degree
of vacuum which could be obtained, was no more than 27 inches of mercury. The engine worked four lifts of pumps to the depth of 576 feet, 4500 lbs. 14 strokes in a minute, 6 feet each, with a cylinder 6 feet long, and 19 inches diameter, with a great deal of inertia and friction in the rods and buckets; some of the latter of which were not more than 3/4 inches diameter; and this it did, under all these disadvantageous circumstances, with 70 lbs. of coal (light coal) per hour."

To reduce this to the standard of one foot high, we must put the load 4500 lbs. \times 6\text{ feet stroke} = 27,000 lbs. which the engine raised one foot high at every stroke; 27,000 lbs. \times 14\text{ strokes per minute} = 378,000 lbs. raised one foot high each minute; 378,000 lbs. \times 60 = 22,680,000 lbs. raised one foot high per hour, or with 70 lbs. of coal. As the coals are fitted to be light, we will take them at only 84 lbs. per bushel, instead of 88 lbs. as Mr. Siemens did, and say as 70 lbs. = 22,680,000 lbs. = 27,240,000 lbs. of water raised one foot high with a bushel of coals, which is a very good performance, but not greater than Mr. Watt's.

In this engine, Mr. Hornblower says that two remarkable circumstances presented themselves to the advantage of this application of the principle: the one was, that the man who attended the engine would sometimes detach the smaller cylinder from the beam, and work only with the large one, and then the boiler would scarcely raise the steam enough to keep the engine going; but no former was the small cylinder-rod attached to the beam, than the engine resumed its wonted activity, and the steam would blow up the safety-valve.

The next circumstance, that is, when the detent, which kept the exhausting-valve shut, happened to miss its action, the piston would be checked, as it were, not being permitted to rise through the whole of the returning stroke; and it would, by an instructive nature, come down again and again, until the detent performed its office, which is a practical argument for the power of the engine at the termination of its stroke.

In 1792, Mr. Hornblower made application to parliament for an extension of the term of his patent, but it was not granted; and he was prosecuted by Mellor, Boulton and Watt for infringement on their patent in using the condenser and air-pump. We believe none of these engines have been erected since the expiration of Mr. Watt's patent in 1800, until Mr. Woolf took up the subject of double-cylinder engines.

**Mr. Woolf's Double-Cylinder Expansion-Engine.**—In 1834 Mr. Arthur Woolf had a patent for improvements in steam-engines. The specification of his invention states, that he has ascertained by actual experiment, and reduced to practice, the following particulars respecting the expansibility of steam. That, in practice it is found that steam, acting with the expansive force of four pounds-preteriore square inch against a safety-valve exposed to the atmosphere, is capable of expanding itself to four times the volume it then occupies, and still to be equal to the preffure of the atmosphere: that, in like manner, steam of the force of five pounds the square inch, can expand itself to five times its volume; and that mallees or quantities of steam of the like expansive force of fix, seven, eight, nine, or ten pounds preteriore square inch, can expand to fix, seven, eight, nine, or ten times their volume, and still be respectively equal to the atmosphere, or capable of producing a sufficient action against the piston of a steam-engine, to cause the same to rise in the atmospheric engine of Newcomen with a counterpoise, or to be carried into the vacuum state of the cylinder of the improved engine, first brought into effect by Mr. Watt; that this ratio is progressive, and nearly, if not entirely, uniform; so that steam preffuring with the expansive force of 20, 30, 40, or 50 pounds the square inch against a common safety-valve, will expand itself to 20, 30, 40, or 50 times its volume; and that generally, as to all the intermediate or higher degrees of elastic force, the number of times which steam of any temperature and force can expand itself, is nearly the same as the number of pounds it is able to sustain on a square inch exposed to the common atmospheric counter-preffure; provided always, that the space, place, or vessel, in which it is allowed to expand itself, be kept at the same temperature as that of the steam, before it is allowed room to expand.

Respecting the different degrees of temperature required to bring steam to, and maintain it at, different expansive forces above the weight of the atmosphere, Mr. Woolf states that he has found by actual experiment, setting out from the boiling point of water, or 212° of Fahrenheit, at which degree steam of water is only equal to the preffure of the atmosphere; that, in order to give an increased elastic force equal to five pounds on each square inch, the temperature must be raised to about 227 1/2°, when it will have acquired a power to expand itself to five times its volume, and still be equal to the atmosphere, and capable of being applied as such in the working of steam-engines, according to its invention. Various other pressures, temperatures, and expansive forces of steam, are shewn in the following table.
STEAM-ENGINE.

And so in manner, by small additions of temperature, an expansive power may be given to steam to enable it to expand to 50, 60, 70, 80, 90, 100, 200, 300, or more times its volume, without any limitation but what is imposed by the fragilable nature of every material of which boilers and other parts of steam-engines can be made. And prudence dictates, that the expansive force should never be carried to the utmost which the materials can bear, but rather be kept considerably within that limit.

Having thus explained the nature of his discovery, Mr. Woolf proceeds to give a description of his improvements grounded thereon.

If the engine is constructed originally with the intention of adopting these improvements, it ought to have two steam-cylinders of different dimensions, and proportioned to each other according to the temperature, or the expansive force determined to be communicated to the steam made use of in working the engine; for the smaller steam-veffel or cylinder must be a guide for the larger. For example, if a steam of forty pounds the square inch is fixed on, then the smaller cylinder should be at least one-fortieth part the contents of the larger one. Each cylinder should be furnished with a piston, and the smaller cylinder should have a communication, both at its top and bottom, (top and bottom being here employed merely as relative terms, for the cylinders may be worked in a horizontal, or any other required position, as well as vertical,) with the boiler which supplies the steam; and the communications, by means of cocks or valves of any construction adapted to the use, are to be alternately opened and shut during the working of the engine. The top of the small cylinder should have a communication with the bottom of the larger cylinder, and the bottom of the smaller one with the top of the larger, with proper means to open and shut these alternately by cocks, valves, or any other well-known contrivance. And both the top and bottom of the larger cylinder should, while the engine is at work, communicate alternately with a condensing vessel, into which a jet of water is admitted to halt the condensation; or the condensing vessel may be cooled by any other means calculated to produce that effect.

Things being thus arranged, when the engine is set to work, steam of a high temperature is admitted from the boiler to act by its elastic force on one side of the smaller piston, while the steam which had last moved it has a communication with the larger steam-veffel or cylinder, where it follows the larger piston, now moving towards that end of its cylinder which is open to the condensing vessel. Let both pistons end their stroke at one time, and let us now suppose them both at the top of their respective cylinders, ready to descend; then the steam of forty pounds the square inch, entering above the smaller piston, will carry it downwards; while the steam below it, instead of being allowed to escape into the atmosphere, or applied to any other purpose, will pass into the larger cylinder above its piston, which will make its downward stroke at the same time that the piston of the smaller cylinder is doing the same thing; and while this goes on, the steam which last filled the larger cylinder in the upward stroke of the engine will be passing into the condenser, to be condensed during the downward stroke. When the pistons in the smaller and larger cylinder have thus been made to descend to the bottom of their respective cylinders, then the steam from the boiler is to be shut off from the top, and admitted to the bottom of the smaller cylinder. The communication between the bottom of the smaller and the top of the larger cylinder is also to be cut off; and the communication is to be opened between the top of the smaller and the bottom of the larger cylinder. The communication between the bottom of the larger cylinder and the condenser is to be cut off, and the steam which, in the downward stroke of the engine, filled the upper part of the larger cylinder, suffered to flow off to the condenser. The engine will then make its upward stroke from the prelude of the steam in the top of the small cylinder, acting beneath the piston of the great cylinder, and so on alternately, admitting the steam to the different sides of the smaller piston, while the steam last admitted into the smaller cylinder passes alternately to the different sides of the larger piston in the larger cylinders; the top and bottom of which are at the same time made to communicate alternately with the condenser.

In an engine working in the manner just described, while the steam is admitted on one side of the piston into the smaller cylinder, the steam on the other side has room made for its admission into the larger cylinder, on one side of its piston, by the condensation taking place on the other side of the large piston which is open to the condenser; and that valve of steam which takes place in engines worked only by the expansive force of steam, from steam passing the piston, is prevented; for all steam that passes the piston in the smaller cylinder is received into the larger.

In such an engine, where it may be more convenient for any particular purpose, the arrangement may be altered, and the top of the smaller made to communicate with the top of the larger cylinder; in which case the only difference will be, that when the piston in the smaller cylinder descends, that in the larger will ascend, and vice versa; which, on some occasions, may be more convenient than to have the two pistons moving in the same direction.

This engine is exactly the same in its action as Mr. Hornblower's, which we have before described. The novelty consists in the application of steam of a high prelude thereto, and in proportioning the capacities of the two cylinders to the expansibility of the steam, according to his table. But Mr. W. goes on to state, that effectual means must be used to keep up the requisite temperature in all parts of the apparatus into which the steam is admitted, and in which it is not intended to be condensed; and here it may be proper to state, that instead of the usual means of accomplishing this, by placing them in the boiler, or in a steam-cunoenating with the boiler, a separate fire may with advantage be made under the steam-veffel containing the cylinders, in which that event will become a second boiler, and must be furnished with a safety-valve, to regulate the temperature. By means of the last-mentioned arrangement, the steam from the smaller cylinder or steam-measurer may be admitted into the larger cylinder, when kept at a higher temperature than the steam in the smaller cylinder, by which its power to expand itself may be increased; and, on the contrary, by keeping the larger cylinder at a lower temperature than the smaller, its expansibility will be lessened, which, on particular occasions, and for particular purposes, may be desirable. In every case, care must be taken that the boiler, or cafe in which the cylinder is included, the steam-pipes, and generally all the parts exposed to the action of the expansive force of the steam, shall have a strength proportioned to the high prelude to which they are to be exposed.

It is not advisable that the proportion of the capacity of the smaller cylinder or steam-measurer, to the capacity of the larger or working cylinder, should in any case be smaller than the proportion of the expansion of the steam which is to be used in it, as we have stated; yet in the making of the larger, considerable latitude may be allowed; for example, with steam of forty pounds the square inch, a small cylinder or measurer of one-twentieth, or even larger, instead of one of forty of the capacity of the larger or working cylinder,
STEAM-ENGINE.

nder, and so with steam of any given strength. And in many cases, it may be advisable that this should be the case, because of the difficulty of preventing some waste of steam, or partial condensation, which might lessen the rate of working, if not allowed for in the size of the small cylinder or steam chamber.

In all cases when the engine is ready for working, whatever may be the proportion that has been adopted, or intended to be worked with, it should have its power tried by altering the load on the valve that ascertains the force of the steam, in order that the strength of steam belt adapted for the engine may be ascertained, for it may turn out to be advantageous, that the steam should be employed in particular engines of an elastic force, somewhat over or under what was first intended.

Mr. Woolf also states, that Mr. Watt’s engines may be improved by the application of his discovery in making the boiler, and the steam-cake in which the working cylinder is enclosed, much stronger than usual, and by altering the structure and dimensions of the valves for admitting steam from the boiler into the cylinder in such a manner, that the steam may be admitted very gradually by a progressive enlargement of the aperture, so as first to draw the steam, and afterwards to admit it more freely. The reason of this precaution is this, that steam of such elastic force as Mr. Woolf proposes to employ, if admitted suddenly into the cylinder, would strike the piston with a force that would endanger the safety and durability of the engine. The aperture allowed to the valve for admitting steam into the cylinder, or cylinders, should be regulated by the following consideration. If the intention is, that the engine should work wholly, or almost wholly, by condensation, the steam, in passing into the cylinder, should be forced to wire-draw itself only so much, that the piston may perform the whole, or a great part of the stroke, by the time that the intended quantity of steam has been admitted into the cylinder. For example, when steam of forty pounds on the square inch is used, such a quantity of it must be allowed to enter as shall be equal to one-fortieth of the capacity of the cylinder, and so in proportion when steam of any other force is employed; and when the requisite quantity has been admitted, the steam is to be shut off till the proper moment for admitting a fresh quantity. But if it is intended that advantage shall be taken of the elastic force of the steam acting on one side of the piston, while condensation goes on on the other side, then the steam must be admitted more freely, but still with caution, for the reason already mentioned.

This latter is the same thing as Mr. Watt’s expansion-engine; but with the addition of gradually diminishing the aperture of the steam-valve as the piston descends, instead of stopping it altogether at a certain portion of the descent, by which means the action of the engine is rendered more uniform. We think that, by regulating the descent of the valve by an accurate movement, a very good effect may be produced in this manner, without the complication of two cylinders or other parts; the only objection is, that if at any time the valve should be fully opened by accident, the pressure might suddenly become so great, from the strong steam acting upon the whole surface of the piston, as to break the engine to pieces.

In 1805, Mr. Woolf took out a second patent for further improvements, in which he proposes, as before, to apply fire to the cylinder itself, to heat the steam after it is thrown into the working cylinder; and this was to be done by a fire being placed beneath the case containing the cylinder: the space between the case and the cylinder was to be filled with oil, wax, fusible metal, or mercury. He also proposes a method of preventing the passage of any of the steam from the upper side of the piston which is acted upon by the steam, to the other side, which is open to the condenser. In those steam-engines which act as double engines, he effects this by employing upon, or about the piston, a column of mercury, or fluid metals, in an altitude equal to the pressure of the steam. The efficacy of this arrangement will, he says, appear obvious, from attending to what takes place in the working such a piston. When the piston is ascending, that is, when the steam is admitted below it, the space on its upper side being open to the condenser, the steam, endeavouring to pass up by the side of the piston, is met, and effectually prevented by the column of metal, equal or superior to it in pressure; and during the down stroke no steam can possibly pass without first forcing all the metal through.

In working what is called a single engine, a less considerable altitude of metal is required, because the steam always acts on the upper side of the piston; and in this case, oil or wax, or fat of animals, or similar substances in sufficient quantities, will answer the purpose. But care must be taken, either in the double or single engine, when working with this piston, that the outlet which conveys the steam to the condenser shall be so situated, and of such a size, that the steam may pass freely, without forcing it, or carrying with it, any of the metal, or other substance employed, that may have passed by the piston, and at the same time providing another exit for the metal, or other substance collected at the bottom of the cylinder to convey the flame into a receiver kept at a proper heat, whence it is to be returned to the upper side of the piston by a small pump, worked by the engine, or by some other contrivance.

In order that the fluid metal used with the piston may not be oxidized, some oil or other fluid substance is always to be kept on its surface, to prevent its coming in contact with the steam; and to prevent the necessity of employing a large quantity of fluid metal, although the piston must be as thick as the depth of the column required, the diameter need be only a little less than the steam-valve, or working cylinder, excepting where the packing, or other fattings, is necessary to be applied; so that, in fact, the column of fluid metal forms only a thin body round the piston.

We have seen an engine of an eight-horse power of this kind at work, with a fluid metal on the pistons: it effectually prevented the leakage. But as it required to have the cylinders twice as long as usual, in order to have sufficient room for the long or thick pistons which it required, and as these pistons must be of considerable weight, the method is not at all applicable in practice; and, indeed, the increase of the bulk of the moving parts is such as to counterbalance the advantage, which is confined to the saving of steam by leakage: for the friction must be greater than in another engine, because the piston must be packed as tight as usual, to be able to sustain a column of fluid metal, which must be more than equal in pressure to that of the steam; and when the steam presses upon the piston, the pressure of the fluid metal to leak by the piston must be double that of the steam: also, the friction of so great a surface of fluid metal precluding against the inside of the cylinder is very great.

In 1810, Mr. Woolf had a third patent, the object of which is to prevent the waste of steam, from leakage by the piston. For this purpose, he does not allow the steam to come to the piston at all, but cauets it to act in a different way, and transmits the action thereof to the piston by oil or fluid metal: thus, at the side of the cylinder,
cylinder, he places a separate vessel, communicating with the lower part of the cylinder by a large pipe or passage from the bottom of each; then, these, being admitted into this vessel, will press upon the surface of the oil or fluid metal contained in it, and force the same to pass out of that vessel into the cylinder, where it will act beneath the piston to press the fame upwards; a vacuum being at the same time made in the upper part of the cylinder, to give effect to the preflure. The fame is then made to press upon the upper surface of the piston, which is always covered with a quantity of the fluid; and at the fame time a vacuum is made in the separate vessel, so as to relieve the surface thereof from all preflure: in conquence, the piston is made to descend. It is evident that the piston must be packed so tight as to suffer none of the fluid to pass by it; but this is easy, in comparison with the difficulty of making a packing sufficiently tight to refhit the passage of steam, particularly when it is so rare as the expanded steam which Mr. Woolfe sometimes used in his engine. The separate vessel of which we have spoken, is in some cafes to be the jacket or space which surrounds the cylinder, which is then to be open at bottom.

This contrivance is ingenious, but we think the necessity of an additional cylinder is an objection which will prevent its adoption in large engines; and for small engines the advantages are not so great.

Performance of Mr. Woolfe's Engine.—Since his first patent, Mr. Woolfe has erected several small engines, which performed well, and with an evident economy of fuel. But these engines being employed to turn mills, of which the operations do not afford so exact an estimate of the power as the operation of pumping water, Mr. Woolfe's engines did not come to a direct and indispensible comparison with those on Mr. Watt's principle, until 1815, when two large engines were set to work in Cornwall, at Wheal Vor and Wheal Abraham mines, for pumping water; and these have since been regularly reported in Mefli's T. and J. Leaks reports, of which we have before spoken, and of which one of the objects was to ascertain the comparative merit of the double and single cylinder engines.

The report for May, 1815, states the average performance of these engines at $49,980,882$ lbs. lifted one foot high for each bushel of coal; and since that time they have done more than $50,000,000$ lbs.

The engine at Wheal Vor has a great cylinder of 55 inches diameter, and 9-feet stroke; and the small cylinder is about one-fifth of the contents of the great one. The engine works six pumps, which, at every stroke, raise a load of water of $37,082$ lbs. weight, 7½ feet high, which is the length of the stroke in the pumps. This makes a preflure of 14.1 lbs. per square inch on the surface of the great piston, and it makes 7.6 strokes per minute. With respect to its consumption of coal, it raised, in March, 1816, 48,432,702 lbs. one foot high with each bushel; April, 1816, 44,000,000 lbs.; May, 1816, 49,500,000 lbs.; and in June, 1816, 43,500,000 lbs.

From the fame reports we learn, that the engine at Wheal Abraham mine has a great cylinder of 45 inches diameter, working with a 7-feet stroke, at the rate of 8.4 strokes per minute, under a load of 24,050 lbs., which it raises 7 feet at each stroke. Its performance during the above four months was 50,000,000 lbs.; 50,908,000 lbs.; in May, 56,917,512 lbs., which, we believe, is the greatest performance ever made by a steam-engine; and in June, 51,000,000 lbs.

We have before given a similar account of Mr. Watt's engines; but at the fame time we must observe, that the variation in the performance of different steam-engines, which are constructed upon the fame principle, and working under the fame advantages, is the fame as would be found in the produce of the labour of so many different horses, or other animals, when compared with their consumptive food; for the effects of different steam-engines will vary as much from small differences in the proportions of their parts, as the strength of animals from the vigour of their constitution: and, again, there will be as great differences in the performance of the fame engine, when in bad or good order, from all the parts being tight and well oiled, fo as to move with little friction, as there is in the labour of an animal, from his being in good or bad health, or excessively fatigued; but, in all cafes, there will be a maximum which cannot be exceeded, and an average which we ought always expect to attain.

Plate V. Fig. 3. is a sketch to shew the arrangement of the valves and cylinders of these two engines: A is the large cylinder, and B the little cylinder, each inclosed in its steam-cake. The steam is admitted from the boiler into the steam-case of the large cylinder A, by a communication at C; and there is a communication between this steam-case and that of the small cylinder; so that all the steam for the supply of the engine passes through both of the steam-cakes, which therefore become part of the communication between the boiler and the little cylinder, into which the steam is first admitted. D furnishes a communication for carrying back to the boiler any water which may be produced by condensation in the steam-cake, before the engine is heated to the proper temperature. E is the pipe from the steam-case to supply the engine; it has a regulating-valve. F is the valve-box of the small cylinder, the spindle of the one valve working through that of the other; and the passage for the steam from the case into the small cylinder is situated between the two valves. G is the valve that opens the communication between the bottom of the small cylinder B, and the top of the large cylinder A, when the piston thereof is to be preyed down. H is the valve that returns the steam from above to below the large piston, when the piston is to ascend. And I is the exhaustion-valve, to carry off the steam to the condenser.

When the engine makes its down-stroke, the upper valve at F is opened, and admits the steam from the case to press upon the small piston, the valve G being opened at the same time, which suffers the steam to pass from the under side of the small to the upper side of the large piston; and the valve I is opened to make a passage from beneath the great piston to the condenser. These three upper valves, F, G, I, open at the fame instant of time.

When both pistons arrive at the bottom of their respective cylinders, these three valves are shut all together, and the lower steam-valve at F is opened, to return the steam from above to below the small piston; the valve H doing the same to the large cylinder, and both pistons return in equilibrium by the counter-weight; but the upper valve at F can be shut off at any part of the stroke, according to the load of the engine.

Those who are conversant with steam-engines will perceive, from the passages of the steam, as above described, from the upper to the lower side of each of the pistons respeftively, that the engines at Wheal Vor, and at Wheal Abraham, are at present working with a little stroke. Were these engines working double, the steam would, on the down-stroke, be made to pass, the fame as before described, from the under side of the small, to the upper side of the large piston, from the boiler in the mean time coming in upon the small piston, and the under side of the large piston being open to the condenser.

Mr. Woolf's Boiler for raifing Steam of a High Preffure with Safety.—The boilers which Mr. Woolf employs in his engines are different from thoé of other engines which work with feam of a low preffure, the water being contained in several cylindrical tubes of call-iron, which are filled with water, and exposed to the flame nearly in an hori-
zontal position.

Mr. Woolf has a patent for this boiler, which the fpecifi-
fications relates to conflit of two or more cylindrical vessels, properly connected together, and fo dipofed, as to confit-
tute a strong and fit receptacle for the water intended to be
converted into feam of a temperature and under a preffure
uncommonly high, and also to prefent an extensive portion
of convex furface to the current of flame and heated air
from a fire; likewise of other large cylindrical receptacles
placed above the former cylinders, and properly connected
with them, for the purpofe of containing fome water and
the feam.

These cylindrical vessels are feated in a furnace fo adapted
to them, as to caufe the greater part of the furface of
each of them, or as much of the furface as may be con-
venient, to receive the direft action of the fire, or heated
air or flame.

Plate V. firs. 4 and 5, reprefents one of these boilers
in its moft fimple form. It conflits of eight tubes, marked
a, made of call-iron, or any other fit metal, which are
each connected with the larger cylinder A, placed above
them, as is fhewn in the fide view, fig. 5, in which the fame
letters refer to the fame parts as in fig. 4. In fig. 5, is
also fhewn the manner in which the fire is made to act.
The fufpens on the grate-bars at B, and the flame and heated
air, being reverberated from the part above the two firft
smaller cylinders, go under the third, over the fourth,
under the fifth, over the fith, under thefeventh, and partly
over and under the eighth small cylindrical tube, all
which tubes are full of water. The direftion of the flame,
until it reaches the laft-mentioned tube, isfhewn by the
dotted curved lines and arrows. When it has reached that
end of the furnace, it is carried by the flue, O, to the other
fide of a wall, built beneath the main cylinder A, in the
direftion of its length, and the flame then returns under the
opposite end of the feventh smaller cylinder over the fith,
under the fifth, over the fourth, under the third, over the
fecond, and partly over and partly under the firft, when it
paftes into the chimney. The wall before-mentioned, which
divides the furnace longitudinally, answers the double pur-
pofe of lengthening the courefe which the flame and heated
air have to traverfe, giving off heat to the boiler in the
paflage, and alfo of fecuring the flanges, or other joinings,
employed to unite the smaller tubes to the main cylinder,
from being injured by the fire. The ends of the small cylindric

working with fuch boilers, the water carried off by evapo-
ration is replaced by water forced in by the ufual means of
a high-preffure boiler, that is, a foreing-pump; and the
feam generated is carried to the place intended by means
of pipes connected with the upper part of the cylinder A.
In the specifications, means are pointed out for applying
this plan to the boilers of steam-engines already in use, by
ranging a row of cylinders beneath the prefent boiler, and
connecting them with each other, and with the boiler.
Directions are alfo given for constructing boilers com-
posed of cylinders dipofed vertically. In every cafe the
tubes composing the boiler fhould be fo combined and ar-
 ranged, and the furnace fo constructed, as to make the fire
and flame act around and over the tubes, fo as to embrace
the largest poftible quantity of their furface. It must be
obvious to any one, that the tubes may be made of any
kind of metal; but call-iron is the moft convenient. The
size of the tubes may be varied; but in every cafe, care fhould
be taken not to make the diameter too great: for it must
be remembered, that the larger the diameter of any fingle
tube is in a boiler, the ftronger it must be made in
proportion, to enable it to bear the fame expansive force
of steam as the smaller cylinders. It is not effential, however,
to the invention, that the tubes fhould be of different sizes;
but the upper cylinders, especially the one which is called
the steam-cylinder, fhould be larger than the lower ones,
it being the inftrument, as it were, into which the lower ones
fend the steam, to be thence conveyed away by the feam-
pipe. The following general directions are given refe-
pecting the quantity of water to be kept in a boiler of this con-
struction; viz. it ought always to fill, not only the whole
of the lower tubes, but also the great steam-cylinder A, to
about half its diameter, that is, as high as the fire is al-
lowed to reach; and in no cafe fhould it be allowed to get
fo low, as not to keep the vertical necks, or branches,
which join the smaller cylinders to the great cylinder, full
of water, for the fire is only beneficially employed when ap-
plicated, through the medium of the interpoled metal, to
water, to convert it into steam; that is, the purpofe of the boiler
would in fome meafure be defeated, if any of the parts of
the tubes which are expofed to the direft action of the
fire, fhould prefent a furface of feam in their interior, in-
stead of water, to receive the transmitted heat. This muf,
more or lefs, be the cafe, whenever the lower tubes, and
even a part of the upper, are not kept filled with the
water.

Refepting the furnace for this kind of boiler, it fhould
always be fo built as to give a long and waving courefe to
the flame and heated air, forcing them the more effectually
to ftrike againft the fides of the tubes which compose the
boiler, and fo to give out the greateft poftible portion
of their heat before they reach the chimney. Unless this
be attended to, there will be a much greater waste of fuel
than neceffary, and the heat communicated to the con-
parts of the boiler will be lefs from a given quantity of
fuel.

When very high temperatures are not to be employed,
the kind of boiler just defcribed is found to anfwer very
well; but where the utmost force of the fire is defirable for
producing the moft efficacious fteam, the parts are combined
in a manner somewhat different, though the principle is the
fame. In the Philosophical Magazine, vol. xvii. p. 49, are
a defcription and drawing of a boiler of this kind, two of
which were created in 1803 at Mefians, Moux's brewery.
In every cafe Mr. Woolf uses two fafety-valves, at leat,
in his apparatus, to prevent accidents; a precaution which
cannot be too strongly enforced, as it may happen, when

Vol. XXXIV.
but one is employed, that by some accident it may get
locked, and the engine and people about it be exposed to
the danger of an explosion.

In those engines of Mr. Woolf's which we have seen, he
employs boilers like the one described, viz. with two small
tubes beneath, which are full of water, and exposed to the
immediate action of the flames, communicating by perpendi-
cular necks or branches with the large cylinder above,
which has water in the lower part, and flæm in the upper.
The only difference from what we have above described is,
that the lower and upper tubes are placed in the same
direction, instead of being at right angles to each other;
and the flæm proceeds in the same direction of their length,
instead of crossing them; the lower or water
holes are rather inclined upwards. The metal of these
tubes is made very thick, with a view to strength and
durability.

The idea of making boilers for raising strong flæm, by
a number of small tubes, which can be made longer than
one large vessel, is not original with Mr. Woolf; Mr.
Blakey, of whom we have before spoken, having proposed
it in a small tract which he published in French, at the
Hague, in 1776. But his tubes were to be placed over
each other, in an inclined direction; and the water being
admitted at the upper end, ran down within the heated in-
clined tubes, and became converted into flæm.

Woolf's Regulating Steam-Valve.—Besides the common
safety-valves, Mr. Woolf has also introduced a valve of a
new construction into the flæm-pipe itself, to regulate the
quantity of steam that shall pass from the boiler. In fact, it is
a self-acting steam-regulator, and extremely ingenious. A
(fig. 6.) is a part of the great or flæm cylinder of one of
Mr. Woolf's boilers; B B, the neck or outlet for the flæm,
furmounted by a flæm-box C, which is joined to the neck
B B, by the flanges u u. The top or cover of the flæm-
box C, marked with the letter D, is well secured in its
place, and has a hole through it for the rod of the valve
for passing; and the interior of the hole is formed to a box to
hold a stuffing, and make the rod work up and down flæm-
tight; the stuffing being kept in its place by means of a
collar, screwed down in the usual way, as shown in the
figure. By means of a pin b, and the two vertical pieces c, c,
the flæming-valve rod is made fast to m, which is a close
cover to the hollow cylinder n n. The cover, m, fits
flæm-tight into the conical seat, at the upper end of a
collar o o, which is made fast to the flange a a, and descends
into the neck of the boiler, forming a barrel, in which the
cylinder fits close. The cylinder, n n, is open at bottom,
having a free communication with the flæm in the boiler A;
and it has three vertical flits cut out through the sides, one of
which, S, is shown in the plate. The sum of the area of
all these flits or openings is equal to the area of the opening
of the flæm or collar o o, in which the cylinder, n n, works.

When the flæm acquires a sufficient degree of elastic
force to raise the valve, (that is, the cylinder n n, with its
cover m, and the rod R,) together with whatever weight
the rod may be loaded, then the openings S, rising above
the flæm-tight collar or flæm o o, allow the flæm to pass
into the flæm-box C, and to flow off to the engine through
the pipe N. But the quantity of flæm that passes is pro-
portioned to the elastic force it has acquired, and the weight
with which the valve is loaded; because the rise of the
openings, S, above the collar o o, will be in that propor-
tion.

This valve may be loaded by applying weights in any of
the usual methods; but Mr. Woolf prefers the one shown
in the drawing, in which the upper part of the rod, R, is
joined by means of a chain to a quadrant of a circle Q,
with an arm projecting from it, as represented in the plate,
for the purpose of carrying a pendulum weight Z, that ad-
mits of being moved nearer to or farther from the centre of
the quadrant, according as the preflure of the valve is wished
to be increased or diminished.

As the valve rifies, the weight moves upwards in the arc a a,
giving a continually increased Reidance to the farther riving of the valve, proportioned to the horizontal
distance of the weight from the centre of Q, of which the
weight attains a continual increase by its rise in the arc,
according to the horizontal distances measured on the line
Q Q, passing through the centre of the weight by per-
pendiculars from the horizontal line.

Thus, if the weight Z produces down the valve m, with
a force equal to 20 lbs. on the square inch of the aperture
in o o, in its present position, when it rifies to the position
at i, it will presse with a force equal to 30 lbs. ; and at p,
with a force equal to 40 lbs. on the square inch; so that
the rod, Z, may be made to serve at the same time as an
index to the person who attends the fire, nothing more being
necessary for this purpose than to graduate the rod Q Z, by experimental trials. In
the side of the flæm-box C, there is an opening, N, to
allow the flæm to pass from it by a pipe to the flæm-
engine.

It is plain that the adjustment of the positive preflure on
this valve can be determined by fliding the weight, Z, of
the pendulum to a greater or less distance from the centre of
motion. Again, to adjust the rate of the increasing forces,
so as to correspond with the increasing force of the flæm,
the radius of the quadrant, Q, must be apportioned to the
diameter of the valve, and the opening of the flits S, so
that the amount of the weight, Z, in its quadrant will be cor-
respondent to the varying preflure. This adjustment must
be made as nearly as it can be done before the valve is fixed;
and to bring it afterwards to an exact regulation, the chain
is attached to the rod, R, by a nut and screw; by means of
which, any part of the arc can be used that is found most
corespondent with the varying preflure, because the rate
at which the refiltance of the lever increases is more rapid
when the pendulum is near to the perpendicular, than when it
approaches the horizontal position.

The same effect may be produced, by making the flits in
the side of the cylinder narrower at the lower part of the
cylinder, instead of being parallel.

Edelecrantz's Safety-Flæm.—The chevalier Edelcrantz
conceived a safety-valve, some years ago, which has the
same properties as Mr. Woolf's, and is worthy of notice,
as being more simple in its construction. A small brass cy-
linder is fixed on the boiler, and fitted with a piston, which
moves with very little friction, in order that it may defend
by its own weight, after it has been raised up, without
however, permitting the flæm to pass between it and the
cylinder in any quantity. The lower part of the cylinder
communicates with the boiler, and the upper part is closed
by a small cover screwed on to it, and perforated with a
hole, through which the piston-rod passes easily. This cover
serves the double purpose of guiding the rod, and pre-
venting the piston from being blown out. The piston-rod
is furnished with a shoulder, which serves to support dif-
ferent weights which are placed upon it, and they can be
changed at pleasure. The side of the cylinder is pierced
with holes opening to the air; the holes are very small, and
placed above each other at the distance of about a line; but
this
STEAM-ENGINE.

this distance, as well as the number of them, is a matter of indifference.

To give an idea of the effect of this small apparatus, let us suppose the piston lowered, and loaded with any weight, and that a fire is kindled under the boiler. When the vapour has acquired sufficient elasticity to raise the weights, the piston will ascend; and having palled the first hole, some vapour will escape.

If this aperture be of sufficient size for the passage of the quantity of vapour continually produced, the piston will remain there stationary, and in a state of oscillation; if not, it will ascend above the second, third, &c. hole; and if the intensity of the fire is sufficiently strong, above the last, which must be made larger, that, by giving the proper means of escape to the vapour, all accidents may be prevented. This is evident, that, though the greater or less elevation of the piston, as well as the number of the holes open, depend on the variations and different intensities of the fire, these variations, however, have no influence on the interior heat, and the elasticity of the vapour contained in the digester, since their force is always proportioned to the weight with which the piston is loaded, and which is constant. This safety-piston seems likely to afford, for delicate experiments, greater exactness than the usual safety-valves hitherto employed, with levers charged with weights: “for, in the whole course of the space which the cylindrical piston passes over in ascending, the state of the elasticity of the vapour is the same; whereas, when the conical valve in common use is once raised up, nothing indicates whether or how much the present state of the vapour far-palies the first effort it made to open the valve. Besides, the diameter of the piston being once known, the force of the vapour requisite for each experiment can be easily regulated and determined: if we suppose, for example, that the lower surface of the piston is $\frac{1}{4}$th of a square inch, each ounce of weight placed on the shoulder of the piston will be equivalent to the pressure of a pound on each square inch of the surface, and so on in proportion. As this pressure then remains constant, the experiment will be more determinate, and consequently more comparative.

The application of this piston to the boiler of the steam-engine needs no further explanation, except that, in this case, the diameter of the piston must be considerably increased. It seems here to offer the same advantage of greater uniformity in the force of the steam, especially if the motion of the piston be employed to regulate the fire of the furnace, and to prevent the useless diffusion of the vapour, by preventing an excess in the intensity of the fire. The following apparatus may be used for this purpose. Let the aperture of the fire for the current of air which maintains the combustion of the fuel be provided with a regifier, which, by rising and falling, will open or shut that passage of air: if the motion of the safety-piston be combined by any means with the regifier, in such a manner that when the former ascends, the latter descends; so that when the piston is at its greatest elevation, the regifier shall be entirely shut, it is evident that since the heat produced depends on the access of the air, the elasticity of the vapour, being determined by the weight on the piston, will not only remain within the bounds preferred for it, but will regulate itself, by preventing any more air from entering the furnace than is necessary to maintain its force. A figure, representing this useful apparatus more minutely, may be found in the 17th volume of the Philosophical Magazine, p. 162.

Before quitting the subject of double-cylinder engines, we shall notice some others before those of Mr. Hornblower and Mr. Woolf.

Messrs. James and John Robertson had a patent for one in 1800. The so-called object of the double cylinder was to make that portion of steam, which in the bell constructed steam-engines escapes past the sides of the piston in the time of working, and is lost without producing any mechanical effect whatever. MR. Roberton's intention was to prevent so great a quantity of steam from escaping, and in making the steam, which actually did escape, act on another piston, and add to the power of the engine. There are two steam-cylinders, with a piston fitted to each; the one cylinder of a smaller, and the other of a larger size. These two cylinders act together in producing the effect, and are furnished with a condensing vessel and air-pump, similar to other engines. The same patent contains the description of the smoke-burning furnace, which has been very extensively used.

Mr. William Diverell obtained a patent in 1805, for improvements in the steam-engine. He proposes to have two working cylinders, placed near to one another, each having a pipe of communication, with a large vessel, in which the steam, after passing from the small cylinder, is suffered to expand itself, before entering the large cylinder. The pistons in the two cylinders work alternately up and down by means of valves or cocks, opening and shutting as in the common engine. Suppose the small piston has just made a stroke, and a passage is opened to the steam-velvel at the end of the stroke; at the beginning of the next stroke, the valve will be full of steam of about 18 lbs. pressure, admitted from the boiler, but afterwards will only be supplied by the steam thrown into it from the small cylinder. The vessel should be about twenty times larger in capacity than the smallest working cylinder; and the larger it is, the more regular will be the pressure on the great piston, which is worked by the steam coming from the steam-velvel. If the steam in the boiler be of 54 lbs. pressure per square inch, the ratio of the two working cylinders may be as 1 to 3, for then the smaller will supply the larger with steam of about 18 lbs. pressure: the proportion, however, may be varied, though these are thought best by the patentee. The improvements here are represented to consist in the steam going from the smaller working cylinder to the steam-velvel, and then from the steam-velvel to the larger working cylinder, from which it is afterwards drawn off, and condensed. By these means the engine will be very regular in its operations. Suppose the steam in the boiler is at 54 lbs., the smaller cylinder will, at the end of the stroke, be full of steam of the same or nearly the same force; and the steam-velvel being full of the steam delivered to it by the former stroke of the smaller cylinder, at about 18 lbs. pressure, the communication is opened between this vessel and the smaller cylinder, and the steam in each of these will be brought to nearly 20 lbs. pressure, which steam will be used in the great cylinder at the next stroke. But at the end of each stroke of the pistons, before the opening is made between the smaller cylinder and the steam-velvel, the steam in the smaller cylinder will be, as before stated, at about 54 lbs.; in the steam-velvel it will be at about 18 lbs., and in the larger working cylinder at about 18 lbs. also. Hence the medium pressure on the piston of the smaller cylinder will be about 33 lbs. on the inch, while the medium pressure of the steam on the piston of the great cylinder will be about 19 lbs. on the inch; for it will be about 20 lbs. at the beginning, and about 18 lbs. at the end of the stroke. If the steam-velvel be made larger, the difference at each end of the stroke will

N 2
not be so great. If the fleam was let out at 54 lbs. from the smaller cylinder to the open air, there would be but 39 lbs. upon each inch of the piston, in consequence of the re-action of the atmosphere, equivalent to about 15 lbs. per inch; thus, by letting the fleam pass from the smaller cylinder to the fleam-vellet, instead of letting it out to the open air, it loses about 4 lbs. on the inch of the small piston, but it gains about 12 lbs. on the inch of a piston three times as large; and there being but half the fleam required in the common way to condense, there must of necessity be a considerable gain. If the friction and loss of force be equal to 9 lbs, on the inch on the piston of the smaller cylinder, there will be but about 30 lbs. on the inch neat power, when the larger one will work about 12 lbs. on the inch. Here too, if the large cylinder, or piston, or air-pump, or condenser, should be out of order, the small piston may still be worked, by disengaging the large piston from the fleam; on the other hand, if the smaller piston be out of order, the large one may still be worked, while the other is disengaged. The fleam-vellet is to be made of wood, that it may transmit the heat slowly, and the cylinders may be placed within it, if found convenient.

We have examined two engines of Mr. Davenport's which worked with great regularity, but the nature of the work they were performing did not admit of any accurate estimate of their power. The quantity of fuel they consumed was but small. We are disposed to think the addition of the fleam-vellet for the fleam to expand itself in, is advantageous in regulating the preasure, provided the heat is kept up; and for this purpose, the fleam-vellet in one of the engines we speak of was inclosed in the boiler, and we think would, in that case, receive a considerate addition of heat to the expanded fleam within it, which we believe is essential to all these kinds of engines. See the specification at large in the Repertory of Arts, vol. viii. p. 81.

Mr. Fox and Lean have also a patent, dated Dec. 10, 1802, for improvements on fleam-engines, the principal part of which is a double-cylinder engine, very much resembling those which we have described. See the Repertory, vol. xxix. p. 200.

Application of Reciprocating Engines to produce a rotary Motion for turning Machinery.—We have hitherto considered the fleam-engine as being confined to the operation of working pumps for raising water; except in the flight notice which we have taken of the application of the crank to the atmospheric engine. This was a thing so obviously in imitation of the foot-lathe, as to be scarcely considered an invention; but the difficulty of applying it to use arose from the want of regularity in the action of the old engine. An engine to work a crank, mutt at all times make exactly the same length of stroke; and to perform well, all these strokes must be performed in an equal period of time. The old engines had very little exactness in either of these particulars. From the nature of the detent which opened the injection-cock, and the great friction of turning it, the degree to which it was opened was not constantly the same in the succeeding strokes; and a very small difference of opening would materially influence the quantity of injection, and consequently the vacuum and velocity with which the piston would descend. The boilers of the old engines were always made too small, so that the leaf alteration in the intensity of the fire made the engine vary its speed.

At present, in the coal-countries the atmospheric engines are made to work machinery by means of a crank, and perform very well, but they are lightly loaded, and move very quickly. The fleam in the boiler is made much stronger than formerly, to enable it to fill the cylinder with a sudden puff, and thus to displace the air and water in an instant, because the rapid motion of the piston will not allow sufficient time for the discharging to be performed with weak flteam, as is usual. All these circumstances reduce the performance of the engine with respect to coal, and the consumption is very great in comparison with the work they perform. Such engines act very well when the work or resistence is constantly the same throughout the day; but the engine cannot work regularly, except when the counter-weight of the connecting rod is halved, and the engine will increase in its velocity beyond all bounds, so as to work itself to pieces; and as the only remedy is to check the quantity of fleam at the returning stroke, the discharige of the air will be interrupted, and the engine must stop. Mr. Watt's single engine accommodates this circumstance, from the mode of discharging being constant, and not possible to be effected by the work applied to it, whether it be uniform or variable; hence, to lessen the momentum of the counter-weight, it is only to check the entrance of the fleam by any contrivance that will prevent the valve, which admits fleam to enter above the piston, from opening to its greatest limits.

Mr. Watt, for some years after the first introduction of his engines, was so fully occupied in substituting them for the large atmospheric engines at mines, where the expense of fuel was threatening to put a stop to their proceedings, that he found no leisure for new speculations; and although the advantages of applying engines on his principle to aërate machinery had early occurred to him, he did not seriously fix about reducing his ideas to practice until the year 1778 or 1779. In the first model he then made, in order to equalize the power, he employed two cylinders, acting upon two cranks fixed upon the same axis, at an angle of 120° from each other; and a weight was placed upon the circumference of the fly-wheel at an angle of 120° from each of the cranks; which weight was to be so adjusted, as to turn the wheel when neither of the cranks could do so; and consequently to render the power nearly equal. This model performed to satisfaction; but Mr. Watt having neglected to take out a patent immediately, the essential part of the contrivance was communicated, as we are informed in the Edinburgh Review, by a workman employed to make a model, to the persons engaged about one of Mr. Walsworth's engines, of which we have before spoken, and a patent was taken out for the application of the crank by the engineer there employed. This did not deter Mr. Watt from proceeding; and without attempting to dispute a patent which, so long as it continued attached to the common atmospheric engine, could not rival him, he set about other modes of effecting the same thing, and took out a patent for several new methods of applying the vibrating or reciprocating motion of fleam-engines to produce a continued rotary motion round an axis, one of which was that beautiful contrivance of the revolving motion of one wheel round the other, called the fun and planet wheels, from the resemblance to the motion of those luminaries. Mr. Watt's patent is dated October 1782, and entitled, a new method of applying the vibrating or reciprocating motion of fleam-engines to produce a continued rotary or circular motion. It contains six different methods, but the two which have been since brought into ufe

7

are
are the crank, and sun and planet wheels. The crank is applied in the belt manner to produce a regular motion, when a single acting engine is the moving power; this was to apply an iron wheel on the end of the axis of the fly-wheel for a crank, and with a pin projecting from it, to which the connecting rod is jointed: one half of the wheel is made solid, of cast-iron, in order to be heavy on that side in which the pin is fixed, so as to urge round the fly during the returning stroke of the engine; the other half of the wheel is made light, that it may not oppose this weight.

Soon after this patent, Mr. Watt erected some engines in London at the large brevices; the first was at Mr. Good-wyn's, a spirited encourager of improvements, and the next at Mr. Whitbread's. A sketch of the latter engine, which is still working, is given in our plate Porter-Brewery. In these engines he employed the sun and planet wheels, and used a massive connecting rod, of sufficient weight to actuate the fly during the returning stroke, for these engines had not the advantage of the double action.

Double-acting Steam-Engines.—The advantage of a double-acting engine, which shall urge the machinery equally in all directions, is obvious. The first double-acting steam-engine was proposed in 1789, by Dr. Falck, who published an account and description of an improved steam-engine, which will, he says, with the fame quantity of fuel, and in an equal space of time, raise above double the quantity of water raised by any lever-engine of the same dimensions; but he does not appear to have proved the assertion, or constructed even a working model of his proposed engine, which was on Newcomen's principle. The chief improvement which he fuggests is to unite two cylinders, into which the steam is alternately admitted by a common regulator, which always opens the communication of the steam to one, whilst it shuts up the opening of the other. The piston-rods are kept (by means of a wheel fixed to an arbor) in a continual ascending and descending motion, in the same manner as the rods of the common air-pump, by which they move a common axle; to which is affixed another wheel, moving the pump-rods in the same alternate direction as the piston-rods, by which alternate motions of the two pistons the pumps are kept in constant action. Since the improved engines of Mr. Watt have been introduced, this method of combining the alternate action of two single engines has been applied to work machinery. We have seen both the atmospheric engine and the single engine of Mr. Watt working in this manner, but his double engine is much preferable. Mr. Watt faw that this was necessary, in order to perfect the application of his steam-engine; he therefore applied the power of the steam to prefix the piston upwards in its cylinder as well as downwards, by forming the vacuum alternately above and below the piston, and the counter-weight then becomes unnecessary. The only change in the machine beside the arrangement of the valves and their mechanism, was in applying a double chain to the arch-head of the beam, in the same way that the pumps of old extinguishing engines were worked; or he employed a rack and fector at the end of the beam.

This he called the double engine, as in fact it doubled the power exerted within the same cylinder. He had long had in his mind the idea of this improvement, and had even produced a drawing of it to the house of commons, in 1774, at the time he procured the act to prolong his original patent for 25 years; but the first he executed was, we believe, at Soho, in the year 1781 or 1782, and the first public exhibition of it at the Albion mills a few years later.

About the same period, finding double chains, or racks and fectors, very inconvenient for communicating the motion of the beam, he invented and applied what has been called the parallel motion, one of the most ingenious and most perfect contrivances in mechanics. To prevent irregularities in the speed of the engine, arising from variations in the quantity of power used at different intervals in the works to which it was applied, he made an application of the centrifugal force of what is called the governor (before used in wind-mills), to regulate the admission of the steam; by this means keeping the engine always at an uniform velocity, and diminishing the consumption of steam, in proportion to the power exerted. This gave the finishing stroke to the perfection of the motion of the machine, and rendered its regularity nearly correspondent with that of the pendulum of a clock. These inventions are detailed, among many other contrivances, relative both to steam-engines and the application of their power, in two patents, dated 1782 and 1784. Some of these are highly ingenious; a few may have been first ideas, not reduced to practice, and others were not doubt inferred for the purpose of guarding against evasion.

Moffet-Boulton and Watt's Double-Acting Engine for turning Mills.—Plate VI. contains a general elevation of the whole engine, and Plate VII. fig. 1, is a section of the cylinder, inclosed in its steam-case or jacket, the outside of which is coated with platter, to keep in the heat; the internal structure will be described hereafter: a is the piston-rod, connected to the great working beam C D E, by a five-lever b, c, d, m, called a parallel motion, the property of which is, that the rectilinear motion of the piston-rod a, is preserved, though the end, C, of the beam describes an arc of a circle when it rises and falls upon its centre of motion, B. At the opposite end, E, of the beam is jointed the connecting rod D, and at the lower end of this is Mr. Watt's contrivance for communicating the force of the steam-engine to any machine of the rotary kind. G represents the rim and arms of a very large and heavy cast-iron fly-wheel; on the extremity of its axis is fixed the concentric toothed wheel H, called the fun-wheel. The connecting rod, D I, is a strong and stiff iron rod, D, of sufficient weight to balance the piston: to the lower end of it, a toothed wheel, I, is firmly fixed by three bolts, so that it cannot turn round. This wheel is called the planet-wheel, because it revolves round the fun-wheel; it is of the same size and in the same vertical plane with the wheel H, and an iron link or flap (which cannot be seen here, because it is on the other side of the two wheels) connects the centres of the two wheels, so that the one cannot quit the other. The engine being in the position represented in the figure, to explain the action of this movement, suppose the fly, G, to be turned once round by any external force, in the direction from G towards K, it is plain, that since the toothed wheels, being kept together by the link, cannot quit each other, the outer half of the fun-wheel (that is, the half farthest from the cylinder) will work on the inner half of the planet-wheel I, so that at the end of the revolution of the fly, the planet-wheel must have arrived to the top of the fun-wheel H, because the circumferences of the wheels are equal, and the outer end, E, of the beam must be raised to its highest position. The next revolution of the fly will bring the planet-wheel, and the beam connected with it, to their first positions, and thus every two revolutions of the fly will make a complete period of the beam's reciprocating movements. Now, instead of supposing the fly to drive the beam, let the beam drive the fly, the motions must be precisely the same, and each ascent or descent of the piston will produce one revolution of the fly.

For
For instance, when the piston-rod, \(a\), is caused to ascend by the preasure of the steam beneath its piston, it raises one end of the beam and depresses the other; and by the communication of the connecting rod \(D\), causts the planet-wheel \(I\), to turn the wheel \(H\), and the fly-wheel, round with a double velocity. As soon as the piston-rod arrives at the end of its stroke, it receives a new impulse, which brings it down again, and consequently raises the connecting rod \(D\), and planet-wheel \(I\), so as to continue the motion of the wheel \(H\), and fly-wheel \(G\), always in the same direction. The use of the fly-wheel is to acquire an impetus from the force communicated to it, at the time that the centre of the planet-wheel, \(I\), is on the same horizontal line with the centre of the fan-wheel \(H\), at which time the connecting rod exerts all the force of the engine upon the wheel \(H\), to turn it round. This momentum is preferred by the rapid motion of the fly-wheel, which continues to turn all the rest of the machinery, when the planet-wheel, \(I\), is at the top or bottom of its motion, for the centres of the two wheels being in a line with the connecting rod, it has no tendency to turn them round.

To describe the manner in which the power of the steam is given to the piston-rod \(a\), we must turn to the section in Plate VII. fig. 1, where \(A\) is the jacket or steam-cane containing the cylinder, which is of cast-iron, and truly bored; it is closed at top by an iron lid \(l\), screwed on by screw-bolts, passing through a projecting rim or flange at the top, and a similar flange is formed at the lower end of the cylinder, to fall on the bottom. In the centre of the top lid is a fluffing-box, \(l\), for holding a packing of hemp, through which the piston-rod, \(a\), pails, perfectly air and steam tight: \(20\) is the piston, packed with hemp in a channel round its edge, so that the packing lies between its circumference and the inside surface of the cylinder; and while it can move up and down in the cylinder easily, it will not allow any steam to pail by it. The piston is fixed to the rod, \(a\), with a cone, and fast keyed in; the cylinder has a flange or projecting rim round it, a little below the top flange, by which it is held into the jacket \(A\), which is constantly supplied with steam from the boiler of the engine, by a small pipe branching off from the steam-pipe.

The steam-pipe cannot be seen in the elevation, except by the small dark circle near \(g\); and in fig. 2, it is marked 21: it introduces the steam from the boiler, at all times, through a throttle-valve, \(25\), into a box \(g\), called the upper steam-box. In the bottom of this box is the upper steam-valve, which being opened by depressing the end of the lever \(7\), admits the steam into the short paffage 14, which leads to the top of the cylinder. A branch, 12, descends perpendicularly from the steam-pipe, just before it enters the upper steam-box, and conveys steam to the lower steam-box \(i\); and in the bottom of this is a valve, which can be opened by lifting the end of a lever, 10, to admit the steam into the paffage 15, which leads into the bottom of the cylinder. These two valves govern the entrance of steam into the cylinder; and they both open upwards.

The valves for carrying off the steam are situated in two other boxes, \(b\) and \(l\), in which a vacuum is always maintained by their open communication with the condenser \(M\), by the exhausting-pipe 13, which descends from the upper box \(h\), and where it pails by the lower box \(l\), has a small branch leading into it.

These two exhausting boxes are situated immediately beneath the paffages, 14 and 15, which lead to the top and bottom of the cylinder, and the exhausting-valves are situated in the horizontal plate of the partition between the boxes and the paffages, in the same manner as the steam-valves are in the partitions between the steam-boxes and the flame paffages, as is clearly shewn in fig. 3. On opening the upper exhausting-valve, by depressing the lever 8, the steam from the top of the cylinder will be drawn off to the condenser; or by elevating the lever 9 (fig. 2), the lower exhausting-valve will be opened, and the steam will pass off from the lower part of the cylinder to the condenser.

The steam and adution-valves, 7, 8, 9, \(a\), are opened and shut by the levers called spanners, whose handles, 1 and 2, are alternately moved by the plugs fixed to the piston-rod of the air-pump \(N\). This part of the machinery has been called the hand-gear, because it is so constructed that the steam and adution-valves can be worked either by the hand or by the piston of the air-pump.

The valves are connected in pairs to levers upon the axle of the two handles 1 and 2, which are actuated by the pins \(f\) and 24, projecting from the rod, \(f\), of the air-pump, and the arrangement is this; the lower steam-valve 10, and the upper exhausting-valve 8, are connected by rods with levers upon the axle of the lower handle 2, and when that handle is depressed it will open both those valves at once, to admit steam below the piston, and exhaust it from above, which will cause the ascent of the piston. A lever and rod 6, (see the elevation) are applied to the axis of this handle, with a sufficient weight in the ciltern to cause the handle to fall and open the valves suddenly; but when the valves are to be kept shut, the handle, 2, is held up by a catch, and detent 3, the end, \(4\), having a hook to receive the catch, and detain the handle when lifted up, as in the figure.

In the same manner, the upper steam-valve 7, and the lower exhausting-valve 9, are united by rods to levers fixed upon the axis of the upper handle 1; and when this handle is raised, as in the figure, it opens both valves at once, \(f\) as to admit the steam above the piston and exhaust it from beneath it, as is shewn by the arrows in the section, which will cause the piston to descend.

Like the former spindle, a lever, \(5\), and rod are applied to it, with a weight which will lift up the handle, 1, and open the two valves; but when the handle is depressed, \(f\) as to shut the valves, it is held down by the catch entering the hook, 3, of the detent 4. As this detent moves upon a centre-pin, it must be observed, that when one lever catches into the hook it pulls back the detent, and this motion releases the other catch from the hook at the opposite end of the detent, so that moving one handle to shut one pair of valves releases the catch, and the weights immediately open the opposite pair of valves.

The exhausting-pipe, 13, descends to the condenser \(M\), which is a cylindrical vell of cast-iron, immered in the cold water of the condensing ciltern \(L\); it communicates by the valve \(m\), with the air-pump \(N\), which has valves in its bucket opening upwards, and is covered by a lid, through which the rod pails in a fluffing-box; also at the top of the pump is a short pipe of discharge, opening into the well-water \(n\), and this has a valve to prevent the return of the air and water into the pump.

All these parts are exactly the same as those of the single engine, before described, except the injection-cock 16, which is constantly running a small jet of cold water into the condenser, when the engine is at work. There is no necessity for an injection-valve in the double engine, and the use of the cock is only to regulate the quantity, and to stop it when the engine is not at work: it is moved by a handle 17, and there is a divided plate and index, to shew the degree of opening.
STEAM-ENGINE.

The cylinder is bolted down to two strong beams, which cross over the top of the condensing cillin L, and are united at the ends to two vertical posts S, which are framed into another piece situated beneath the cillin, and supported upon a pair of brick-work R: by this means the whole weight of the water in the cillin is applied to hold the cylinder firmly down. X are beams which support the flume of the beam-centre, by bearing up the floor F, on which the centre bearing reits; and the narrow dark line up the middle of the frame K, is a large iron bolt, which ties the frame down to the long groundfils, on which the cillin reits, and with which the beam T, for the centre of the flywheel, is connected by oblique legs and tie-bolts: by this means the external walls, W, W, are relieved from any material strain occasioned by the working of the engine. X X is the flairspace to ascend to the beam-floor. The boiler is not represented, but may be considered the same as that of the single engine.

Operation of the Double Engine.—Supposing every thing in the position of the section, the operation of the engine is as follows. When the water in the boiler is heated by the fire made under its bottom, the heat which enters in combination with the water causes it to expand, and form flume; in this state it rises and fills the boiler, and thence passing through the pipes 21, enters the lower flume-box g; it also enters between the jacket, and warms the cylinder; and by the defending branch, 12, of the flume-pipe, enters and fills the lower flume-box i. Before the engine can be worked, the flume must be heated, until it is expanded so much, that it will rush forcibly out of the boiler when permitted.

The person who attends the engine must now open all the four valves at once, by elevating the handle 1, and depressing the handle 2; this admits the flume from the boiler to pass through the boxes and the cylinder to the condenser, when it rushes through the pipe, 13, into the condenser M, driving the air therein contained through the valve m, and the valves in the bucket of the air-pump, which it opens, and passes into the cillin n, through the discharge-valve, where it is open to the atmosphere, the lid of that cillin being only laid on, and not fitting tight. This operation (called blowing through) being continued for a few seconds, expels all the air from the condenser, and fills it with hot flume. All the four valves are now closed, by pressing down the upper handle 1, and lifting up the lower handle 2; and the injection-cock 16, of which 17 is the handle, is opened; this allows a small stream of cold water from the condensing cillin, L, to enter into the condenser, and condenses the flume or cools it, when it instantly contracts into the same space it originally occupied in the boiler, before it was heated. As the valve, m, closes, to prevent the return of the atmospheric air, a vacuum will be caused in the condenser, because there will be nothing in it but that small quantity of water produced from the flume, and the cold water injected into the condenser.

The engine-man now opens the upper condensing valve 8, and lower flume-valve 10, by allowing the lower handle, 2, to fall down. The communication to the condenser being thus opened, the mixture of air and flume in the upper part of the cylinder will expand itself into the condenser through the pipe 14, and valve 8, by the exhausting-pipe 13; as it occupies more space than it did before, it will be considerably rarefied, and press lightly upon the upper side of the pilon. The flume from the boiler entering through the open valve, 10, is all the while pressing with its full force against the lower side of the pilon, and will perhaps, now a rarefaction is made above it, overcome the resistance of the work and friction, and cause the pilon to ascend, the air-pump rod and bucket moving with it. When the pin 24, upon this rod, reaches the handle 2, it raises it up, and flushes the lower flame-valve 10, and the upper exhausting-valve 8; and by means of the catch prefling back the hook at the lower end of the depet 4, it relieves the catch of the upper handle from the hook 3, of the detent; in consequence of which, the weight applied to the lever 5, throws up the handle 1, and opens the upper flume-valve 7, and lower exhausting-valve 9, while the hook, 4, of the detent, receiving the catch of the lower handle 2, holds it up. This is the situation represented in the section in fig. 1. The operation is now reversed; the flume from the boiler going through the valve 7, and passage 14, into the cylinder above the pilon, as shown by the arrows, fig. 1; and that flume which is beneath the pilon going through the passage 15, and valve 9, to the condenser, where the flume will be condensed, and a vacuum will be formed beneath the pilon: the flume now preffles it down, moving the beam, and turning the fly-wheel and other machinery which it has to drive. When the pilon is at the bottom, the pin, f, on the air-pump rod arrives at the handle 1, and preffes it down; this flushes the upper flume-valve 7, and lower exhausting-valve 9; and when they are completely shut, the catch of the upper handle, in entering the upper hook of the detent 3, 4, disengages the lower hook thereof; and the weight 6, which is applied to the lower handle 2, immediately throws open the lower flume-valve 10, and the upper exhausting-valve 8: the flume entering at the lower passage 15, the pilon will be driven up again.

At each stroke of the engine, when the pilon rises, the valve in the bucket of the air-pump will shut, and all the air and water contained above the bucket will be lifted through the valve, n, into the cillin or hot-well; at the same time, a vacuum being made beneath the bucket, which is more perfect than that in the condenser, the valve, m, will be opened by the water and air in the condenser, which will enter the pump. On the descent of the pilon, and air-pump bucket, the valve, m, and the discharging-valve, n, will be shut, because the pressure which opened them is removed; and the water and air in the pump preffling upon the valves in the bucket will open them, and pass through the bucket as it descends. At its return, it raises and discharges the water and air above it at the valve n, as before.

In this manner, when the engine has made two strokes, all the air which was contained in the cylinder, and mixed with the flume at the commencement of the operation, which was the only part from which it could not be expelled by blowing through, will be pumped out. The operation of the engine is now more perfect; the inhauting-valve is opened, to as to establish a communication from the cylinder full of flume to the condenser, the elasticity of the flume causes it to rush through the valve, down the pipe 13, into the condenser: when it arrives there, it meets the flume of the injection-water, which condenses it, the remaining flume in the cylinder following it surprizingly quick; and in an instant, an almost perfect vacuum is formed in the cylinder, so that the flume acts with its whole force upon the pilon to give it motion, all resistance upon the other side being removed.

The air-pump has now only to draw off from the condenser the water injected into it, the water produced by the condensed flume, and that small quantity of air or gas which goes from the boiler with the flume, and will not be condensed by the cold water. These are delivered by
by the air-pump into the hot-well, \( r \), from which the air escapes; and the water, which still continues hot, runs off, when at a certain level, by a valve-pipe, which is not represented.

The water which is boiled off in steam from the boiler, is renewed from the hot-well by means of a small pump, \( p \), in the elevation, which draws the water from it by a pipe \( s \), conducted up the side of the great frame \( K \), which stands at the end of the condensing cistern \( L \), and supports the bearing for the centre of the great beam. The water is conveyed from the pump by a pipe, to a cistern placed at the top of a vertical pipe, which descends into the boiler. The top of this pipe is closed by a valve in the cistern, which valve is raised by means of a lever, and the other end has a wire hooked to it, going through a small flting-box into the boiler, where a flite is hung to it. This flite is balanced by a weight suspended at the other end of the lever, so that when the flite is covered with water, the weight keeps the valve shut, and prevents any water getting down into the boiler; but as the water sinks in the boiler by the evaporation, the weight of the flite overcomes the weight, and opens the valve: the water in the cistern then runs down the pipe into the boiler, and raises the water therein, and the balance-weight lifts up the flite, so as to close the valve.

The cistern being constantly supplied with hot steam, which gives out its heat, it would at length render the water surrounding it in the cistern so hot, that it would condense no more. To prevent this, it is constantly supplied with cold water from a pump \( O \), worked by a rod \( P \), from the great beam. The water from the condensing cistern runs off by a valve-pipe at the back of the cistern, but not seen in the figures. The safety-valve is contained in a short pipe fixed upon the boiler, with a lid and a flting-box, through which a rod passes to open the valve within, and discharges the steam when the engine is not to be worked any longer. When at work, the valve is profiled down by a lever and weight. If at any time, when the engine is not at work, the steam should be heated, so as to be in any danger of bursting the boiler, the valve will lift up the weight, and allow the steam to escape through the pipe which opens into the chimney.

**Other Particulars of the Double Engine.** — Mr. Watt's mode of regulating the engine is a most beautiful contrivance, and so perfect, as to put the steam-engine on an equality with a water-wheel, in the regularity of its motion, even when the resistance is very variable. The throttle-valve, which regulates the supply of steam, is placed in the steam-pipe at \( z \) (Plate VII. fig. 2.) : it is a thick circular vane in the pipe, turning on a pivot across its centre, which comes through the pipe, and has a small handle fixed on the end of it: by turning this handle, the vane and vane within the pipe are turned also. When the vane is set, so that its plane is perpendicular to the axis of the pipe, it nearly fills the circular pipe, and allows very little steam, if any, to pass by it: but when the vane is turned edgeways, it presents a very small surface, and the steam passes by without obstruction to the steam-boxes \( g \) and \( l \). By turning the handle of the throttle-valve, the engine-man can at any time regulate the speed of the engine, the friction of the axis being sufficient to retain it as it is placed.

This method of regulation is sufficient for many engines; but when the steam-engine is employed to drive machinery, in which the resistance is very variable, and where a determinate velocity cannot properly be dispensed with, Mr. Watt has applied the conical pendulum, which is represented in the elevation (Plate VI.) at \( b s \), for procuring uniform velocity. (See also Regulator and Mill-work) This regulator has two pendulums, consisting of heavy balls, \( b, s \), suspended by iron rods, which move on a common joint, \( v \), at the top of the vertical axis \( x z \), which is put in motion by an endless rope, \( g \), passing round a pulley on the axis of the fly-wheel, and round another pulley upon a small horizontal axis, from which, by means of a pair of heaved wheels, \( r \), the motion is communicated to the vertical axis \( x z \), which is caused to revolve, and carry the pendulum with it. In this motion, their balls, \( b \) and \( s \), describe a horizontal circle, and the velocity is sufficient to make the balls fly out by their centrifugal force, the arms of the pendulums moving upon their centres: in this motion, the upper ends of the arms \( a w \) draw out a collar, \( x \), which slides on the square part of the axis, and operates on a lever \( x \), and by another lever \( y \), and rod \( w \), communicates with the flite or throttle-valve. The action of this beautiful contrivance is this: as the velocity of the fly-wheel increases and diminishes with the quantity of steam that is admitted into the cylinder, let us suppose that too much is admitted; then the velocity of the fly-wheel is increased, and the velocity of the vertical axis \( x z \) will also increase, and the balls \( b, s \), will recede from the axis by the augmentation of their centrifugal force. By this recedes of the balls, the extremity, \( z \), of the lever is depressed, its contrary action on the vertical axis \( x z \) causes the vane of the throttle-valve to present more surface, to close the passage a little, and diminish the supply of steam. The impelling power of the engine being thus diminished, the velocity of the fly-wheel and the flying balls decreases in proportion, and the balls resume their former position, and the engine works regularly.

The advantage of the sun and planet wheels has been exhibited to the public in making the fly-wheel revolve with a double velocity to that which would be produced by a simple crank, by which means a fly-wheel of smaller dimensions becomes sufficient to regulate the motion of the engine. Of late years, this ingenious contrivance has been laid aside in favour of the simple crank, because it has been found that the cogs of the two wheels, when they become worn and loose, act with a disagreeable jerk at every change of the motion from the ascent to the descent. As it is in many cases an advantage to make the fly-wheel revolve with a double or triple velocity, a large cog-wheel is applied upon the axis of the crank, and this turns a pinion of only one-half or one-third of the size, fixed upon the axis of the fly-wheel. Here the same defect of the jerk, by the looseness of the cogs, will be experienced; but the wheels being larger than can be used in the sun and planet wheels, a greater number of cogs are brought into action, and the wear upon each will be less: also, this form of the engine can be included in less room, because the centre of the large fly-wheel may be brought beneath the middle of the beam.

The power of the engine, when transmitted by the crank, is extremely variable throughout the different periods of the stroke: at first beginning, the crank being in a line with the connecting rod, the force of the piston has no action at all to turn the crank; but as the crank begins to make a sensible angle with the connecting rod, the force of the piston begins to operate upon the crank to turn it round, and this with a force increasing with the angle at which the connecting rod acts upon the crank, until they are at right angles to each other; and then the whole force of the piston operates to drive round the crank. To show the increments and decrements of this varying force, we have made out the following table from a projection of an engine on a large scale.

**A Table**
STEAM-ENGINE.

A Table shewing the force which the connecting rod of a steam-engine has to turn round the crank at different parts of the motion. The parts of the engine are supposed to have the following proportions: length of the stroke, 1:1 length of the beam, 2:1 length of the crank, 3:1 length of the connecting rod, 3:1.

</table>

The third column of this table also shews the force which is communicated to the fly-wheel, expressed in decimals, the force of the pileon being 1.

The above table explains itself by the titles of its different columns, and it is only necessary to remark, that the variations of force are not to be considered as an absolute los of power, because, when the crank has but light power, on arriving towards the top or bottom of the stroke, the pileon defeces proportionally slow; and, in consequence, the beam has more time to flow into the cylinder, and pres upon the pileon with a greater power; therefore, what the pileon loses in force upon the crank, it makes up in some degree by an increase of its force; and, from moving slower, it consumes less time than when moving with its whole velocity, and acting with full force upon the crank. Hence both the power and velocity of the pileon in the cylinder are to be considered as varying continually; and if the fly is sufficiently heavy, it will be found that the rotative motion is very nearly regular, while the ascent and descent of the pileon are accelerated from nothing at the top of the cylinder, to its greatest velocity at the middle, or near the middle, and from that point it is retarded till it comes to nothing at the bottom of the motion. The table shews the exact increments and decrements.

It has been considered desirable to have such a motion, that the power and velocity communicated to the fly-wheel shall be at all times equal and constant. This was one of the first attempts to produce a rotatory motion, as we have mentioned, by Mr. Fitzgerald, at Hartley colliery, in 1768: it has been repeatedly attempted since that period. The most practicable form in which it has been tried was by Mr. Murray, who, in a patent dated 1799, for the improvement of steam-engines, describes a very ingenious movement for the purpose. The defect of all these contrivances for obtaining equal power on the rotative axis is, that the pileon must act upon it at all times with a sudden shock, which in course of time destroys the bell contrived mechanism.

In the Philosophical Journal is a description of a contrivance by Mr. Samuel Clegg, for producing a rotative motion from a reciprocating one, which not only simplifies the machine very much, but exceeds the power of the common crank one-third, in consequence of its acting being always perpendicular to the radius of the wheel, which is done by a vertical double rack and wheel. The two vertical parts of this rack are joined by a femicircle at the top, and both parts are teethed on the infide, so that the teeth of the vertical wheel are constantly in contact with some of the teeth of the fork formed by the two vertical bars and the femicircle uniting the double racks. The wheel and racks are constantly kept in gear by means of a small roller, a sliding-bar, and a plate, serving, instead of a groove, to keep the roller from deviation in this way. Although the change from the upward to the downward motion of the pileon-rod must be gradual, the change from the downward to the upward motion must be instantaneous; or at least the pileon-rod must be brought to rest at once, from an uniform motion downwards, and then receive instantaneously a finite velocity in the opposite direction.

A mode of giving a more uniform action to the crank, was attempted in an engine erected by Mr. Hornblower about 1795, at the brewery of Mr. Meux and Co., where the alternate power of two reciprocating cylinders was applied by chains acting upon circular arcs, at a constant distance from the centre of the lever; while the end of the lever which was connected to the crank by the connecting rod continually varied in its action, and consequently in its force on the crank, nearly in an equal proportion to the alteration of the leverage of the crank. (See the sketch of this contrivance at fig. 7, Plate V.) The two cylinders, A, B, of this engine made an alternate action on a band-wheel, D, by means of two chains. The lever which carried the connecting rod, F, was a wheel fixed on the same shaft with the band-wheel, and had a pin, E, near its periphery, to which the connecting rod, F, was attached. This pin traversed about 120° of the whole circle, and thereby determined the end of the lever, which, in its action upward to 6, and downward to f, ascended and receded to and from the centre of motion; and had it traversed through the remainder of the femicircle, it would then have pressed on the crank, G, proportionately to the sine of every angle it made in its revolution. But considering the great preface on this pin in the crank-wheel, it would have demanded a degree of strength in that part which would have been preposterous, compared with the rest of the work.

This engine has its merits and its defects; it is subject to much more friction than a double-acting cylinder, by having two cylinders and their appendages; and unless the communication between the cylinders is clothed with the best materials for that purpose, a great los of heat must ensue; because the surface exposed in two cylinders, compared with one double-acting cylinder, is as 2 to 1, and the friction of the pistons will be nearly in the same proportion.

The air-pumps in this engine (for it had two, though only one condenser) were worked by a small band-wheel, upon the same axis as the great band-wheel D; and from the opposite fides of this, the rods, x, y, were suspended by chains. The air-pumps were open at top, and the preface of the atmosphere always acted upon their pistons; but as the two were acting in opposite directions, they balanced each other, and threw power;
power: in this the inventor adopted the common double-barrelled air-pump of Haukbee, instead of the more perfect air-pump of Smeston, which Mr. Watt employs. This engine was considered of 36 horses' power, and for many years performed all the work of the brewery. We have also seen some smaller engines built on the same plan, one of them with atmospheric cylinders.

It may be considered as an advantage in this engine, that it has a double air-pump, whereas the double cylinder has only a single air-pump, which draws out the air from the condenser while the piston is making its ascending stroke; but during the descent of the piston the air-pump is inactive. We have seen many proposals for double-acting pumps.

Mr. Murray, in 1801, had a patent for a new air-pump, (see the specification in the Repertory of Arts, 2nd series, vol. xvi.); but we have not had an opportunity of ascertaining the performance of an engine to constructed; and as the ingenious inventor does not now adopt it in the steam-engines which he makes, we may presume it is not of great importance.

The proportion usually given to the air-pump of a double engine is about two-thirds the diameter of the cylinder, and half the stroke, or from one-fourth to one-fifth the capacity of the cylinder; the condenser is of the same size. Whether it is owing to the circumstance of the single air-pump or not, we are unable to determine; but it appears that double-acting engines do not in general produce so great an effect from the fuel they consume as single engines of the same dimensions.

In Melfirs' reports of the engines in Cornwall, which generally contain the accounts of 20 or 25 engines, there are several enormous double engines for pumping the mines, with cylinders of 66 and 65 inches, and four of 63 inches. The belt of these appear to be on Williams' mine; cylinder 63 inches diameter, and working with a stroke of 6 feet 9 inches, under a pressure of 16.6 lbs. per square inch; it works 10 pumps, which are a load of 704.41 lbs., at the rate of 61 strokes per minute, of 6 feet 9 inches each. Its performance with respect to coal was, in June 1816, 30,074.507 lbs. lifted one foot high for each bushel consumed. This is a very good performance; but all the other double engines are less, one of the 63-inch cylinders is 27 millions, the others 25, 22, 21, and even 17 millions.

The advantages are all on the side of the double engine; the diminution of surface which is exposed to condensation, the vis inerter of the parts in motion is much less, and the friction of the piston is very much reduced, although the friction of the joint for communicating the motion must be increased, because they must be bound tight, so as to have no shake or looseness; but this must be considerable.

Before quitting the subject of double engines, employed to give a rotary motion to machinery by a crank, we must notice the remarkable difference, shown by Melfirs' reports, between the performance of the small engines employed in drawing the matter out of the mines, and those in pumping water.

We should think the loss of power from friction in drawing up buckets by a rope, could not be greater than the friction of pump-buckets, and of the water moving in the pipes; therefore all the difference must be attributed to the application to the rotary motion, and to the smallness of the engines: these are usually 14, 16, and 24 inches in diameter, but their performance, with respect to coal, is only 3, 32, 4, and 5 millions. The belt engine they have drawn only from 9 to 11 million pounds one foot high for each bushel of coal, which is only one-third of the produce of the belt large engines employed in pumping.

One of Woolf's double engines at Wheal Fortune mine, in May, 1816, drew only three million pounds one foot high with each bushel; but another at Wheal Vor mine drew six millions.

**Elimination of the Force of Steam-Engines in Horses' Power.**

—The method of expressing the mechanical power of any machine by the weight of water or other matter which it will raise to a given height, in a certain period of time, or with a given quantity of fuel, is the most unequivocal expression that can possibly be obtained; but as steam-engines are frequently substituted in the room of horses, it has been customary to calculate their mechanical energy in horse-power, or to find the number of horses which could perform the same work. This, indeed, is a very vague expression of power, on account of the different degrees of energy which different horses possess; but still, when we are told that a steam-engine is equal to sixteen horses, we have a more distinct conception of its power, than when we are informed that it is capable of raising a given number of pounds weight through a certain space in a certain time.

Prior to Mr. Watt's application of the steam-engine to produce rotary motion, the great manufactories of the kingdom had their mill-work put in motion by the agency of water, wind, or of horses; and the latter had for many years been almost exclusively employed in the breweries and distilleries of the metropolis. It was, therefore, natural for those who wished to sublimate the power of steam for that of horses, to flate the number of those animals, to which the new power, under given conditions, ought to be equivalent; and it is probable that Melfirs, Watt and Boulton felt, that such a mode of comparison would be more intelligible to common apprehensions, than a more accurate and scientific formula: it gave the power of an engine expressed in numbers, of which the ordinary strength of a horse is the unit. This, no doubt, is not in itself very exact, the unit being large, and subject to considerable variation. Relative to the purpose for which it was used, it was, however, sufficiently correct; and on this, as on many similar occasions, a more minute measurement would have been less useful. But to give this unit all the accuracy which can be defined, they have assumed, from the result of experiments made with the strong horses employed by the brewers in London, that the standard of a horse's power is a force able to raise 32,000 lbs. one foot high in a minute; and this, no doubt, was meant to include an allowance of power sufficiently ample to cover the usual variations of the strength of horses, and of other circumstances that might affect the accuracy of the result. In forming the estimate just mentioned, we think the power of a horse is rated above the ordinary average, a circumstance which cannot be complained of by the public, as it tends to represent the advantage of the engines less than it will be found in real practice.

Dr. Brewster, in his edition of Ferguson, states that Melfirs. Watt and Boulton suppose a horse capable of raising 32,000 lbs. avoiding one foot high in a minute; whilst Dr. Defagghers makes it 27,500 lbs. and Mr. Smeston only 22,383 lbs. If we divide, therefore, the number of pounds which any steam-engine can raise one foot high in a minute by these three numbers, each quotient will represent the number of horses to which the engine is equivalent, according to the estimate of these different engineers. We will take, for example, an engine having a double-acting cylinder, on Mr. Watt's plan, 24 inches diameter, and which makes 20 strokes per minute, each stroke being five feet long, and the force of steam being equal to a pressure of 10 lbs. per square inch. Required the number of horse-power of such an engine.

The square of the diameter of the cylinder being multiplied by the decimal number .7854, will give the area of the piton:
pilum; thus, \(24 \times 24 = 576 \times 0.7854 = 452.4\) square inches, which are exposed to the preflure of the beam. Now if we multiply this area by 10 lbs., the preflure upon every square inch, we shall have \(452.4 \times 10 = 4524\) lbs., the whole preflure upon the pilum, or the weight which the engine is capable of raising with a certain velocity. To find this velocity, we fay that the engine performs 20 double strokes, each of five feet long, in a minute; the pilum must, therefore, move through \(20 \times 5 \times 2 = 200\) feet in the fame time; and, therefore, the power of the engine will be reprefented by \(4524\) lbs. avoirdupois, raised through 200 feet in a minute, or by \(9\frac{1}{2}\) hogheads of water, at mean fpeed, raised through the fame height in the fame time. Now this is equivalent to \(4524 \times 200 = 904,800\) lbs. or \(9\frac{1}{2} \times 200 = 1848\) hogheads raised through the height of one foot in a minute. This is reduced to the horse-power of Meffrs. Boulton and Watt, by dividing by 32,000, their estimate of the horse-power: thus, \(904,800 \div 32,000 = 28\frac{1}{2}\) horsef.

According to Smeaton, \(904,800 \div 2916 = 32\frac{1}{2}\) horsef.

According to Daferger, \(904,800 \div 27500 = 33\) horsef.

In this calculation, it is fuppofed that the engine works only eight hours a day, fo that if it worked during the whole 24 hours, it would be equal to twice the number of horsef found by the preceding rule.

Other Constructions of Mr. Watt's Double Engine.—A great mass of matter must neceffarily be put in rapid motion at every stroke of the reciprocating engine, and the motion muft be altered and returned at the end of the stroke. This is an evident difadvantage under which the double engine labour; for though all objection to the reciprocation, on account of the irregularity of motion, is done away by the application of a fly-wheel, the regularity thus attained is at the expence of the power, as we have fhewn in the practical refults of the large engines for pumping, and the engines for drawing from the mines. The most obvious improvement in this particular, is to lighten the mass of the great working beam, or to difpence with it alto-gether. The enormous strain exerted on its arms requires a proportionant strength, and this requires a vaft mass of matter, not less indeed (in an engine with a cylinder of 52 inches diameter) than three tons and a half, moving with the velocity of three feet in a second, which muft be communicated in about half a second; fo that this mass must be brought into motion from a flate of rest, and muft again be brought to rest, again into motion, and again to rest, to complete the period of a stroke. This consumes much power; and engineers have not been able to load an engine with more than 10 or 11 lbs. on the inch of the pilum, and prefer a fufficient quantity of motion, fo as to make 12 or 15 seven-feet strokes in a minute. Many attempts have been made to lighten this mass, by using a light framed wheel, or a light frame of carpentry, in place of a solid beam.

An example of this is fhewn in the beam of Newcomen's engine (Plate II.), a method which was introduced by Mr. Smeaton; and another is fhewn in Mr. Hornblower's (Plate V., fig. 1.) The form of this beam is fuch, that it would be stronger than a solid beam containing a great many times the quantity of timber, as there is fearely any part of it which is exposed to a tranverse strain, but every piece is either pushed or pulled in the direction of its length. The only evident improvement of which it admits, is to apply a strong tie-bolt along the whole length of the upper beam; because when tie-beams of wood are used, it is very difficult to connect the iron flaps to the ends of them in fuch a manner, that they will not become loose in time. This is an objection to framed working beams, for although they are abundantly strong at first, yet, after being some time employed, the flaps and bolts with which the wooden parts are connected, cut their way into the wood, and the framings become loose in the joints, and, without giving any warning, are liable to break to pieces in an instant. A solid massive beam of sufficient strength bends, and feebly complain (as the carpenters express it,) before it breaks. In all great engines, there-fore, Mr. Watt at first employed fuch solid beams as were found the most durable, and leeft likely to break in a long course of work.

They were sometimes strengthened, in a very fimple and effective manner, by placing a king-poit perpendicular to the length of the beam, over its centre, and extending iron tie-bolts from the top of the king-poit to the two extremities of the beam, fo that the beam thus framed forms a triangle, of which the beam is the base, the king-poit the perpendicular, and the iron ties the fides, meeting the perpendicular at the vertex of the triangle.

This was an expedient generally refered to, when the beam was found to yield from a long continuance of the action. There is, perhaps, no example, except the mill of a ship, in which a piece of timber is exposed to such a severe strain as the beam of an engine, becaufe it is neceffarily made as small as poiffible; and it is relieved from the strain 15 or 20 times every minute, fo that all the fibres are tried to the utmost: we accordingly fee old beams, full of cracks lengthwise from the fibres, separating laterally, and after this the beam lofs its strength.

Of late years, wooden beams have been altogether difdifed, and cast-iron beams substituted. We have already defcribed the mode of making the beam for the largest engines, by two plates or fitches put together parallel, and leaving a space between them. For double engines, which are not of the very largest dimensions, it is ufual to have the beam call in one piece, of a form bent adapted to give the greatest strength in the leaff weight. (See Plate IX. Steam-Engine, Parallel Motions.) The extremities of the beam are turned in a lathe to form cylindrical pins, and upon these pins are fitted sockets or pieces, which have other pins projecting from them to form the joints of the parallel motion and connecting rod; fo that when the sockets are fixed on the ends of the beam, the pins will project from the beam in a direction perpendicular to its length, and parallel to its axis of motion. There are two pins thus projecting from each end of the beam, that is, one pin on each tide of the focket: the two links of the parallel motion are fitted to the two projecting pins at one end, and the double joint of the connecting rod is fitted on the two pins at the other end of the beam. The advantage of this con-struction is, that the joints at the ends of the beam become universal joints, having liberty of motion in all directions: thus, in the direction in which the joints of the parallel motion and connecting rod are required to bend for the motion of the beam, as fhewn in the figure, the motion will be upon the projecting pins of the sockets, but if, from the axis of the beam not being rightly placed, or from any other caufe, a lateral flexure is required in the motion of the beam, the sockets of the joints will turn a little sideways upon the end of the beam, and allow the deviation, without any strain on the moving parts: were it not for this contrivance, the smallest possible deviation from the perpendicular direction of the cylinder would cause a great friction in the perpendicular motion, and the flapping-box and joints. In Mr. Murray's belt engines, the crankpin is also jointed to the connecting rod by a universal joint. See Plate VIII. fig. 4.

All the joints of the parallel motion, the connecting rod, and
STEAM-ENGINE.

and crank, in short, all the moving joints of a double engine, must be fitted with brass sockets, which may be tightened round the pivots, so as to prevent all shake or looseness, which, in an engine that works both in ascending and descending, would be destructive of its action. The two great links of the parallel motion are each composed of a flar or loop of iron, bent so as to make a double link, in the upper bend of which are two brasses for the pivots at the end of the beam, and at the lower end are two others, for the pivots which project on each side from a pocket, which is fixed on the top of the piston-rod. The brasses of the latter joint are held in by wedges, or cross-keys, put through the two links at the lower end, so that by driving the wedges farther, the brasses can be drawn tight at pleasure. The two inlets: brasses, that is, the lower brasses of the upper joint, and the upper brasses of the lower joint, are kept extended to their proper distance by a piece of wood, or a light frame of iron, fitted in between them.

But we have not yet satisfactorily explained the action of the parallel motion. It is plain that the piston-rod must ascend and descend in a perpendicular right line, and also that the end of the beam must ascend and descend in the arc of a circle. When the beam rises into the position of Plate VI. from a horizontal one, it gives the piston-rod a tendency to move from its perpendicular towards the centre of the beam, which must move towards it, was not the link, b, attached to the beam and piston-rod by flexible joints; and while the lower end of the link, b, rises, the end of the bar or lever m, dotted, which is moveable on a fixed centre n, also rises at the same time, and the angle between m and e increases, and likewise the angle between b and c increases slowly; so that the vertex of the angle between b and e would move towards B, if the bar, m, was not confined to move round the fixed point or centre m, while the other end rises along with the rod b. While m, therefore, rises upon its centre, the adjoining bar, d, moves round the joint at its upper end, and draws e, and the lower end of b, from the centre of the beam, the angle between d and e increases, and the joint between d and e recedes from the centre of the beam; and as it cannot approach nearer to the joint between b and c, because of the rod c, it keeps a, and the bottom of b, in a perpendicular position; so that whatever tendency the joint between b and c has to approach towards the centre of the beam by the increase of the angle between b and c, is corrected by an equal tendency of the lever, m, to draw the angle between d and e in a contrary direction; but as the beam, B, falls into a horizontal position, all these motions are reversed. In adjusting the parallel motion for work, when the piston-rod, a, is found to rub much upon the side of the collar of the flaring-box nearest to m, the fixed centre point, m, must be shifted a little in the contrary direction, w.r.t. to remove it nearer to the centre of the beam, and in an opposite direction if it is found to rub on the other side.

That the nature of this parallel joint may be better understood, it is proper to observe, that all the bars which have been mentioned are made double, which cannot be shown in the figure, and that the two levers, m, m, are placed at a sufficient distance from to allow the links b, and the rods e, to descend between them.

Of late years, the framing for the support of the engine has been wholly made of cast-iron. A very good form is to make the collar, L, of cast-iron, all in one solid piece, and to fix the cylinder A upon it with four feet: a single column is then erected upon the end of the collar L, to support the center of the beam: the fly-wheel is supported by small cast-iron standards rising from the ground; and the center of the lever m, of the parallel motion, is supported by a small bracket or flanean erected from the flange of the cylinder. By this arrangement, all the parts of the engine are so united, that they cannot deviate in the least from their position, unless the parts are actually broken. An engine on this plan is fully described in the British Encyclopedia, vol. vi.

The engine represented in Plate VIII. fig. 4. is perhaps the most complete of all. It is of the form in which Messrs. Murray and Wood construe their engines, when they are not of a very large power.

Steam-engines without Beams.—These have been made in a variety of forms. The simplest of all is to connect the piston-rod at once with the connecting rod, and to place the crank over the centre of the cylinder: the piston-rod must be guided by a parallel motion, or by sliders. The objection to this is, that the fly-wheel becomes elevated to too great a height for the communication of its motion, except in very particular circumstances, without shortening the connecting rod, which occasions the irregularity of the action of the crank to be greater than that of our table, in which the length of the connecting rod is supposed to be six times that of the crank, or three times the stroke of the engine, as a shorter cannot be made to work well. There is also a difficulty in balancing the weight of the piston-rod, connecting rod, and crank, and in giving motion to the air-pump. The balance-weight is usually placed on the rim of the fly-wheel; and the air-pump is either worked by a second smaller crank upon the axis of the fly-wheel, or by a short beam.

Engines of this kind are frequently placed with the cylinder horizontally, and for small engines this answer very well; but in large ones, the weight of the piston acting always at one side wears the cylinder irregularly. Mr. Murray included this plan in his patent of 1799, which we have before mentioned, for producing the rotatory motion without a crank; and he proposed to place rollers in the piston to bear it up.

Steam-engines with horizontal cylinders are used with the greatest advantage in steam-boats, as they can be made to lie low beneath the deck of the boat. Mr. Symington, we believe, first introduced this plan.

We have seen several engines working without a beam, in which the crank was placed immediately over the cylinder, and with the axis of the crank little more than its length above the top of the cylinder. For this purpose, the piston-rod is prolonged upwards to a length of three or four times the stroke of the engine, and the top is guided in a groove, or by a friction-wheel: near the upper end of it is jointed the connecting rod, which descends down to the crank-pin, situated behind the rod, and as close above the cylinder as it can turn round clear of its top. By this means, the alcent and descent of the piston-rod produce the rotation of the crank, the lateral deviation of the crank from the perpendicular being allowed for in the angle which the connecting rod makes with the prolonged piston-rod.

In this way the crank must be placed behind the piston-rod, or out of the line of it; but it is not then thought to work so well.

To remedy this the crank is made double, and the prolonged piston-rod has an opening in it for the crank-pin to pass through, and a connecting rod is placed on each side of the piston-rod, so that it is worked between the two. It is evident that the opening through the piston-rod must be a groove, equal in length to the stroke of the crank, so that the whole of the motion of the crank-pin, from one side to the other, can be admitted in the opening, without influencing
STEAM-ENGINE.

A very ingenious method of converting the reciprocating motion of the piston-rod at once to a rotatory motion is represented in Plate IX. fig. 5. Parallel Motions. A touched wheel, C, of a diameter equal to half the stroke of the engine, is made to roll round within a ring or fixed wheel A, having interior cogs, and being of a diameter equal to the whole stroke, or twice as great as the internal rolling-wheel C, which is carried round in a circular orbit, so as to work in the cogs of the ring, by having the crank-pin, R, for its centre of motion. By this means, every half turn of the crank will produce half a revolution of the centre of the small wheel in its orbit; and as it is all the time engaged by the cogs of the ring, it makes, during this motion, a whole revolution upon its own centre. The consequence of this is, that a point taken in the circumference of the small wheel, will travel up and down, acrofs the centre of the interior ring, in every revolution of the small wheel in its orbit; that is, it will describe a right line, which is a diameter of the ring. A pin, F, being placed in a proper point of the circumference of the small wheel, and the top of the upper end of the perpendicular arm being attached to it as it ascends and descends, will produce a rotation of the crank, upon the axis of which the fly-wheel is fixed.

This parallel motion is described in the article Parallel Motion. It has been employed by Mr. Murray in many of his engines: the objection to it is, that the cogs in time grow loose, and it then makes a very noisy and unsteady motion.

Bell-Crank Engine.—This is a very compact form of the steam-engine, which Mellers, Boulton and Watt began to make soon after the expiration of their patent.

The cylinder is supported by brackets from the caft-iron condensing cistern, and is placed over one end of it. The beam is formed like a bell-crank, that is, a right-angled triangle, the centre of motion being at the right angle, and the axis of it is supported by bearings screwed to the cistern at the lower side and at the end opposite to that upon which the cylinder is placed, the horizontal arm of the triangle forms the working arm of the beam, to the extremity of which the power of the cylinder is applied. At the upper end of the perpendicular arm the end of the connecting rod is jointed, and extends to the crank, which is supported in bearings screwed to the cistern at the same end at which the cylinder is placed, the centre of motion being at the same level with the top of the cistern; and beneath the cylinder, the hypotenuse of the triangle of the beam forms a brace to strengthen it. Two of these beams are used, and are applied on opposite sides of the cistern, upon the same axis of motion, and are united together by crofs rods, so that they move together in the same manner as if they were one. There are, therefore, two connecting rods and two cranks; but they are formed upon one common axis of motion, which is prolonged, to carry the fly-wheel. To connect the piston-rod with the ends of the arms of the beam, or what we have called the base of the right-angled triangle, a rod is fixed upon the top of the piston-rod, across the same, at right angles; and to the two ends of this two rods are fixed, which are jointed to the beam, and are jointed to it at the ends. By this means, the ascents and descents of the piston-rod produce a corresponding motion of the beam upon its centre of motion, and the upper end of the perpendicular arm moves backwards and forwards, and by means of the connecting rods turns the cranks. The perpendicular arms of the beam are shorter than the arms to which the cylinder-rod is attached, so that the motion of the connecting rods, and the sweep
STEAM-ENGINE.

sweep of the cranks, are less than in an engine where the
arms of the beam are equal.

The rods which descend from the bar which is fixed
across the top of the piston-rod to the ends of the beams,
are of finc length, that the obliquity which is occasioned
by the circular motion of the ends of the beams is small,
and the engine does not require any parallel motion to keep
the pinion-rod perpendicular. The fame of the air-pump,
which is placed in the middle of the cylinder, and is worked
by two rods jointed to the horizontal arms of the beams, at
half the distance from the centre of motion at which the
cylinder-rod are applied.

In these engines, valves are not used for admitting
and taking away the steam from the cylinder; but to perform
this office, a slider, invented by Mr. Murdoch, and repre-
vented in Plate VII. fig. 9, is used: the motion is commu-
nicated to the slider by an eccentric wheel or rim, fixed
on the fly-wheel. The bell-crank engine is very compact,
and is well adapted for temporary use, as it stands wholly
upon the cillern, and requires no fixing. We have seen
it used in a steam-boat.

Different Methods of admitting Steam alternately into the
Top and Bottom of the Cylinder.—The arrangement of
the four valves invented by Mr. Watt has been described.
This is now almost universally laid aside, in favour of
more simple contrivances, though we think there is not
any method so complete in its action, or so durable. For
large engines, four separate spindle-valves are still used;
but the method of lifting them is changed, the spindle of one
valve being formed like a tube, for the spindle of the other
to pass through. This plan is described in the specification
of Mr. Murray's patent of 1801, the fame which was for the
improved air-pump.

The arrangement of the pipes and passages is the fame,
and the valves are situated in the same places; but the
boxes which contain them, instead of being square, are
cylindrical, and the spindles of the valves are placed con-
centric with the axis of the cylindrical box. The spindles
of the two steam-valves are perforated through the centre,
in the manner of tubes, and rise through a flushing-box in
the top of the box, and levers are there applied to
lift them, instead of the lever or sector within the box, as
defcribed in the first engine. Through the tubular axis of
the upper valves a small rod is conducted, which forms the
spindles of the lower valves; and this junction is made
tight by a flushing-box formed at the top of the tubes.
The operation of the valves is in every respect the fame as
for the former; the only difference is in the mode of commu-
nicating motion to them from the outside, and at the top of
the steam-box, both pair of valves being moved by rods
through an opening in the lid of the box. See Plate VII.
figs. 4 and 5.

This method is neat in its appearance, and answers equally
well with the other when properly made, but it is not easy to
make it like the other; for if the lid of the steam-box, when
furnished on, deviates in the smallest degree from the central
position of the valve-spindle which passes through its flushing-
box, both the valves will be prevented from applying them-
sefes exactly to their seat. It is necessary for the two
valve-fields, and the flushing-box through the lid, to be made
precisely on a common centre, line, or axis; and for this pur-
pose, the upper part of the cylindrical box which contains
the valves is bored out correctly within and, and the conical
sockets in which the bell-metal seats for the valves are to
be placed, are bored at the same time; then the lid of the box
which has the flushing-box in it, being turned in the lathe,
with a small projection beneath its flange to drop into the
top of the cylindrical box, it will be certain to apply itself
exactly in the centre of the box, and also perpendicular, when
it is screwed down in its place, because the under surface
of the lid, and the upper surface of the steam-box, have been
accurately formed each of them concentric with, and
perpendicular to, the axis of the valves; but it is neccessary
in general caution in applying packing between these two
surfaces, because it will yield unequally, if the screws at one
side are screwed down more forcibly than those on the other
side, and thus put the flushing-box out of the perpendicular.
To prevent this, Mr. Murray makes the lid of the box with-
out any flange, but it is exactly fitted into a small recess or
 rebate, formed for it all round at the top of the steam-box, by
enlarging the diameter thereof a small quantity, as shown in
fig. 15. There is no packing applied to the joint, and it is
then certain that the lid of the box will come to its true
place. To prevent leakage, an iron ring is applied all
round with a packing beneath it to cover the joint; and this
packing and ring being screwed down by four screws makes
it tight, and at the same time keeps the lid flat; but by
removing the ring, the valve can be taken out of it, to repair them.
Mr. Murray's patent was reflected by a writ of jeire facias, at the influence of Mellers. Boulton and
Wat., who had previously practised some things contained
in the patent; but we believe Mr. Murray was the first who
made valves in the manner represented in the figure.

In small engines, the machinery now employed for opening
and shutting these four valves is different from Mr. Watt's
original engine, and much more simple. The motion is
given by a rotative motion from the main axis of the fly-
wheel: a wheel is fixed on the axis of the fly-wheel, and
communicates motion by other wheel-work to a horizontal
axis (Plate VII. figs. 4 and 5), upon which are two eccentric
wheels, which open and shut the valves alternately. Each
of the boxes may be considered as being divided into three
compartments by the two valves, and the steam is always
admitted into the top of the upper box, where the upper steam-valve
is situated; its use is to admit steam which comes from the boiler
through the steam-pipe into the middle compartment of the
box, which is the passage, 14, communicating with the top
of the cylinder. In this compartment is the upper condensing
valve, 9, which is moved by a rod passing through the rod or
spindle of the upper steam-valve 7; the valve 9 is for opening
a passage from the top of the cylinder to the condenser,
through the exhausting-pipe 13. In the latter manner, the
upper valve, 5, of the lower box is called the lower steam-
valve, and is for the purpose of admitting the steam which
defends through the pipe, 12, into the bottom of the cylinder,
below the piston. The valve 5 is for connecting the
bottom of the cylinder with the condenser, and is therefore
called the lower condensing valve.

The two rods, L, M, connect the four valves together in
pairs; thus, the rod L has an arm projecting from it at
each end, one at its top, fastened to the stem of the upper
condensing valve, and the lower steam-valve is connected
with it at its bottom; it will consequently, when it is lifted
by the eccentric wheel, which is contained within an
opening in the rod, open those two valves, and, by causing
a vacuum above the piston, and a pressure of steam
beneath it, will force it upwards to the top of the cylinder.

The rod M is connected with the upper steam-valve at the
top, and with the lower condensing valve at the bottom.
When it is lifted up by the eccentric wheel, which works in
an opening in the rod, it admits steam above the piston, and
causes a vacuum below, in which situation the piston will
defend. One of the rods which connect the valves must be al-
lowed to defend by its weight an instant before the other is
lifted,
STEAM-ENGINE.

lifted, otherwise the steam will have a free passagé from the boiler to the condenser, a fault which is called blowing through, but is an operation practiced every time at setting the engine to work, after having been some time at rest, for the purpose of expelling the air from the condenser. To blow through with this engine, all the four valves must be opened at once, which is done by lifting the two rods, L, M, both together.

Fig. 6, represents an ingenious form in which Mr. Murray makes the eccentric movements for working the valves, so that they shall move all at once, and not have the liberty of returning until the proper time.

The eccentric triangle, A B, has its sides formed by arcs of circles: the axis of motion is made to coincide exactly with one of the angles, A, and the arc, B, is described from that centre. The eccentric triangle is included within a parallel groove, C D, in an iron frame, in which it exactly fits, as in the figure. In this position, it is evident that the frame is immovable; it cannot ascend, because the circular part, B, bears against the lower side, D, of the groove; nor can it descend, because the angle, A, bears against the middle of the upper side, C; at the same time, the eccentric triangle can move round a certain part of a revolution before the rod will be moved at all, and then it will rise all at once; so that the middle of the lower side of the groove, D, will bear against the angle or centre of motion, A, and the upper side, C, will be borne by the arc, B, of the eccentric triangle.

Four-paffaged Cock.—Of late years, instead of the four valves invented by Mr. Watt, cocks and slides have been much used for alternately admitting the steam into the cylinder above and below the piston: they have the advantages of simplicity and cheapness, as one cock or slider is made to answer the purpose of the four valves.

What is called the four-paffaged cock is the most readily applied to practice. This is represented in Plate VII. fig. 6, which is the cylinder of an engine made by Mr. John Dickinson, who erected a great number exactly the same: the cylinder and its piston, with the lid and stuffing-box for the rod, are evident from inspection. The cylinder has a flange or projecting ring round it, a little below the middle, by which it is held in a jacket or cafe of cast-iron ecc, which is constantly supplied with steam from the boiler by the pipe e f f', which is a pipe, cast at the same time with the cylinder, leading from the top of it, and by a crooked passagé to the cock E; g g is another similar passagé from the bottom of the cylinder to the cock, and entering it diametrically opposite to the other passagé: h is an opening, bringing steam from the jacket ecc, by means of a short pipe, not seen in the figure, being behind the cylinder, but cast at the same time with it, and joining at bottom to the flange, by which it is held in the jacket. The bore of this short pipe is, however, continued through the flange, and opens into the jacket; and when they are screwed together, the steam has free access from the boiler through the jacket into the short pipe, and thence into the passagé h, which advances horizontally forwards, as represented by the dark circle h, fig. 6, and turns into the cock; the short pipe has a thin circular vane in it, turning upon a pivot to form the throat-valve, as we have before described.

When the steam is not made to pass through the jacket, the circular passagé, h, may be considered as the continuation of the steam-pipe coming immediately from the boiler; and then the throat-valve is placed in some part of the same pipe: p p is the pipe conveying the steam away from the cylinder to the condenser, which is of the ordinary construction. K is a handle fixed upon a spindle, on which is a rack, turning a cog-wheel upon the end of the cock E; this rack is partly seen in the drawing, but the piston is concealed. There are two pins fixed upon the rod of the air-pump, which take the handle K, as they move up and down, and thus turn the cock a portion of a turn each time; there is also a lever fixed upon the spindle of the handle K, the ends of which stop against the ends of a crooked steel-spring screwed to the iron frame supporting the bearings for the spindle of the rack; so that the motion allowed thereby to the handle, K, and the rack, will turn the cock one-fourth of a whole turn, but no more. N is a cock communicating (when open) from the jacket ecc to the pipe p p, and thereby to the condenser, for the purpose of blowing through at first starting the engine. Now, suppose the steam flowing through the steam-pipe, e, from the boiler, it enters between the jacket, ecc, and the cylinder, passes through the short pipe and throat-valve into the opening h, thence through the crooked passagé in the cock E, to the pipe f f', leading to the top of the cylinder, thus causing the piston to descend. The steam in the lower part of the cylinder escapes, by the pipe g, through the other passagé of the cock E, and by the pipe p p, into the condenser. When the piston arrives at the bottom of the cylinder, the pin on the air-pump rod carries down the handle, K, which, with its rack acting in the piston on the end of the cock E, turns it into the position seen at fig. 7. The operation is now reversed, the steam enters from the jacket at h, through the cock E, and by the pipe g, into the bottom of the cylinder, forcing the piston to the top; at the same time the steam contained above the piston escapes through the opening f f', and the cock E, by the pipe p p, into the condenser. When the piston on the air-pump rod reaches the handle, K, in its ascent, it returns the cock to the position at fig. 6, when the operation is repeated.

Nothing can be more simple, or appear more perfect, than this contrivance, which was originally used by Papin in his air-engines; and Leopold, in his Theatrum Mechanicum Hydraulicae, vol. ii, has shown the manner of its application to a high-pressure steam-engine.

In practice it has several objections. The pipe leading from the top and bottom of the cylinder to the cock is so much added to the volume of the cylinder, and the quantity of steam which they contain must be wasted every stroke without any advantage; but in the four valves, there is no greater loss than of the small quantity of steam which is contained in the passagés at the bottom of the steam-pipes, when the cock is open, and which are purposely made as narrow as they can be to admit the steam freely. Secondly: The passagés cannot conveniently be made large enough to admit a full supply of steam, though it should be under-foot, that, in the other direction, they are three or four times as wide as they appear in the section, fig. 6.

In these engines the steam is always wire-drawn in passagés through the passagés; hence the steam in the boiler must be made stronger than it is intended to be used in the cylinders, to which, however, there is no objection, as it gives it something of the expansive action. Thirdly: These cocks do not wear equally; because there is much less surface exposed to friction in the part where the passagés are; and as the surface which is interposed between the passagés is so small, they leak immoderately from one passagé to the other, unless the setting of the cock is perfect. For these reasons, the four-paffaged cocks have been confined to small engines, and principally those which work with high-pressure steam, because that will pass through very small openings.

Mr. Bramah has made several steam-engines, in which he employed a four-paffaged cock on a construction somewhat different from the above. The steam from the boiler is made to enter into a hollow at the large end of the cock of
of the cock, and to pass away to the condenser by a passage at the small end of the cone of the cock, which, by this means, is always pressed into its seat by the force of the steam acting upon a surface equal to the small end of the cock, from which the prelude is relieved. This keeps the cock always tight; and to prevent the movable part from being fixed by the prelude, the cone is made much more obtuse than usual. The passages for the steam between the cock, and the top and bottom of the cylinder, are nearly the fame as in fig. 6. Mr. Bramah had a patent for this in 1802; and another improvement was, that he made the cock to turn continually the fame way round one-fourth at a time; by which means the frame effects are produced as by turning it backwards and forwards, but the wear is rendered more equable.

Mr. Maudslay has adopted in his engines a four-paflaged cock, in which the steam is made to pass the cone into its feet.

**Sliding-Valves by Mr. Murray.**—With a view of remedying the inconveniences of the four-paflaged cock, the frame effect has been attained by a plate sliding upon a flat surface, in which the passages are formed. A cylinder, with a slider upon this construction, is represented in Plate VII. fig. 8. It is used by Mr. Murray in small steam-engines, and found to answer the purpose extremely well, from the simplicity of its construction, and its durability, but, above all, from not being subject to wear or get out of order. A A represent the cylinder, included in a cast-iron jacket, and surrounded with frame; it is furnished with a pinion-bid, and stuffing-box, for the rod to pass through in the usual manner; c is the passage for the steam to enter the top of the cylinder; and e, the passage into the bottom, to admit steam below the piston. The steam is conveyed from the boiler by the pipe B, passes through the throttle-valve c, and into the steam-box d d, from which it is distributed to the cylinder by its different passages, as required. This steam-box is secured by a flange against the flat surface of a pipe D, extending from the top of the cylinder to the bottom, and attached by dove-tailed joints to the two necks, a b, of the cylinder. In the flat surface of the pipe D, there are three openings, m n o: the upper one, m, communicates with the top of the cylinder, through the passage a; the middle opening, n, communicates with the condenser by pulling out ladders to the ejection-pipe, as at the dark circle at p; and the lower opening, o, communicates with the bottom of the cylinder by the passage b: c is the slider, made in the form of a box or cover, and ground round its edges, so as to fit exactly flat against the surface of the steam-pipe D, in which the three openings are made, and which is ground also. This slider is moved up and down by the small sector s, acting in the teeth of a rack, fixed to the back of the slider. The spindle of the sector passes through a stuffing-box in the side of the steam-box, and is moved on the outside by an eccentric wheel on the axis of the fly-wheel. The motion of the slider r, up and down, either connects the openings of the two passages m and n, or the two openings n and o. In the drawing, it is represented as connecting the upper passage m with n, which leads to the condenser, at the same time leaving the opening o uncovered, to receive the steam from the steam-box; consequently the steam enters below the piston, through the neck b, causing it to rise, and escapes from the top of the cylinder through the neck a; and by the connection of the opening m with n, it passes out at p into the condenser. Now if the slide is moved down, by turning the sector s, so that the lower passage o is connected with n, which leads to the condenser, the top opening m will be open to the steam-box, and the steam will enter at the top of the cylinder, and cause the piston to descend, while the steam in the bottom of the cylinder will rush through the opening h, and by the connection of the passage a with n, it will pass into the condenser. In this manner, by alternately moving the slide up and down, this action is repeated, and the engine kept going.

In the figure of Mr. Murray's small engine (Plate VIII. fig. 4.) the eccentric circle B is plainly seen upon the axis of the fly-wheel; it operates exactly the same as a short crank, and has an iron frame or collar embracing it. By this a motion backwards and forwards is communicated by the rod D to an axis, upon which are levers, giving motion to the lever of the sector, which moves the sliding-valve. The whole of the engine is upon an excellent construction: the air-pump is worked by the rod R, at the outer end of the beam.

In 1799, Mr. William Murdoch of Redruth, in Cornwall, obtained a patent for several improvements in steam-engines, amongst which is a simple construction of the steam-valve, or contrivance by which the steam is distributed to the cylinder, or withdrawn from it at the proper period.

This contrivance is a sliding-valve, which performs all the offices of the four valves which we have described for the double engine. Mr. Murdoch's patent has been adopted by Messrs. Watt and Boulton in most of their small engines, for many years past; and they have lately, with some alterations, introduced it into large engines. In Plate VII. fig. 9, A A is the steam-cylinder of the engine; B, the piston, and C, the piston-rod; D is the upper opening or steam-way into the cylinder; E is the steam-cage: in this is applied the sliding-valve, which performs the office of all the four steam-valves in the manner following. G G is a semicylindrical steam-pipe, (but which may be cylindric, triangular, or of any convenient form,) communicating with the steam-cylinder both at its upper and lower openings, and firmly fixed or connected to the steam-cage, or with the cylinder itself, where no steam-cage is used.

This tube has an opening, H, on its side, with a regulating valve for the admission of steam from the boiler; and another opening, I, at bottom, which leads to an opening on the top, which is covered with a plate T, having a hole and stuffing-box to admit the sliding-rod K, which is jointed to, or connected with, an inner moveable pipe or tube L M, open at both ends. To one side of the sliding-tube are fixed the solid plates or valves L M, intended to slide upon the plates at D and E, and occasionally to cover and uncover the upper and lower openings D and E of the cylinder. Opposite to these plates the remaining circumference of the tube, L M, is furnished with projections or flanges of brass, or other metal, with an interface between them, to receive a packing of hemp, or other proper substance, which will permit the tube, L M, to move up and down, steam-tight, in the fixed tube G G. There are openings provided in the steam-pipe G G, which are shut with plugs or plates, screwed or otherwise fixed to it, which may be removed to repair the packing.

When the sliding-tube, L M, is in the position shown in the figure, the steam enters through the steam-pipe H, and filling the interstices between the steam-tube G G, and the sliding-tube L M, p asses into the cylinder at the upper opening D. As the lower opening, E, is open to the condenser, a vacuum will be formed within the sliding-tube L M, and also below the piston, through the passage E, which is uncovered by the rise of the sliding-rod. In consequence, the piston descends; and when it has got near the bottom
of the cylinder, a bracket, attached to the top of the pis-
pton-rod C, strikes a projection upon the sliding-rod K, and
causes the tube, L, M, to defend a small quantity in the
steam-pipe G. The sliding parts, L, M, by this motion, slide
up and down along the projections D and E of the cylinder, so as to
be beneath them; and the steam, which is above the piston,
flows at the upper opening, and passes down the inside of
the tube L, M, into the condenser. At the same time, the
steam continuing to pass from the boiler through the pipe
H, and the interface between the steam-pipe and the
sliding-rod, enters the cylinder by the lower opening E,
and forces up the piston and piston-rod, with its bracket,
which, near the end of the ascending stroke, encounters
another projection of the sliding-rod K, and raise the
tube, L, M, into its former position of the figure. The
operations are then repeated. This is the plan used in
Mefirs. Watt and Boulton's bell-crank engine, and it is very
good, because no steam is lost, as in all other constructions,
where only one cork or slider is used.

If the sliding-plates, where they apply together, are made
of steel, and hardened, they then wear extremely well.
In some of Mefirs. Watt and Boulton's latest engines, they
have used similar sliders for large engines; but, in this case,
they make the two sliders separate, being moved only by
a rod of communication because, if they were applied to a
strong moving pipe, there would not be so great a certainty
of their complete action, as the least deviation of the two
sliders at the top and bottom of the cylinder would cause a
great change.

There are many other methods of distributing the steam
alternately to the top and bottom of the cylinder, but
as we have described those which are brought to such a
degree of perfection as to be commonly used, it is unnec-
essary to pursue the subject any farther.

Regulation of the Velocity of an Engine.—This is a matter
of considerable importance. The most common method, as
we have noticed, is by the governor or revolving pendulum;
but there are others which, in particular circumstances, are
very applicable. One is to have a small pump worked by
the engine, and raising up water into a cistern, from
which it runs out again in a constant stream. By this
means, the water will accumulate and rise in the cistern, if
the engine works rapidly, so as to pump more water into
the cistern than will flow out of it in the same time; and
on the other hand, the surface of the water will sink in the cistern,
if the engine works slowly; and a float being placed in the
cistern, and connected with a wire to the throttle-valve, will
regulate the motion of the engine. See REGULATOR.

In 1805, Mr. Job Rider obtained a patent for improve-
ments in the steam-engine. These improvements consist,
first, in lining the steam-cylinder with a soft metal, of a suf-
cient thickness to admit of finishing the inside of the cy-
linder of such metal, by drawing, boring, or otherwise;
secondly, in applying a hollow piston-rod, answearing the
purpose of an education-pipe; thirdly, in the order of opening
and shutting the valves; and fourthly, in regulating the
speed of the engine by a pendulum. The nature of this
latter contrivance is very ingenious, and may perhaps be un-
derstood from the following description. Upon an horizontal
arbor, which we will denominate the main arbor, are placed
three wheels, a drum or harrel, and a pinion: one of these
wheels, that is to say, the main wheel, is fitted by means
of a socket upon the main arbor, so as to turn round upon
that arbor, and has main teeth both upon the exterior and in-
terior periphery of its rim. Within the circle of the interior
cogs of this wheel a pinion is fixed to the arbor, its diameter
being one-third of the interior diameter of the main wheel;
and this pinion has teeth surrounding its convex surface. The
moveable barrel turns freely upon the main arbor; its di-
diameter is rather less than the exterior diameter of the main
wheel, and it carries a cord, with a weight hanging at its end,
which is called the barrel-pinion; its teeth work in the teeth of
the pinion; the latter wheel may be called the barrel-pinion; its teeth work in the teeth of
the pinion, and also in the interior teeth of the main wheel.

By these means, the barrel may be turned round upon the
main arbor, while the arbor itself is turned by the pinion,
which is acted upon by the barrel-pinion, at the same time
that this pinion acts upon the interior teeth of the main
wheel. The external teeth of the barrel turn the pinion
of a scapement-wheel and pallets, nearly similar to
those in Graham's dead-beat. Near one end of the main
arbor there is a ratchet-wheel, and wheel and click; and
near the other end a wheel, which is acted upon by an end-
less screw upon a horizontal shaft, worked by the general
operation of the steam-engine.

This arrangement serves to regulate the rate of the engine's
motion; for the turning of the worm-wheel, by the general
motion of the engine, causes the weight to be raised which
hangs to the cord that winds upon the barrel; and this
weight is connected to one end of a lever, the other end of
which is attached to the steam-valve in such a manner, that
the degree of opening of that valve depends upon the altitude
of the weight which is raised. The aperture of this
valve is formed like an inverted cone; and while this valve
shuts and opens twice at every stroke, the lever does not
prevent such opening and shutting, but merely limits the
extent of the opening by the springing up of a rod con-
ected with it. By this contrivance it happens, that when
the weight is highest, the valve is least opened; and when
the weight is lowest, the valve is most opened. Hence it is
evident, that should the engine wind up the weight, by
turning the worm faster than the pendulum permits it
to descend by the turning of the barrel, the aperture of the
valve will be contracted; and vice versa. Little power is
lost by these means, and the speed of the engine can be ac-
curately regulated by properly adjusting the length of the
pendulum, and the numbers of teeth in the wheels and
pinions. As to the ratchet-wheel and click, these serve
not only to prevent the weight from drawing the line off the barrel,
but also to regulate the speed of the engine at work, and
think it would operate very well.

Mr. Cartwright's Engine.—In giving the history of Mr.
Watt's inventions, we mentioned that the condensation by
external cold was one of his first ideas, and given up, be-
cause he found it better to employ injection. We have also
described his single engine, in which the piston rises in
vacuo. In 1797, Mr. Cartwright took out a patent for
improvements in the construction of steam-engines, in which
the condensation is performed by the application of cold to
the external surface of the vessel containing the steam.

The manner Mr. Cartwright effects this is by admitting
the steam between two metal cylinders, lying one within the
other, and having cold water flowing through the inner
one. By these means, the very thin body of steam is exposed to the greatest possible
surface of cold metal. By means of a valve in the piston,
there is a constant communication at all times between the
condenser and the cylinder, either above or below the pis-

Vol. XXXIV.
Steam-engine.

tion; so that whether it ascends or descends, the condensation is always taking place, in the same manner as Mr. Watt’s engines, where the piston rides in vacuo. But what was probably esteemed one of the most important circumstances attending the mode of condensation, was the opportunity it afforded of habituating ardent spirit, either wholly or in part, in the place of water, for working the engine.

For as the fluid, with which it is worked, is made to circulate through the engine without mixture or diminution, the using alcohol, after the first supply, would be attended with no very great expense; on the contrary, the advantage was expected to be great, even equal to the saving of half the fuel. If, indeed, the engine could be applied, as Mr. Cartwright occasionally purposed, both as a mechanical power and as a still at the same time, the whole fuel would be saved.

Mr. Cartwright has been very attentive in simplifying all the other parts of the engine, his engine having only two valves, and those are as nearly self-acting as may be: in consequence, the engine is rendered applicable to purposes requiring only a small power, and for which any other engine would be too complicated and expensive. See a figure of Mr. Cartwright’s engine, Plate V. fig. 8, where $a$ is the cylinder, which is supplied with steam from the boiler through the pipe $b$; $c$ is the piston in the act of going up; $d$ is the ejection-pipe that conducts the steam into the condenser $w$, which consists of two cylinders, one within the other, leaving a small space between them, into which the steam is admitted; while the inner cylinder is filled with cold water, and also the external cylinder surrounded by the same; so that, by this means, the very large surface of steam is exposed to the cold of the water, though no water is suffered to come in actual contact with it.

To the bottom of the piston $c$ is attached a rod, with another piston $e$, working in the barrel $d$, which is in reality the air-pump of the engine, and has a pipe, $f$, to the condenser. When the piston $c$ arrives at the bottom of the cylinder, a valve, $r$, which is in the piston is opened, by its tail pressing against the bottom of the cylinder, which opens the communication from above the piston to the condenser, while the spring $k$, fixed to the rod of the piston, presses down the top part of the piston, and thus the steam-valve $c$, which admits the steam from the boiler. The steam therefore within the cylinder, both above and below the piston, being condensed, runs through the lower pipe, $f$, to the air-pump, and the piston, being relieved from all pressure, is drawn up in the cylinder by the fly-wheel. The piston $c$ of the air-pump arriving at the top of the barrel, in which it works at the same time with the working piston, draws the air from the condenser, and on its return at the next stroke, presses upon the condensed water, flushes the valve $f$, and forces the water up the pipe $g$, into the box $b$: the air which is disengaged from the water rushes to the top of the box, and by its elasticity forces the water through the pipe $a$, which carries it back again to the boiler. When the air accumulates in the box to such a degree as to depress the water, the ball cock falls with it, and opens a valve in the top of the box, which suffurs some of the air to escape.

When the piston arrives at the top of the cylinder, it presses up the steam-valve $c$, which admits the steam again from the boiler, to force it down as before; and the valve, $r$, in the piston flushes by pressing up beneath the top of the cylinder. The pressure of the steam is now above the piston, and a vacuum beneath; the piston therefore descends, and when at the bottom, flushes the steam-valve $c$, and opens the valve $r$, in the piston.

When all the steam in the upper part of the cylinder is condensed, the motion of the fly attached to the machine brings the piston up again, its valves now remaining shut by their weight.

$i$ and $m$ are two cranks, upon whose axes are two equal cog-wheels working in each other, for the purpose of converting the perpendicular motion of the piston-rod into a rotary motion for working the machinery attached to it.

As it is evident, from its construction, that the whole of the steam is brought back again into the boiler, it affords the means of employing ardent spirit instead of water, and thus having a great deal of fuel.

Cartwright’s Metallic Piston.—The most valuable part of this engine is in the construction of the piston, which Mr. C. made wholly of metal, so as by means of springs to fit the cylinder very exactly.

This not only saves the expense and trouble of packing, which must be frequently renewed in all other engines, but also a great deal of steam, on account of the more accurate fitting of the piston. This piston is made in the following manner: Two metal rings are ground, by means well known to good mechanics, into the cylinder, so as to fit it as perfectly as art and industry can make them; that is so well, that no steam can pass between them and the cylinder: their upper and under sides are also ground perfectly flat, and applied one upon the other. Though not absolutely necessary, for greater security two other rings are fitted to the inside of these. On the upper rings is placed a plate of metal, also ground perfectly flat, and of such a diameter as almost to fill the cylinder. A similar flat plate is placed below the under ring; and the two plates, with the rings between, are attached firmly to each other by means of the piston-rod that passes through them, and they thus form a shell, in which the other rings are contained.

It is plain then, supposing neither the outside rings nor the cylinder are able to wear one another, that such a piston would remain steam-tight; but as conical friction must inevitably tend to enlarge the cylinder, and diminish the diameter of the rings, the piston, after some time, would cease to fit, if a contrivance had not been made to remedy the evil. The rings are each of them cut into three pieces, and in cutting them, such a portion of the metal is taken away as to leave the rings, when the frame is brought to the room to introduce between two of the pieces, a spring in form of the letter $V$, the open end of which is placed outwards, almost close to the circumference; by which means the two pieces against which the two sides of the spring act are pressed, in the direction of the circumference, against the ends of the third piece; so that the three pieces are thus kept uniformly in contact with the cylinder, that the longer the machine is worked the better the rings must fit.

To prevent steam palling through the cuts in the rings, the solid parts of the upper rings are made to fall upon the divisions and springs of the under ones, so as to form a break joint.

The stuffing-box round the piston-rod was proposed to be done in the same manner.

The metallic piston has been found advantageous, and Mr. Woolf uses it in his engines, which is the greatest trial of a piston, because of the rarity of the steam. Plate VII. figs. 10 and 11, represent a piston of a four-horse engine, which was made by Meffrs. Lloyd and Oftel. $A$ is the piston-rod, and $B C C$ the solid metal of the piston, firmly fitted and keyed to it: the lower edge, $C$, of the plate, $B$, is made very nearly to fit to the cylinder; but for the actual fitting, dependence is placed on the four rings, $D$, fitted one upon another, and each divided into four segments, as shown by fig. 10. The interior surface of these rings is made rather conical, and a second set of smaller rings, $E$, is accurately fitted.
STEAM-ENGINE.

Woolf's improved Piston.—The common method of packing the piston of a steam-engine with hemp, will be so well understood after what we have said, that a particular description of it in this place is not necessary; suffice it to say, that the hollow part round the piston is filled with rounds of hemp, loosely twitted into a soft rope, which is pressed into a pretty compact form by a ring, and worked down by the screws distributed round the ring, which work into the body of the piston; by this means the packing is made to fill the diameter of the cylinder pretty closely, and to prevent, while the packing remains found, any steam from paffing between the piston and the cylinder. In the ufual method, whenever the piston, by continued working, becomes too easy, and fo occasions a want of steam, it is necessary to take off the top of the cylinder, even when fresh hemp or packing is not wanted, merely to get at the screws, which serve to force the upper ring nearer to the bottom of the piston, by which means the packing is forced onwards against the side of the cylinder.

This being heavy laborious work, it is generally deferved, by the man that attends the engine, as long as the engine can possibly be made to work without taking this trouble; and in confeguencc of this neglect, a great and unneceffary waste of steam is occafioned, and a waste of fuel in proportion.

Mr. Woolf's improvement on the piston is fuch as to enable the engine-man to tighten the piston, without the neceffity of taking off the cover of the cylinder; except when new packing becomes neceffary. He accomplishes this by either of the two following methods. He faltens on the head of each of the fcrews a fmall cog-wheel, &c., &c., (Plate VII. figs. 12 and 13,) which wheels are all connected with each other by means of a central wheel $d$, which works loofe upon the piston-rod in fuch a manner, that if any one of the fmall wheels and its fcrew be turned, it turns the central wheel, and the latter turns all the other three wheels and screws. That one which is to be firft turned is furnifhed with a projecting square head $f$, which rife up into a recefs in the cover of the cylinder. This recefs is furnifhed with a cap or bonnet, which being eafily taken off, and as eafily put again in its place, there is little difficulty in fcreening down the packing at any time, by applying a key to the square head of this fcrew. The parts are fo clearly expreffed in the plates, that no farther defcription is neceffary to make any perfon comprehend it.

Mr. Woolf contrived another method for fmall pinions, which is fimilar in principle, but a little different in construcfion. Instead of having feveral fcrews, all worked down by one motion, there is in this but one fcrew, and that one is cut upon the piston-rod itself; on this is placed a wheel of a convenient diameter, the centre of which is furnifhed with a fquare head, which wheel is turned round, and screwed down by means of a pinion, which is furnifhed with a fquare projecting head, rife into a recefs of the kind already de-

feribed. The upper ring of the piston is prevented from turning with the wheel by means of two steady pins.

High-Pressure Steam-Engine.—The operation of the high-pressure steam-engine is effected solely by the expansive force which is not condenfed in the manner of the atmospheric or Watt's engine. To this end, water is put into the boiler, and heated far beyond the boiling point, to acquire a great expansive force, and exert an immense preffure to escape from any vessel in which it is confined, even as great as four or five times the preffure of the atmosphere. This steam being allowed to enter into one end of a cylinder, while the other end of the fame communicates with the open air, it will exert a force upon the piston of the cylinder, and move it from one end to the other. This is the principle of the high-pressure engine, which has been much introduced of late, on account of some advantages which it polifhes in particular fuitations over other engines: firft, from the simplicit of its construction and cheapnefs; secondly, the small space which it occupies; thirdly, its requiring no condenfing water, which in some fuitations is very difficult to procure, and in one inftance is altogether impracticable; and for drawing of carriages, for which purpofe this engine has been fucceffully used. To fet a-gainst these advantages, the high-pressure engines are extremely liable to blow up, if not attended very carefully, for they are frequently worked with a preffure of from fixty to eighty pounds on the square inch. These engines require a greater quantity of coal, in proportion to the force exerted, than the engines of Mr. Watt, and consequentfly are not worked with advantage in a fuitation where coals are dear.

The firft application of high-pressure steam to an engine, is what we find defcribed in 1724, by Leupold, in his Thesaurus Machinarum Hydraulicae, vol. ii. p. 93. He describes the invention to Papin, on account of his having given him the idea of applying the expansive force of steam for the purpofe of raising water, and also because he took the construction of the four-paffaged cock, to communicate alternately with two cylinders, from Papin's air-machine, which has been defcribed in the former part of this article. The engine defcribed by Leupold confifts of two fingle cylinders, placed at foine distance from each other, with a piston fitted to each, and applied to two separate beams, which at the opposite ends work two forcing-pumps. Between the two cylinders is the four-paffaged cock, the fame as defcribed in Plate VII. Steam-Engine, fig. 6, for admitting the steam from the boiler alternately into the bottom of each cylinder, or allowing it to escape from the cylinders into the air. The boiler is fupported beneath the two cylinders, and communicates with the cock by a short upright pipe. The action of this engine is very fimple: the steam being raised very strong in the boiler, is allowed to enter through the cock into the bottom of one of the cylinders, at the fame time that the air or steam escapes from the bottom of the other, through the other passage of the cock into the open air. In this way, the preffure of the steam caueth the afcent of the firft-mentioned piston, and the other defends by its counter-weight. By turning the cock round one-fourth, the operation is re-verted, fo that the steam enters the bottom of the fecond cylinder, and the steam which was contained in the firft escapes through the pipeage of the cock into the air.

The next proposal for a high-pressure engine is Mr. Watt's patent of 1769. See the fourth particular of his specification, which we have given, but we do not know that he ever practifed it, finding his own invention fo much fuperior.

The high-pressure engines at present in ufe were introduced by Mr. Trevethick, in conjunction with Mr. Vivian, who obtained a patent for the fame in 1802: this was princi-
steam-engine.

principally for their application of the engine to the purpose of driving of carriages upon rail-roads.

This engine contains no novel parts which are not used in other engines, and before described, it may be explained without a drawing. The boiler consists of a large cylinder of cast iron, made very strong, and placed with its axis horizontally upon short feet or pillars of cast iron: the boiler has a flanch at one of its ends, to screw on the end or cover, which has the requisite openings for the fire-door, the man-hole, the exit for the smoke, and the gauge-cocks. The fire is contained within the boiler, in a cylindrical tube of wrought iron, which is surrounded with water on all sides, in the same manner as the fire in Mr. Sweaton's portable engines, of which we have given the description; but there is a little difference in the application; one end of this tube is flanched to the end or cover of the boiler, and is divided into two parts, by having the fire-grate extended across it: the fire-door closes the opening in the upper half, which is the fire-place, the lower half forming the aft-pit: the tube extends nearly to the end of the boiler, where it is reduced in size, then doubles, and returns back in a direction parallel to the first tube or fire-place to form the flue or chimney, till it arrives at the end or cover of the boiler, through which it paffles at the side of the fire-door, and a flue is then conducted from it into the chimney, to carry off the smoke.

At the part where the tube enters the boiler, there is a small door, to remove any foot that may have accumulated. On the top of the boiler is a safety-valve, kept down by a lever and weight, to allow the steam to escape in case it becomes too strong as to endanger the bursting of the boiler. The steam-cylinder stands in a perpendicular direction, and is included within the boiler, except a few inches of its upper end, at which the four-paffaged cock is situated, and the flanch which serves on the lid, with the flutting box for the piston-rod to pass through. The boiler has a projecting neck, into which the cylinder is received, and it is falfed in its place by a flanch round the upper end of the neck of the boiler, which is united by screws to a flanch projecting from the cylinder at about one-third from its top flanch. The upper end of the piston-rod is falfed to the middle of the cross-bar, which is placed in a direction at right angles to the length of the boiler, and guided in its ascending and descending vertical motion, by sliding upon two perpendicular iron rods, fixed to the boiler, parallel to each other, being connected together at top, and firmly supported there by two diagonal flays, extending from the other end of the boiler, and falfed to the flanch, which serves on the end of the boiler. At the ends of the cross-bar of the piston-rod the two connecting rods are jointed, and the lower ends of them are connected with two cranks, fixed upon an axis, extending across beneath the boiler, and under the centre of the cylinder: the axis is supported in bearings made in the legs which support the boiler, and the fly-wheel is fixed in it. One of the cranks is formed by a pin which is fixed into the arm of the fly-wheel, at the same radius as the opposite crank. The fly-wheel is situated close to the side of the boiler, and the pin for the other crank is fixed into the arm of a large cog-wheel, fixed on the axis of the fly-wheel, at the opposite side of the boiler. This cog-wheel communicates the power of the engine to other cog-wheels. As the piston is alternately forced up and down by the prefixed the flanch, it carries the cross-bar with it, and by the connecting rod turns the two cranks, together with the fly-wheel and cog-wheel.

It now remains to shew the means by which the steam is brought to act alternately on different sides of the piston. On one side of the cylinder, just above the flanch which fixes it into the boiler, and beneath the top flanch, which falfes down its lid, is a protrusion of cast iron, to contain the four paffages and the cock, similar to that shown in figs. 6 and 7. One paffage rises directly from the boiler, and brings steam to the cock at one side, to be distributed either to the top or bottom of the cylinder, according to the position in which the cock stands. A second paffage rises from the upper side of the cock, and proceeds to the top of the cylinder, for admitting steam above the piston. The third paffage from the under side of the cock connects with the bottom of the cylinder by a pipe cast close to the side thereof, and connecting to the bottom. The fourth paffage from the cock is on the opposite side to where the steam enters from the boiler, and this paffage is open to the walle-pipe, which carries the steam into the external air, and allows it to escape after it has passed through the engine. Now suppose the paffage leading to the top of the cylinder, and that one which brings steam, are from the boiler to be connected with the cock, and the paffage from the bottom of the cylinder to be connected with the walle-pipe, the steam will enter above the piston, and force it down, at the same time that the steam in the bottom of the cylinder will escape by the connection of the walle-pipe with the open air.

When the piston arrives at the bottom of the stroke, the cock is turned one quarter round, by means of a rod jointed to the cross-bar of the piston-rod, and defending perpendicularly, being guided at bottom by palling through a part of iron falfed on the flanch of the cylinder: this rod has two pins projecting from it, which move the handle of the cock up and down alternately; by this the cock is turned on the completion of the defending stroke, so that the paffage to the bottom of the cylinder is connected with the boiler, and that from the top with the open air: the steam in confluence enters below the piston, and forces it up, palling out from the upper part of the cylinder into the open air at the same time. In this manner the motion of the engine is kept up by the pins alternately turning the cock, first at the top of the stroke, and then at the bottom.

The boiler is supplied with water, as fast as it evaporates, by means of a small force-pump worked by the engine; but as it would be a great loss of heat to inject cold water at once into the boiler, it is first rendered nearly or quite boiling by a very simple contrivance. The walle-pipe, which conveys the steam away from the cylinder after having performed its office, is included within an external pipe or jacket, leaving a space of about an inch all round; through this space the cold water is forced to enter at one end by the small force-pump, and the boiler is supplied with water by a branch from its other extremity. By thus carrying the water some dilution in contact with the hot walle-pipe, through which the steam passes, it is heated, and a considerable quantity of heat is faved, which would otherwise be lost.

The velocity of the engine is regulated, or its motion can be entirely stopped, if required, by a cock situated in the fourth paffage from the boiler to the four-paffaged cock, so as to regulate the paffage between the boiler and the cock. The handle of this cock may be connected with a governor, similar to those used in other engines. The construction of the four paffages and cock is exactly similar to what is represented in figs. 6, Plate VII., except that it is placed near the top of the cylinder, because all the lower part of the cylinder is concealed in the boiler; and also that the axis of the cock is directed to the centre of the cylinder. High-pressure engines have been sometimes made with beams and parallel levers; but more frequently the cylinders have been placed horizontally, and the piston-rod jointed at once to the connecting rod.

Several very terrible accidents have occurred from the bursting
STEAM-ENGINE.

burting of high-pressure boilers, either from their being made too weak to resist the force they are intended to bear, or from some mismanagement, as loading the safety-valve too much. Some years ago, an engine that was employed to drain water from the tide-mills, while building between Woolwich and Greenwich, was blown up by overloading the safety-valve, when several people were killed. Many provisos have been made to guard against these accidents by Mr. Treverhick, who first brought the high-pressure engines into use, at first he proposed inclining the safety-valve in such a manner, that no one might get access to it to increase the head beyond what was intended to be employed. Secondly, he drilled a hole in the boiler, which he plugged up with lead, at such a height from the bottom, that the boiler could never boil dry without expelling the lead to be melted, and consequently making an opening for the steam to escape. This contrivance is calculated to prevent the boiler being burst by suddenly forcing water into it, when it has been allowed by carelessness to boil dry, and become red-hot. A metal plug should always be inserted into such a boiler. The plug should be made of such a composition of the fusable metal, that it will melt whenever the contents of the boiler attain that degree of heat which produces steam of a dangerous placticity. Another precaution which should always be taken, is to have two safety-valves fixed in different parts of the boiler; so that if by any accident one of them becomes fixed fast in its seat by rust or other means, the other will be in a state to act, thereby diminishing the chance of an accident to half; and the larger these safety-valves are made, the more certainly they will operate.

The mercurial steam-gauge used in many engines is a long curved tube, or inverted fiphoen, in which the mercury rises by the force of the steam and indicates the pressure. If this kind of steam-gauge is applied to the high-pressure engine, it requires a very long tube, which is an additional security against the burting of the boiler, because the mercury will be blown out of the tube, and permit the steam to escape when the pressure is too great.

Before the boiler of a high-pressure engine is set to work, it should be proved effectually, first by drilling small holes through it at different places, to actually measure the thickness of the metal, and ascertain that it is equal throughout; and then it should be proved by injecting water into it, until the pressure lifts the safety-valve, when loaded considerably more than is intended to be when the engine is set to work; but this proof should not be too severe, because the metal may be weakened, although it is not burst, by the proof; and, in consequence, may afterwards burst with a much less pressure of steam. At the same time, the engineer who undertakes to make these engines, should fully inform himself of the real strength of metal boilers of determinate thicknesses, which could be easily done, without danger, by injecting water into the boilers until they actually burst. We do not know if such experiments have ever been made; and in those boilers which have been burst by the explosion of steam, the pressure at the moment of the accident has not been known.

We have an account of a trial of a small high-pressure engine made in 1804, in Wales, to ascertain its powers to raise water: the cylinder was 8 inches in diameter, and 44 feet stroke; it worked a pump 18½ inches in diameter, and 44 feet stroke, which raised water 28 feet high. It worked at the rate of 18 strokes per minute, and consumed about 80 lbs. of coals per hour; this, when reduced, is about 17½ million pounds raised one foot high for each bushel. Thus, the weight of the column is 3266.5 lbs. for the area of the pump (18.5 × 18.5 = 342.25 × .7854 = ) 268.8 square inches × .434 lbs. = 116.1 lbs. the weight for every foot of the column × 28 feet = 3266.5 lbs. the total weight of the column. The motion of the piston per minute is (4½ × 18) = 81 feet, or 4860 feet per hour × 3266.5 lbs. = 15,875,160 lbs. raised one foot high per hour. The coals consumed in the hour is 80 lbs.; therefore, as 80 lbs. = 1,575,160 lbs. = 17,450,076 lbs., the number of pounds raised one foot high for each bushel of coals. The area of the piston is (8 × 8 = 64 × .7854 = ) 50½ square inches, and the load 3266.5 × .504 = 65 lbs. pressure per square inch on the surface of the piston.

Manufacture of Steam-Engines. — The great demand for these machines, which has taken place since their value has been so fully understood, has occasioned them to be manufactured in the large way by several engineers, who adopt the fame fystem as is pursued in making of watches and clocks, viz. that of having workmen instructed in making the separate parts, and employing machines and tools for every operation which admits of such aid. The frill of these manufactories is that of Meffrs. Watt and Boulton, at Soho, near Birmingham, owners of the inventor and his associate, who established the manufactury about 1775; and until the expiration of Mr. Watt's patent in 1800, it was the only place where his engines were made. It has continued ever since to furnish the greatest proportion of engines, as well for this country as abroad. There are now other manufacturers who approach the original in the beauty and perfection of the workmanship.

Since the expiration of the patent, there has been a total change in the manner of constructing and putting together every part of the engine, and many advantageous improvements have been made, as far as respects the durability and accurate performance of the machine; though nothing, except the second cylinder of Hornblower and Woolf, has been added to Mr. Watt's engine since he first brought it to a standard, by which its powers are at all increased, with respect to the consumption of fuel, but rather the contrary. At the first establishment of these manufactories, on the expiration of Mr. Watt's patent, many ingenious mechanics attempted to improve the structure of the machine, and the records of the patent office contain more upon this subject than any other. All kinds of parallel motions have been tried; cylinders have been inverted, placed horizontally, made of long and short proportions; large air-pumps have been used; and for the minor parts, such as valves, and the machinery of condensation, they were made alike for many years, until by, the result of a vast deal of invention and experience, those methods which we have described became settled into established forms; but none of them are superior to the original of Mr. Watt's. Refecting parallel motions, and the proportions of the parts, no methods have been found so good as the original engine; and we accordingly find, that all the most established and experienced manufacturers make engines which are not altered in any great feature from Mr. Watt's original engine, with a beam and parallel motion acting on a simple crank; and they give them all the advantages which can be derived from superior workmanship, and improved methods of putting the parts together, which experience has pointed out.

Meffrs. Fenton, Murray, and Wood, of Leeds, Yorkshire, are the manufacturers of the most established reputation after Meffrs. Watt and Boulton. The engines they fend out cannot be excelled in beauty and perfection of workmanship, and they perform as well as any others. Their factory at Leeds is very extensive, and provided with every convenience for making all the parts of the engine in the best manner; and with the least labour. They have three
STEAM-ENGINE.

Steam-engines in the works, one for boring cylinders, and turning large lathes; a second for turning small lathes, grinding, drilling the centres of wheels, tapping screws, &c., and for blowing the furnaces of the foundry; and a third engine for working a great forge hammer, by which the heavy wrought iron work is forged. The boring machines for cylinders, of which they have three in number, are very capital, as by an ingenious movement, invented by Mr. Murray, for drawing the borer through the cylinder, it is made to advance regularly from one end to the other, without any interruption. These machines are worked by a separate steam-engine, which is never stopped during the operation of boring a cylinder through, as it is found to make a feasible mark or ring if the motion is stopped. The best means are also taken to prevent the cylinder from changing its figure by its weight, or by the prelure of the parts which hold it in its position. The whole of the factory is lighted by gas lights in winter time. The boilers are manufactured by the aid of several machines to cut out the plate, pierce the holes, and bend the joints. Before any of the smaller engines are sent away, all the parts are put together in a building on purpose, where there are boilers and other parts always tried, to insure that every part is perfect: they are then taken to pieces, with marks and directions for putting them together, and packed up for carriage, which is very easy, as there is a canal at the gates, which has communication by water to every part of England. For such engines as are too large to be put to work at the factory, workmen are sent out with them, to assist and direct in setting them to work.

In London, Mr. Maudslay has made many very excellent steam-engines upon the plan represented in our Sketch; but his belt engine, which is in the saw-mill at Woolwich, is with a beam upon Mr. Watt's plan. He has lately made a large engine for a steam-boat invented by Mr. Brunel, which has two cylinders acting alternately upon different cranks, formed upon the same axis at right angles to each other, so that the motion is continued without a fly-wheel: one boiler is placed between the two cylinders, and one air-pump and condenser exhausts them both. By this means a powerful engine is contained in a small space, and is not heavy to load the boat.

Some engines of Manchester make very good steam-engines, chiefly for the great cotton-mills. At most of the iron furnaces in the country, steam-engines are now made, and some of them produce very capital engines, as at Butterly in Derbyshire, Low Moor in Yorkshire, and others. Their workhops are in general managed by engineers who have been instructed at Soho, or at Leeds. Mr. Woolf's engines are made in London by Mr. Edwards, and by himself in Cornwall.

Rotative Steam-Engine. — The reciprocating motion of a steam-engine has always been considered as a great defect; for though all irregularity of motion can be obviated by connecting it with a fly-wheel, yet a great mass of matter must always be kept in a constant succussion of changes from rest to motion; and the irregularities which this would produce, can only be governed by putting a great mass of matter in the fly-wheel, and causing it to move with a rapid motion, so that its momentum or vis inertiae shall be vastly greater than that of all the reciprocating parts together. With a view of obviating this objection, and of obtaining the action of steam by more simple machinery than a cylinder and piston, many attempts have been made to produce a circular motion at once by the steam. It has been made to blow on the vanes of a wheel of various forms. But the rarity of steam is such, that even if none is condensed by the cold of the vanes, the impulse is exceedingly feeble, and the expence of steam, so as to produce any serviceable impulse, is enormous. Mr. Watt, among his first speculations on steam-engines, made some attempts of this kind; but he has not given such a description of the valves for this purpose, as to enable an engineer to construct one of them. From any guess that we can form, we think the machine very imperfect. One of Mr. Watt's first trials was uncommonly ingenious; it consisted of a drum, turning air-tight within another, with cavities so disposed, that there was a constant and great prelure urging it in one direction. But no packing of the common kind could preserve it air-tight with sufficient freedom of motion. He succeeded by immersing it in mercury, or in an amalgam which remained fluid in the heat of boiling water; but the continual action of the heat and steam, together with the friction, soon oxidated the fluid, and rendered it useless. He then tried Parent's or Mr. Barker's mill, inclining the arms in a metal drum, which was immersed in cold water. The steam rushed rapidly along the pipe which was the axis, and it was hoped that a great re-action would have been exerted at the ends of the arms; but it was almost nothing. The reason of the want of success was, that the steam was condensed in the cold arms. It was then tried in a drum kept boiling hot; but the impulse was very small, in comparison with the expence of steam: this must be the cafe.

Mr. Watt has described in his specification of 1782, lodged at the patent office, some more perfect contrivances for producing a circular motion by the immediate action of the steam. One of these produces alternate motion upon a centre, and is analogous to the double engine; another produces a continued motion. See his first specification of 1769.

We do not find that Mr. Watt has ever erected a continuous circular engine: he has doubled his arms in such attempts inferior to the reciprocating engine with a fly. A very crude scheme of this kind may be seen in the Transactions of the Royal Society of Dublin, 1787.

Mr. Cartwright, in a patent of 1797, proposes some improvement of Mr. Watt's rotative engine, but it was never brought into use. Mr. Jonathan Hornblower had a patent in 1798 for a rotative engine, which is the most ingenious of all the specifications on this subject, but too complicated to be carried into execution; and in 1805 he had another patent, for a machine which is quite different from the former, and is ingenious, but still less likely than the first to answer the intended purpose.

Mr. Samuel Clegg has made a rotative engine, the piston of which makes a complete revolution in a channel at a different rate from the centre of motion. We have seen this engine at work, which acted in a very regular manner; but we think the friction must be greater than that of a common engine, although it gets rid of the reciprocation. Mr. Clegg had a patent in 1809 for his invention.

Mr. Turner has lately obtained a patent for a rotatory steam-engine, the principle of which is the same as Mr. Clegg's, but each of them has its peculiar advantages in the manner of fitting up, and in the arrangements of its parts. Mr. Turner's is packed in all the moving parts with metallic packings instead of hemp, and we have been informed that his engines operate very well, and without any fly-wheel. Mr. Clegg's engine only requires a small fly at one part of its movement. We think, that if ever rotative engines are brought to perfection, it will be by something of the nature of these two engines, which are the most practicable, and promise greater probability of success than any before invented.

For the application to steam-boats, and to the purpose of drawing carriages, or locomotive engines, as they are now called, rotative engines would be so advantageous, that they would
STEAM-ENGINE.

would be very useful, even though they should consume rather more fuel than reciprocating engines of the same power, provided they were certain in their action.

Cement for making Joints in Steam-Engines. — In joining the flanges of iron cylinders, and other parts of hydraulic and steam-engines, a strong and durable cement is required. The following are receipts for cements proper for such purposes.

Mix boiled linseed oil, litharge, red and white lead, together to a proper consistence: this cement is to be applied on each side of a piece of flannel, previously flapped to fit the joint, and then interposed between the flanges, before they are brought home to their place by the screws or other fastenings employed, which will make a close and durable joint. The quantities of the ingredients may be varied without inconvenience, only taking care not to make the mass too thin with the oil. It is difficult, in some cases, to make a good fitting of large pieces of iron work at once, and this renders it necessary sometimes to join and separate the pieces repeatedly, before a proper adjustment is obtained. When this is expected, the white lead ought to predominate in the mixture, as it dries much slower than the red. A workman knowing this fact, can exercise his own discretion in regulating the quantities; but it is safest to have too much rather than too little white lead, as the durability of the cement is no way injured thereby, only a longer time is required for it to dry and harden. When the fitting will not admit of so thick a substance as flannel being interposed, linen may be substitutted, or even paper or thin plateboard, the only reason for employing any thing of the kind being the convenience of handling. This cement anwers well also for joining broken flanges, however large. Ciliers built of square flanes put together with this cement, will never leak or want any repairs: in this case the flanes need not be entirely bedded in it, for an inch or even less of the edges that are to lie next the water need only be fo treated, and the rest of the joints may be filled with good lime.

Another cement, which is preferable to the former for withstanding the action of steam, is compounded as follows: Take two ounces of sal ammoniac, one ounce of flour of sulphur, and 16 ounces of call-iron filings or borings: mix all well together by rubbing them in a mortar, and keep the powder dry. When the cement is wanted for use, take one part of the above powder, and 20 parts of clean iron borings, or filings, and blend them intimately by grinding them in a mortar: wet the compound with water, and when brought to a convenient consistence, apply it to the joints with a wooden or blunt iron spatula. — By considering the affinities of these ingredients, those who are at all acquainted with chemistry, will be at no loss to comprehend, that a degree of action and re-action takes place among the ingredients, and between them and the iron surfaces, which at last causes the whole to unite as one mass: in fact, after a time, the mixture and the surfaces of the flanges become a species of pyrites, holding a very large portion of iron, all the parts of which cohere strongly together. Another cement of the same kind is made by mixing together two parts of flour of sulphur, and one part of sal ammoniac, and making them into a stiff paste with a little water. When the cement is wanted for use, dilute a portion of the above paste in urine, or in water rendered slightly acidulous; and to this solution add a quantity of turnings or borings sifted, to get rid of the grogger particles. This mixture, spread upon or between the flanges of iron pipes, or put into the interstices of other parts of iron work, will in a little time become as hard as flone.

Mr. Murray's Rule for the Weight of Fly-Wheels to Steam-Engines. — Mr. Buchanan, in his valuable treatise on propelling vessels, printed at Glasgow in 1816, gives the following rule, as the result of Mr. Murray's long experience in building engines.

Rule. — Multiply the number of horse-power of the engine by 2000, and divide it by the square of the intended velocity of the circumference of the fly-wheel in feet per second, the quotient will be the weight of the fly-wheel in hundred weights.

Example. — To find the weight of a fly-wheel proper for an engine of 20 horses' power, supposing the fly-wheel to be 18 feet in diameter, and to make 22 revolutions per second: wheel 18 feet diameter = 1132 feet circumference × 22 revolutions per minute = 60 = 204. feet motion per second for the motion of the circumference of the fly-wheel. Then 204 feet per minute squared = 4204, and 20 horses' power × 2000 = 40000 ÷ 4204 = 96.4 cwt. of the wheel required.

Smoke-Burning Furnaces for Steam-Engines. — The great quantity of smoke which is thrown out by the furnaces of steam-engines, becomes a great annoyance in a town such as Manchellor or Birmingham, where there are many engines together. To avoid this, as well as from an idea of obtaining a greater water effect from the combustion of the smoke, many inventors have been induced to contrive furnaces which shall not produce any smoke. The black smoke which is usually discharged at the top of the chimney, is, in fact, so much good fuel, which only wanted a sufficient heat, and the contact of fresh air, to inflame it under the boiler. It is a fact well known, that the flame which is often seen issuing from the top of the chimneys of founderies, furnaces, &c. has no existence except at the top of the chimney; for while it is ascending the flue, it is only dense, black smoke, consisting of the azote of the atmospheric air which has passed through the fire, of hydrogen gas, coal-tar, and carbonaceous matter; and this smoke is of such a high temperature, that it only requires oxygen to make it inflame instananeously: this it obtains from the atmospheric air, into which it descends on issuing from the top of the chimney, and then presents such appearances, as would make a hasty observer adopt the opinion that the flame had ascended, in the state of flame, from the fuel in the furnace, through the whole height of the flue, up to the top of the chimney; but this is by no means the case, and a consideration of this simple fact will convince any person, that it is not an inconsiderable proportion of the fuel that is thus wasted. Nor is this the only loss sustained: a quantity of heat is required, not merely to render such a portion of the fuel volatile, but to give it a temperature sufficient to our producing the spoileine inflammation at the top of the chimney, of which we have taken notice. This must be furnished at the expense of an extra and unnecessary quantity of fuel.

The first of the smoke-burning furnaces was Mr. Watt's patent of 1785. His method consists in causing the smoke, or flame, of the fresh fuel, while passing from the fire to the flue or chimney, to pass, together with a current of fresh air, through or among fuel which has already ceased to smoke, or which is converted into coke, charcoal, or cinders, and which is intensely hot; by which means the smoke, and gasser parts of the flame, by coming in close contact with the intensely hot fuel, and by being mixed with the current of fresh or unburnt air, will be congealed or converted into heat, or into pure flame, free from smoke. This invention is put in practice, first, by slopping up every avenue or passage to the chimney or flues, except such as are left in the interstices of that part of the fuel which is ignited; secondly, by placing the fresh fuel above, or nearer to the external air, than that which is burning, and already converted into coke or charcoal; thirdly, by contriving the fire-place in such manner,
manner, that the fresh atmospheric air which animates the fire, and the smoke or flame which rises from the fresh fuel at the first application of the heat, nullifies downwards, or laterally, so as to pass through the whole mass of burning fuel, and issue from the interior of the burning fuel at the most remote part, or internal end of the fire-place, to escape into the flues or chimney. In some cases, after the flame has passed through the burning fuel, it is made to pass up a very hot funnel, flue, or oven, before it comes to the bottom of the boiler, by which means the smoke is more effectually confined.

This invention of Mr. Watt’s has been very extensively practiced; but another plan, by Mr. Roberton of Glasgow, has since been found preferable: it is nearly on the same principle as Mr. Watt’s. The opening through which the fuel is introduced into the furnace is shaped like a hopper, and is made of cast-iron, built into the brick-work of the furnace. From the mouth, or entrance of the hopper, it inclines downward to the place where the fire re-ignites on the bottom grate.

The coals in the mouth-piece, or hopper, answer the purpose of a fire-door; and the principal point to be attended to in the management of this furnace is, that the hopper shall be kept full of coal, either wholly or in part with small coal, to prevent as much as possible the air entering by that passage. The coals which are in the lowest end of the hopper are brought to a state of ignition by the heat of the fire upon the bars, before they are forced upon the bars to be burned.

Beneath the lower part of the hopper the furnace is provided with front bars, which serve to admit air among the fuel which lies upon the grate, and offers a ready mode of forcing the ignited fuel, which has just flulled from the lower part of the hopper, back upon the fire-grate, where it is completely consumed, and by thus forcing it back, a space is made, into which fresh fuel falls from the lower part of the hopper; but all the smoke which rises from this fresh fuel nullifies through the burning fuel, which lies upon the farther part of the grate, and is thus consumed. By this arrangement, the fuel is brought into a state of ignition before it reaches the farther side of the bottom grate, where it is flugged by a rising breath of brick-work; therefore, any smoke which is liberated from the raw coals in the mouth-piece, nullifies over these burning coals before it can reach the flue of the chimney; but this, though it would cause a large quantity of the smoke to be burnt, would not completely prevent the escape and ascent of smoke up the chimney; for it is not sufficient that the smoke should be exposed to a heat sufficient to ignite it before it escapes; as, unless a quantity of fresh air, able to furnish a sufficiency of oxygen for the combustion of the smoke, can be brought at the same time in contact with it, it will fill escape in an undecayed flame.

The principal merit of Mr. Roberton’s invention consists in a judicious admission of fresh air, in such a manner that it can reach the smoke without previously passing through the fire, and parting with its oxygen in its passage, and that it shall be in such quantity, as merely to cause the smoke to burn, and not to cool the bottom of the boiler. Beneath the upper side of the mouth-piece, or hopper, which inclines the fresh fuel, and at the distance of about three-fourths of an inch from it, (this space being a little more or less, according to the size of the furnace,) is placed a cast-iron plate, which is above the hopper containing the fuel; and in the space between it and the top of the hopper is an open space for the admission of a thin stream of air, which, rushing down through the opening, comes first in contact with that part of the fire which is giving out the greatest part of the smoke; viz. the fuel that has been left introduced from the lower end of the hopper upon the grate-bars, mixes with the smoke before it passes over the burning fuel upon the interior part of the grate-bars, where it is in a high state of combustion: this enables the smoke to inflame completely. The quantity of air thus admitted to pass over the upper surface of the fuel newly introduced, is a matter of importance to the complete action of the contrivance. The opening for air is regulated by a very simple contrivance. The plate which forms the upper side of the opening for the passage of the air, rests at one end on a fluid, or pin, projecting from the cheeks of the mouth-piece, or it is furnished at each end with a pivot, which works in the cheeks. These pins, or pivots, being placed about halfway between the outside and inside of the mouth-piece, or hopper, by elevating or depressing the outer edge of the plate, the opening for the admission of air between the lower end of the hopper and the lower edge of this plate can be diminished or enlarged. When that degree of opening which produces the best effects is obtained, which is easily known by experiment, the plate is kept in its place by means of a piece of iron introduced above it, and answering the purpose of a wedge. These furnaces have been adopted by many manufacturers at Leeds, Manchester, and London, where many works have been indited as a nuisance for not having adopted the improvement; the magistrates arguing, that though the welfare of the place required that such inconveniences should be submitted to while no possible remedy for them was known, the health and comfort of the inhabitants equally demand, now that evil can be done away, that smoking furnaces should not be permitted in the place. On this account, Mr. Roberton’s furnaces have been very much adopted; but we have seldom seen them in such order as to make any diminution in the smoke, which they do completely, if the regulation of the quantity of air is properly made.

A recent invention by Mr. John Cutler in 1815, is found to burn the smoke most perfectly in common fire-grates, such as are used for warming apartments; and we have seen an experiment of this plan upon a small engine boiler, which seemed to promise great success in applying it on a larger scale; but such trials have not yet been made, nor the best form of the apparatus settled.

Mr. Cutler’s invention consists in applying beneath the place in which the fire is to burn, a chamber or magazine, which is made as close as can be on all sides, except the top, and is of sufficient capacity to contain within it a magazine of fuel, sufficient to supply the combustion for a whole day, or other required space of time. The fire is made upon the top of the mass of fuel which is contained in the magazine, and there are no grate-bars upon which the fire is to lay; but instead, the bars are placed at the side, in a sloping direction, so as to incline the fire in a grating, which will admit sufficient air sideways to supply the combustion. The bottom of the magazine is made moveable up and down in the chamber; and by means of a rack and pinion, a worm, or some other mechanical power, the whole weight of the coal contained in the magazine can be raised up, and a portion will rise up into the grate part, where air is supplied to it, so that it can burn; for the principle of this invention is to make the magazine-chamber beneath so close as to exclude the air from it, so that the fire cannot burn the fuel contained in it, and to provide that part of the fire-place which is immediately above the top of the chamber with a plentiful supply of air to burn the fuel. By means of the machinery, any quantity
quantity of fuel can be raised up out of the magazine-chamber to supply the deficiency occasioned by the combustion.

The manner in which it burns the smoke, is by obliging it to pass through the burning fuel which lies upon the top of the mass of coal contained in the magazine, because this burning fuel communicates sufficient heat downwards to make the smoke rise from the fuel, and this smoke must pass through the fire above it; but before the fuel comes to be actually burned, the smoke is so far extracted, that the coal is in the state of coke.

The machinery by which the bottom plate of the magazine and the fuel contained in it is raised up, is simply an axle, with chains winding upon it; at least that is the contrivance which Mr. Cutler used in the small stoves for warming apartments; but what method will be found best on a large scale, for its application to steam-engines, remains yet to be determined. We shall give a more minute description of this valuable invention under the article Stove.

The Application of the Steam-Engine to propel Boats or Ships.

—This is one of the most valuable applications of the power of steam, next to that of draving mines; and though proposed at a very early period, has been but lately brought into use.

Captain Savery, in 1702, mentions the application of his engine to a ship, but gives no account of the manner of carrying it into execution; probably he only intended it for pumping out leakage-water.

Mr. Jonathan Hull’s patent of 1736, for carrying vessels or ships into or out of any harbour, port, or river, against wind or tide, or in a calm, is the first idea of applying the steam-engine to the purpose of propelling vessels. The engine of Newcomen was made to actuate a wheel placed in a frame projecting from the head of the boat, and the oars or paddles of the wheel were to strike in the water, and advance the boat or vessel containing the engine, which would draw after it the ship or vessel that was to be rowed into or out of the harbour. We have no account of any actual trials made by Mr. Hull; but besides his patent, we have a small pamphlet, printed in 1737, with an engraving.

The account which Mr. Buchanan gives of the introduction of steam-boats in his treatise on propelling vessels, is, that Mr. Miller of Dalfinoun, who made many models and experiments with a view to the improvement of naval architecture, appears to have made the first attempt at working a vessel with steam. The vessel was double, with the paddle-wheels in the middle; the experiment, however, did not succeed to his satisfaction.

About the year 1795, Lord Stanhope constructed a vessel, which was tried in Greenland dock; the paddles were made in the imitation of the feet of a duck, and were placed under the quarters of the vessel, but the mechanism did not answer his lordship’s expectation.

In the year 1801, Mr. Symington tried a vessel propelled by steam on the Forth and Clyde Inland Navigation, but it was laid aside, on account of the injury which it threatened to the banks of the canal, by the surge of water which it made. It does not appear that he tried this vessel on any river.

Mr. Symington’s steam-boat is slightly described in the Journals of the Royal Institution for 1803, from which it appears, that the method employed by him for making the connection between the piston and the water or rowing wheel, was by placing the cylinder nearly in a horizontal position. This is attended with several advantages: the necessity for a beam is avoided, which has ever been a troublesome and expensive part of the common engine. The piston is sup-

ported in its position by friction-wheels, and communicates, by means of a rod, with a crank connected with a wheel, which gives a motion to the rowing-wheel somewhat slower than its own; the water-wheel serving at the same time as an addition to the fly. The steam-engine differs but little in its action from that improved by Mr. Watt; there is, however, an apparatus for opening and shutting the cock at pleasure, in order to reverse the motion of the wheel, and put the boat back whenever it may be necessary. The water-wheel is situated near the stern, and in the middle of the breadth of the boat, so that it becomes necessary to have two paddles, connected together by rods, which are moved by a winch near the head of the boat; by this means the person who attends the engine is able to steer also.

Another part of Mr. Symington’s invention consisted in the application of flammers at the head of the boat, for the purpose of breaking the ice on canals; these were to be raised in succession by means of levers, the ends of which were depressed by the pins of wheels, turned by an axis communicating with the water-wheel. Mr. Symington stated, in a calculation he made, that a boat doing the work of twelve horses, could be built for eighty or nine hundred pounds; and he had ascertained by experiment, that it would travel at the rate of two miles and a half per hour. This is a very slow motion, compared with the present steam-boats, as we shall see.

In 1807, Mr. Fulton of New York introduced steam-boats into America, which were the first that succeeded in a large way, so as to become profitable; they had before this been used in America, and were begun there by Mr. Symington. In 1812, a large boat was set to work on the Clyde, in Scotland; and since that time, great numbers have been made both in Scotland and in different parts of England.

There are several different methods of applying the force of machinery to row boats; the most obvious is by means of oars, similar to those with which a boatman rows; but this action is very difficult to imitate by machinery, and has never been brought into practice. Several ingenious schemes may be found in the Machines Approvées per l’Académie.

The next is by means of paddle-wheels, which are similar to an under-shot water-wheel; and when turned rapidly round by the engine, the floats dip into the water, and row the boat along. This plan was first put in practice by the ingenious captain Savery, in 1702; but to be turned by men working at a capstan instead of a steam-engine, is now adopted in all the real working steam-boats which have been made. Two wheels are usually placed at the sides of the boat, at about one-third of the length from the head. Attempts have been made to place one wheel in the middle of the boat, but they have not succeeded so well as the others.

Another method is by forcing a stream of water out at the stern of a boat by a large pump, which at the same time draws the water in at the head of the boat. This was suggested by Dr. Franklin, after M. Bernoulli, and was very effectually tried by the late Mr. James Linaker, master millwright of the dock-yard at Portsmouth, but found inferior to the paddle-wheels. It has been also proposed to force air under the stern of the vessel by a pump, but we do not think it likely to succeed.

A fifth method is by a screw applied at the stern of the vessel, and turned round by the engine.

Lastly, various forms of oars have been applied at the stern of the vessel to move from side to side, and impel the vessel on the same principle, as what seamens call skulling a boat, by an oar at the stern.
STEAM-ENGINE.

As none of these schemes, except the paddle-wheels at the outsides of the boat, have been brought to any practical utility, we shall not enter into any further particulars, but describe one of the boats of these vessels, such as is employed on the Clyde at Glasgow, where steam-boats have been brought to the greatest perfection.

All these vessels are upon one general plan, viz. that of having paddle-wheels, similar to underfoot water-mill wheels, on each side of the boat, which are put in motion by the steam-engine. In some of these vessels the paddles are placed parallel to the axis of the wheel, in others they are placed obliquely, and in others again they are curved; and it is not yet ascertained which is the best form; for although some boats are found to move with a much greater velocity than others, it is difficult, where so many causes are combined in the operation, to ascertain which one singly produces the advantageous effect. Experiments are yet wanting to ascertain the belt number for the paddles on the wheel, and with what velocity they should move. It would doubtless be of advantage to have the means of changing the velocity of the paddle-wheels, according to the circumstances of the current of the water in which the boat moves; because when the boat is moving with the current, the paddle strikes against the water in contrary direction to its motion, and therefore has the greatest force to urge the boat forwards, at the same time that the boat is moving in the direction of the current, and therefore moves more easily. On the other hand, suppose the boat moving against the current, the paddles will row the water in the direction of the current, so that supposing they move only with the same velocity, they must have much less force to advance the boat, at the same time that the boat, having to oppose the current, requires a greater force to propel it. One of the steam-boats on the Clyde has eight paddles to each wheel, but it is probable even would be more effectual; because it is evident, that if too many paddles are used, the water will be so much broken, that it cannot afford that resistance to the motion of the paddle which alone causes the boat to advance.

For an extreme case, suppose so great a number of paddles that they would nearly touch, the wheel would then resemble a solid cylinder, and have no effect to propel the vessel. The velocity with which the paddle strikes the water must be considerable, to obtain a great resistance from the water; but the stroke must not be too frequently repeated, or the water which the paddle removes will not have time to return to its level before the succeeding paddle makes its stroke.

The steam-engine is placed near the middle of the vessel, and the smoke is carried up in a large plate iron tube, which serves the purpose of a mast, to hold a sail when the wind favours. The greatest number of boats at present in use are fitted up for passage-boats, as that is the most profitable employment: they have two cabins, one before the engine, which is smaller, and considered inferior, while the second, or large cabin, abaft the engine, is more elegantly fitted up. Plate VIII. Steam-Engine, fig. 1. is an elevation of the whole vessel, as it appears in the water, and fig. 2. a plan with the deck removed, to shew the arrangement of the apartments, and to explain the steam-engine and machinery by which the vessel is propelled.

That part of the boat which is beneath water, is built like an ordinary boat, which draws but little water, and she is so formed at the stern-ports as to cause her to steer readily. The head must be built more bold or rounding for those boats which are intended for the sea, than those for rivers, which are generally made very sharp at the head, so as to divide and move more freely through the water. The rudder and tiller are constructed the same as other boats. The width of the vessel above water is considerably increased, by the addition of galleries or gangways, X, X, which are fixed projecting from her sides and gunwale: they are composed of a thin planking, and are supported by knees and flanchions, so as to form a gangway to walk round, and at the same time a defence to the paddle-wheels B, B, which are placed close to the sides of the vessel in the width of the gangways. These wheels are put in motion by the steam-engine, and by their action against the water propel the boat forward. The paddle-wheels are constructed nearly in the same manner as underfoot water-wheels, except that the floats or paddles are placed inclined to the axis, instead of being perpendicular before the rim of the wheel. The upper parts of the wheels are inclosed in semi-circular cases of thin boarding Y (fig. 1.), to prevent the action of the wind upon their floats, which, without this precaution, would materially impede their motion, because the floats at the upper part of the wheels move in a contrary direction to those at the lower part, where they dip into the water.

The steam-engine which gives motion to the wheels, is situated in the middle of the boat; but it must be placed low, and, if possible, beneath the water-line, so as to act in part as ballast to the boat, which will otherwise require a greater quantity of ballast than usual to counteract the weight of the engine. It is a great advantage to these boats to be light, and draw little water; these engines must therefore be made as light and compact as is possible, that none of the parts shall break. The principal parts which require strength should be made of good wrought iron, in preference to cast iron, which is used for other engines; for instance, the beam and connecting rods, and also the cranks and shaft for the fly-wheel, as well as those for the paddle-wheels. The wheels themselves are made of thick iron plate or wood; the boiler A (fig. 2.), in which the steam is produced, is made of wrought iron plates, and as large as the space which can be allowed for it will admit, that it may produce a regular supply of steam to the engine: it is placed sometimes across the vessel, and sometimes in the direction of its length, as shown in the figure; and the fire-place is an iron tube contained withinside: / is the fire-door: the smoke, after passing through two or three turns of the tube in the boiler, passes off through the chimney C, which is an iron tube, erected perpendicularly in the centre of the vessel, to a considerable height, as shown in the elevation, and is flayed, in the same manner as a malt, by two ropes, or sometimes by iron chains from its top, going fore and aft, with a purchase to each to draw them always tight. There is a safety-valve at d, by which the steam escapes into the chimney when it is produced in too great a quantity, and becomes too strong; or when the engine is not in motion: e is the steam-pipe, which conveys the steam from the boiler to the steam-box f, which contains the four valves for distributing the steam into the cylinder G, alternately above and below the piston, so as to give motion to the engine. These valves are made to work on the plan of Mr. Murray's patent, with the spindle of one through the other. The top of the piston-rod is jointed to the middle of a crofs-rod. From the ends of which the two iron rods descend, one on each side of the cylinder, and are jointed to the beam, G P, which is made double, or composed of two levers, joined together in the manner of a frame, so that the cast-iron condensing cistern of the engine is contained between the two, as they work up and down: the beam-centre, or axis of motion, is supported by two bearings fixed up to the bottom of this cistern, so that the beams lie close to each side of the cistern: the cylinder is fixed down upon one end of the condensing cistern, and the bearings for the axis of the crank, R, are supported on the other end. The beams, G P, are united together at the extremity most remote from the cylinder by a crofs-rod, on the
STEAM-ENGINE.

the middle of which the connecting rod is jointed, which rises upwards to the crank R, on the shaft or axis of the fly-wheel M; this crank-axi is supported in bearings close on each side of the crank, which are framed to the condensing cinders; and also two others at the extremities of the axis, which are placed on the gunwale of the boat, so that the shaft extends completely across the vessel, passing through the boiler A, in a tube which extends across it, as shown by dotted lines at a. On each end of the crank-axi two cog-wheels are fixed, engaging in the teeth of two other wheels, O, O, fixed upon the shafts of the paddle-wheels B, B. These last-mentioned shafts are each supported in two bearings, one on the outside beam of the gangways or platforms, and the other on the gunwale of the vessel: the cog-wheels, O, O, are fixed on the extreme ends of the shafts within the vessel, and they are one-third or one-fourth larger than the wheels on the axis of the crank, so that the paddles do not turn so fast as the fly-wheel of the engine.

It is needless to enter into a description of the action of the steam-engine; the construction of the valves in the same as described in a former part of this article (Plate VII. fig. 5.), and the engine acts the same as Mr. Watt's double-acting engines; but it is necessarily modified, to suit its particular situation, which occasions some defects. The cylinder must be made very short, to come into the height of the boat; and the connecting rod is so short, that the obliquity of its action on the crank is very great. The air-pump, H, is worked by a cross-rod, which moves up and down with the beams, being connected to them by perpendicular rods. The requisite movement is communicated to the valves of the engine by the rod j, one end of which has a circular hoop, that embraces an excentric wheel p, fixed on the axis of the fly-wheel; so that in turning round, it pushes the rod j p backwards and forwards, in the manner of a crank, and thereby alternately opens and shuts the valves at the proper instant to produce the motion. There is a throttle-valve placed in the steam-pipe at e, for regulating the velocity, or stopping the engine, when required.

The arrangement of the apartments in a steam-vessel may be varied according to the purpose for which she is to be employed. In the drawing, we have given the arrangement which appears best adapted for the convenience of passengers, in a vessel for quick travelling. (See the plan, fig. 2.) The after or grand cabin, marked i in the figure, is generally fitted up and furnished in an elegant style, for the use of the boat company, who also occupy the deck and gangways abaft the chimney. The entry to the grand cabin is at the stern of the vessel. The grand cabin is generally situated in the after-part, on account of there being the mull room in that part, the engine being always placed considerably nearer the head of the vessel than the stern; a small room for the use of the passangers, and has a door coming out on the gangways. The entry to the engine-house is by steps from the gangway on the opposite side; and the same entry serves for a small room 4, in which the steward keeps his stores. The coals for working the engine are stored beneath the floors of the cabins, and the engine-man draws them out with a long hook as he wants them. The forward-cabin, 5, is for passengers who pay less than the others: it has a large counter or chile in the middle, which will contain all the luggage, and serves also as a table for those who fit round it. These passengers have a seat to the crank forwards of the chimney; but the gangways at that part are almost entirely occupied by a large water-calk on each side, the cable, spare sails, or whatever the vessel may require. The rigging of the boat is evident from fig. 1: the carries two large lugger-fails, one fore and the other aft; but as these are only intended to be used in fine weather, with a fair and light wind, the masts and cordage may be as light as is convenient. A pair of hajiards should be provided to the chimney, to hoist occasionally a large light lugger-fail; and if the chimney is not sufficiently strong, a pair of extra stays may be set up to strengthen it. The chimney is generally made to lower down, for the convenience of passing bridges, when the vessel navigates a river.

The paddle-wheels of one of the boats on the Clyde, which, Mr. Buchanan says, is considered as a standard, are 8 feet 10 inches diameter, and 4 feet wide, and are calculated, when the engine makes 45 strokes per minute, to move at the circumference, or strike the water at the rate of 13 miles per hour. She is about 80 tons burden, and is 69 feet from stem to stern, and 15 feet 2 inches wide in the beam. The engine is of 14 horses' power, and the goes at an average six miles per hour in still water: therefore, if there is a current, the will go as much faster or slower than six miles per hour as the velocity of the current. The motion of the paddles is rather more than twice that of the boat.

Steam-boats have been built with much more powerful engines, even 20, 25, and 30-horse power; but the increase of the velocity has not been in proportion to the increase of the power of the steam-engines. This will not be surprising, when it is considered that the resistance to which a boat is subject, increases not in an arithmetical proportion, (as 1, 2, 3, 4, 5, 6, 7, 8, 16, 32.) In other words, to make the same vessel move with ten times a given velocity, it requires one hundred times the power; and it is farther to be considered, that one or more powerful engines above mentioned are heavier, and require a greater floating body to support them, which of course increases the resistance.

On railways, an increase of velocity requires only an arithmetical increase of power; and to draw a carriage on a railway with ten times a given velocity, would require only ten times the given power.

Steam-boats require a greater power of stature than any other vessel of their size, as those hitherto constructed are less easily turned than vessels impelled by sails only. The tendency of the wheels acting so near the centre line of the vessel, is to propel her straight forward; whereas in turning a sailing vessel to the wind, the sails aid her in coming about, and even common oars act so far out from the side of the vessel, that they have much more power to bring her round than the wheels of a steam-boat can possibly have.

A most important point is to have a good steam-engine. All the engines hitherto used in Scotland have been made on Mr. Watt's principle; but those in America have been high-pressure engines, which being more simple, and less expensive, some have been constructed in England. But one of them having exploded in an American boat, the proprietors of some of the English boats have changed their engines for others on Mr. Watt's principle, to avoid similar accidents. We think it quite unjustifiable in any engineer to advise the construction of steam-boats with high-pressure engines, at least for passage-boats, in which so many persons are always assembled together, and so near to the engine, that they would be all destroyed in the event of the boiler bursting.

Those engines which work with a bell-crank, or a double beam, below the cylinder, and on each side the ciphers, instead of a beam working above, are found to strain the vessels; those having the beam above, work much more readily.
STEAM-ENGINE.

The engines that Messrs. Boulton and Watt have hitherto constructed have had beams; other engines have had cylinders horizontally. Mr. Brunel's engine, of which we have before spoken, has two cylinders acting alternately, so as to require no fly-wheel; but many engines, on the common construction, have been made without fly-wheels, by having the paddle-wheels sufficiently heavy to answer the purpose.

With regard to fuel, it is obviously much more difficult to have every thing kept in proper order in a boat, where the engines are much confined, and the cylinder is made to work with very short strokes, by which the action on the crank is so oblique, and changes its direction so frequently, that the greater part of the power is lost. The quantity of fuel constantly used in steam-boats has been much greater than the usual allowance for Messrs. Boulton, Watt, and Co.'s steam-engines. For one of 14-horse power, they allow 1 cwt. 1 qr. 20 lbs. per hour of good Newcastle coal; but Glasgow coal is much weaker. One of the boats, with an engine of 33-horse power, requires 3 tons 12 cwt. from Glasgow to Greenock (fully 29 miles), and back to Glasgow. One of 15-horse power, and another of 8-horse power, take each the same quantity, viz., from Glasgow to Greenock (26 miles), and back to Glasgow, 1 ton 1 cwt. For farther particulars on steam-boats, see Robertson's El�� on Propelling Vessels, 8vo. 1816.

The Application of Steam-Engines to driving of Carriages.—There are now called locomotive engines, and we may date their introduction with the patent of Messrs. Trevethick and Vivian in 1802, for the high-pressure engines, which were expressly intended for working carriages. It would have been very difficult to have succeeded with any other kind of engine, as the weight of the water necessary to effect condensation must be so great. Mr. Trevethick made a locomotive engine in South Wales in 1804, which was tried upon the rail-roads at Merthyr Tydfil. The engine was the same as that of which we have given an account of its work in speaking of the high-pressure engines, having an eight-inch cylinder, and a four-feet six-inch stroke. It drew after it, upon the rail-road, as many carriages as carried ten tons of bar-iron; at a distance of nine miles; and it performed all that diligence without any farther supply of water than that contained in the boiler at setting out, travelling at the rate of five miles per hour.

Since that period they have been tried in many places upon rail-roads, but we do not think they had been really put in practice, so as to work constantly, until 1811, when Mr. Blinkinop, proprietor of the Middleton coal-works, which supply the town of Leeds, adopted them for conveying the coals on his rail-road.

Mr. Trevethick's first engines consisted of a high-pressure engine, with a boiler of cast-iron, of a cylindrical form, five feet long, and four feet three inches diameter, the fire-place being within the cylinder. The cylindrical boiler was mounted horizontally upon four wheels, and the cylinder of the engine was placed vertically in the end of the boiler, having two connecting rods descending from the cross-bar of its pinion-rod to two cranks, upon an axis extending beneath the boiler and cylinder, and communicating its motion, by means of wheel-work, to the two fore-wheels, upon which the engine runs; and by this means the alternate ascending and descending motions of the pinion-rods act to turn round the crank and wheels, and draw the carriage forwards; in this way no fly-wheel was necessary, because the movement of the carriage to advance itself forwards on the road, continued the motion of the wheels and cranks sufficiently to make the cranks pass the lines of the centre. Where these engines were tried, it was found difficult to make the wheels take sufficient hold upon the railway to draw any considerable load after it, unless the weight of the engine and work relling upon the wheels was made very considerable, and then the common iron rails of the railway were sometimes broken by the pulling of the engine.

Mr. Blinkinop, when he adopted the locomotive engine, took up the common rails on one side of the whole length of the road, and replaced them with rails which had large and coarse cogs projecting from the outside. These cogs are cast at the same time with the rail, and are hollow beneath, to be as light as is sufficient with strength and durability. The pitch of the cogs, or distance from centre to centre, is fix inches, so that each rail, of three feet in length, has only fix cogs. A wheel, which is fixed on an axis at one side of the carriage, works in the teeth of the rails; and as it is turned by wheelwork from the axis of the cranks, the whole machine is caused to advance along the railway. When we saw Mr. Blinkinop's first trial, he employed a small condensing engine, but finding the water to grow to hot that he gained but little by the condensation, he applied a high-pressure engine with a wrought-iron boiler, and two cylinders in it acting upon separate cranks, so as to produce a constant action to advance the carriage without the necessity of using a fly-wheel.

A similar machine has been tried at Newcastle, but they have attempted to employ the wheels alone, without cogs upon the rails. To relieve the weight upon the rails, and obtain greater re-action to advance the carriage, they applied fix wheels for the carriage to run upon; and to make the bearing equal upon all fix, the two middle wheels were applied to the pinion of a small cylinder beneath the carriage, into which steam was admitted, and by its pressure bore up a portion of the weight of the engine; and accommodated itself to any inequalities of the railway.

At present, locomotive engines have been confined to moving upon iron-railways: to make steam-engines draw carriages upon public roads, is a refinement not yet attained. In drawing up this article, we have derived considerable affluence from books, as our numerous references will testify; but at the same time we cannot refer to any one work in the English language for a more detailed account of the steam-engine than we have here given. Many detached memoirs on particular points of the principle or construction of the steam-engine, may be found dispersed through the forty-six volumes of the Philological Magazine, and the Philosophical Journal. The first and second volumes of the quarto series of the latter work contain a sketch of the history of the invention, but no particulars which are not given more at large in this article.

The Repertory of Arts, Manufactures, and Agriculture, consisting of sixteen volumes of the first series, and twenty-eight volumes, now published, of the second series, contains the specifications of a great number of patents for inventions relating to the improvement of steam-engines, of which we have noticed nearly all in this article, which appeared to pollute merit, or to have been successfully put in practice.

The article Steam-Engine in the third edition of the Encyclopædia, which was written by Dr. Robison, is the best and most philosophical view of the subject, but he has not entered at all into details: and as this was composed twenty years ago, the improvements made since that period, in the construction of the machine, have made a total change.

The fullest account of the improved steam-engine is by the celebrated French engineer, M. Prony, who devotes the second volume of his " Nouvelle Architecture Hydraulique," 1796,
STE

expressly to that subject. He describes four or five engines, with a great number of large plates, containing every detail of their construction. The work is little more than a description of the plates. These engines are not the best specimens of Mr. Watt's invention; they were all constructed in France by M. Perrier of Paris, who, in 1780, erected a large engine at Chalott, to pump up the water of the Seine for the supply of the town, and another of smaller dimensions on the opposite side of the river at Gros Caillou. These engines are still at work, and the writer of this article visited them in 1814; they are upon the plan of Mr. Watt's first engines, though, for want of attention to some minute particulars, they do not produce any great effects. M. Perrier had visited England to obtain the requisite instructions for making these engines.

The double-acting engine of Mr. Watt was carried into France by M. Betancourt, whose experiments on the expansive force of steam are referred to in this article. This gentleman came to London in 1788, with a view of collecting models of improved hydraulic machines for the court of Spain, and was admitted to examine the steam-engines made by Messrs. Boulton and Watt at the Albion Mills for grinding corn, which were the first large double-acting engines they had made. M. Betancourt has, in effect, made a kind of secondary claim to the invention of the double engine; for he informs us, that he saw in part the exterior construction and operation of those machines, but the interior mechanism was so concealed from him, as well as from others who had had the same curiosity before him, that he could only guess at the nature of the construction. He observed, that the chains which are usually applied to the extremities of the beam were suppressed, and that, instead of these, they had applied the parallel motion; that the different parts of the machine were so marked by the distribution of the building, which isolated the exterior parts into different apartments, as to prevent him from comprehending their correspondence; but, from the result of all his observations, he concluded the machine was of double effect.

On returning to Paris, M. Betancourt made a model of a double cylinder, on a scale of an inch to the foot; and, as he did not know the arrangement of Messrs. Boulton and Watt's valves, he invented those parts himself; and M. Perrier, from this model, constructed a large machine in 1790, at the Isle of Cygnes, in Paris, for grinding corn. By examining the construction of this engine, which is fully described by M. Prony, it will appear that M. Betancourt made good use of his observations, for we find the engine to be the same as Mr. Watt's in every particular, except in the arrangement of the valves, which part is very defective, as both the steam-pipe and exhaust-pipe must be filled with steam, and emptied at each stroke, in addition to the content of the cylinder, without producing any effect to work the engine. A different construction by M. Betancourt, with two cocks, is also described, but it has the same defect, of which M. Prony was sensible; and in a second machine which he describes, points out the remedy, by varying the arrangement of the valves, so as to bring them very nearly the same as Mr. Watt's, though externally of different appearance. None of these engines have steam-jackets for the cylinders, nor is the expansion principle mentioned by M. Prony. The beautiful contrivance of the regulation by the flying-balls is not described, but all the engines are regulated by a water-cistern and pump, which we have here described. See also **Regulator**.

It must be regretted, that none of our experienced engineers have undertaken to write a work on steam-engines, as there is not any subject in mechanics so interesting and useful.

Almost every introduction to philosophy contains a description of the atmospheric steam-engine, and most of the modern ones a short account of Mr. Watt's improvements; but these are in general very slight and defective; the best is in Breckman's edition of Ferguson's Lectures, which gives a sketch of Mr. Watt's double engine, with the parallel levers and rotatory motion; and we believe it was the first description published of that valuable invention, though it had been in general use for twenty-five years before. The engine is clearly described in the British Encyclopaedia, Svo.

**Steam-Boiler, in Agriculture**, the name of a simple convenient contrivance for preparing different sorts of cattle-food by means of steam, in a small way.

A perfectly convenient and practical contrivance of this nature for farms, where the extent of this sort of food is not required upon a large scale, has been described in the first volume of Communications to the Board of Agriculture: the part in which it is set is of stone or brick, built in a cubical form, about three feet every way; it has the door of a furnace, and an ash-pit: and a shallow iron kettle, about twenty inches in diameter, and seven or eight inches in depth, is placed over the furnace. There is a flat smooth stone covering the whole top part of the building, in the middle of which a round hole is cut out, to admit the iron kettle being fitted closely into it. A cauldron, the bottom of which is perforated with a number of auger-holes, is placed over the steam-kettle, which is about half filled with water. The cauldron is then filled with potatoes, and is closely luted or clayed all round the bottom, to prevent the steam escaping between it and the stone; the cover is put on also very closely, and there is a short thick plug put tightly in a hole in it, to give air; or this hole may be covered with a piece of lead, fitted closely upon it, and movable on a leather hinge, that it may of itself give way, to prevent the cauldron being endangered by the steam. The flue or vent may be built to the wall of any house, or any other convenient place. When the potatoes are steamed or boiled sufficiently, which may be known by taking off the cover, they are either taken out with a shovel, or else the cauldron is turned over, and emptied into a barrel or tub, and again filled, if necessary. By having it suspended in the middle, on two pins in a frame, it might be made to readily turn upside down, and empty the potatoes or other roots with great convenience. Though this is one of the most simple contrivances of a steam-boiler, it may be sufficiently to explain the nature of it. But they may be made of various other contrivances, according to the extent required, and one steam-kettle may be made to boil several caulls at the same time; or instead of caulls, there may be fixed boilers with sliding bottoms, for emptying the potatoes into little wagons, or barrows, wheeled in under. The potatoes might also be taken out of a fixed boiler by means of an iron basket, made to fit the inside of the boiler; which basket might be easily taken out with a lever, a small crow, or some other familiar contrivance.

And another excellent contrivance of this sort has been made use of by Mr. Stares, which is described in the Annals of Agriculture. But the most complete apparatus for this purpose, where the business is conducted in a very extensive manner, is that which has been fitted up and described by Mr. Curwen in the fourth volume of Communications to the Board of Agriculture, and which description will be given and further noticed upon, in speaking of the use of steaming of cattle-food. It may be suggested, that if steam-boilers be fixed up in a contiguous manner to the kitchens or sculleries of farm-houses, they may be occasionally converted to the use of the families; as this method
it preferable to the practice of boiling in water for most culinary purposes. See *Steaming of Cattle-Food*.

Some other simple and cheap inventions of this kind have also been made and had recourse to in different parts of the country, as will be seen under the head just alluded to.

**Steaming of Cattle-Food**, the operation or process of preparing different sorts of roots or plants, by means of steam, for the feeding of cattle. It is a practice that may be highly advantageous in such situations and districts as those where both fuel and labour are cheap; but in others it can perhaps seldom be had recourse to with profit. It has been long known that many sorts of roots, and particularly the potato, become much more valuable by undergoing this sort of preparation. And it is equally well known, that when thus prepared they have been employed alone as a substitute for hay, and with cut chaff both for hay and corn, in the feeding of horses, as well as other animals. It has, indeed, been observed, that to a farmer who keeps many horses or cattle, or even swine or poultry, the practice of boiling their food in steam is so great a saving and an advantage, that it deserves the most particular attention. It has, however, till lately, been confined to such narrow bounds, that it is known but to very few. And though potatoes have often been given raw to both horses and cattle, they are found to be infinitely preferable when boiled in steam, as they are rendered thereby much drier, and more nutritious, and better than when even boiled in water: this has been long since drawn from the experiments of Mr. Wakefield of Liverpool, who, in order to ascertain it, fed some of his horses on steamed, and some on raw potatoes, and soon found the horses on the steamed potatoes had greatly the advantage in every respect. Those on the steamed potatoes looked perfectly smooth and sleek, while the others were quite rough. Mr. Eccleston, near Ormskirk, in Lancashire, also found them useful instead of corn for their animals; and the extensive and accurate trials of J. C. Curwen, esq., have placed the utility and advantage of them in this way beyond all dispute. His statements have been in some measure given in speaking of potatoes. See *Potatoes*.

It is well known that this, as well as many other sorts of food, may likewise be rendered a great deal more useful and beneficial for feeding and fattening neat cattle and sheep by undergoing the preparation by steam. And probably for some other animals.

Mr. Curwen has found, that in their preparation in this way, the waste of the potato is about 34th part; and that straw, when given along with them, answers equally well as hay, as the horses keep their condition, and do their work equally well.

The plan of his washing and steaming-house, or apparatus for this purpose, is curious and interesting. It has, in the ground-plan, a well, and a conduit which takes the water from the potatoe-washing-machine. The potatoe-washer has a frame, over which a crane moves in a circular manner, which takes the machine out of the tub when the potatoes are washed, and which empties them into a back, which is raised from the floor the height of one of the steaming-tubs, or will meet another crane, which will place them on the lead-pots, where they are steamed. The boiler has a steam-pipe, which connects with the lead-pots near the place where the tubs stand upon whilst steaming. There are cocks which let off the condensed water; and a conduit which takes it away. The lead-pots stand upon a framing or platform, which should be ten inches above the floor. There are stone troughs, too, in which the potatoes are bruised for use before giving them to the animals. In the washing-machine, the handle goes twice about for the washer's once. And the crane and jack which wind up the washer is disengaged from the axle by a jointed notch between the two lead-rocks. The water-back is supplied by a fount from a pump, in order to fill the boiler; also, a shorter fount is applied to fill the tub which the washing-machine runs in. And it is remarked that a plug is in the bottom of the tub, to let off the dirty water. The boiler consists of two iron pans, screwed together by two flanges; and each pan will hold 40 gallons. The lead-pipes, which leads from the boiler, and conveys the steam to the lead-pots, is one inch in a quarter in diameter. It is observed that the lead-pots are 12 inches in diameter, and 9 feet in depth. There is a brass cock, which stops the steam when the tubs are taken off; also two other cocks are applied; one to open from the water-back, in order to fill the boiler; and the other to know when the boiler is sufficiently filled with water. There is likewise a steam-valve fixed upon the top of the boiler, of about 4 lbs. to a square inch. The tubs are 2 feet high, and 20 inches wide at the top, and 17 inches at the bottom, and will hold about 11 stone of potatoes.

It is also remarked, that the boiler will steam the four tubs in from 15 to 20 minutes. One or two tubs may be steamed at a time, by plugging up the steam-holes in the leaden pots. The tubs are let upon the lead-pots with flannel between, nailed upon the tub-bottom; and each tub-bottom is perforated, to let the steam ascend among the potatoes; and the lids of the tubs are held down by iron ball cleavers, four to each tub. When the potatoes are steamed, the other crane removes the potatoes to the stone trough to be made use of; and also places and replaces the tubs. It is observed, too, that the washer should be about two-thirds filled, and that it will most completely do the potatoes in two minutes. When taken out of the box, it is necessary to either pump or throw a pail of water over them, and to let it drain through them. The size of the washer must be according to the work required to be done.

Another method has, however, been suggested by Mr. Pierpont of preparing this root, and which he considers as superior in respect to, or so far as the goodness of the food for the use of cattle is concerned, as may be seen under the article *Potatoes*. This is by means of boiling or roasting them in ovens proper for the purpose. The ovens may be constructed in different ways; but that which is here described is three feet six inches by two feet six inches in width, and one foot nine inches in height. It has a cast-iron plate for the bottom, and is provided with flues. The oven, when complete, will contain fix digellers. It may be noticed, that in speaking of the process of baking the potatoes in these ovens, it is observed in the fourth volume of Communications to the Board of Agriculture, that three bushels of potatoes were weighed separately, each bushel weighing 60 pounds before they were put into fix digellers. The potatoes from the two first digellers, taken out of the oven when baked, and weighed together, were 55 pounds; and those from the second two were 54 pounds; and those from the third two, 54 pounds likewise. That the carpenter measured the wood with which they were baked, and he tells the writer that a well-lacked cord of good fuel-wood will bake 90 fets, or 90 times 6 digellers, each containing half a bushel of potatoes, at the rate of wood it took to bake the above fix, which was the second set baked that day. And he adds, that a cast-iron plate five feet long by two feet ten inches, instead of three feet ten inches
inches by two feet ten inches, which will hold eight digel- 
ters, and by adding a small fire thus,

<td>inches long, and six high.</td>
<td></td>
</tr>
</tbody>
</table>

...on each side the great fire-place, will, in his opinion, accelerate the baking from 15 to 20 minutes in every set, as well as fove fume. 

Also, in a subsequent communication, it is stated that the cord, or, as it is often called, the flack of wood, mentioned in the experiment, is 24 feet long, 3 feet wide, (that is, the wood is first cut into three-feet lengths,) and 1 foot 10 inches high; and is sold for 12s. on the spot in his neighbourhood. Each of the 6 digelters holds 6 gallons wine meafure, but in potatoe measure each will only hold half a bufheil; fo that 1, 2, or 3 bufheils, are baked at a time with one part out of 90 of the above cord, or flack of wood. He has never had occasion for more than 5 fix baken in a day; which 6 baken, that is, 6 flacks, or 18 bufheils, at 60 lbs. the bufheil, were done within twelve hours, the wood being in a dry flate. He believes that eight digelters, with the heat properly spread, would be done in somewhat less time, allowing for that of filling and emptying the two additional ones; and this should be sufficiently satiafactory for any perfon willing to use the method on a larger scheme.

Representations of these different apparatus for flameing of cattle-food may be seen in the second volume of the "General Dictionary of Agriculture and Husbandry."

There are some other more fimple and cheap contrivances in use in different districts for flameing of cattle-food, fuch as a hoghead cut in halves, the bottom raddled, and mortared half way into a small copper, and coarsely covered with a wooden lid. By this contrivance potatoes are fo quickly flameed in Suffolk, it is faid, that flax tubs are done in the course of the day, which is nearly double the number that could be boiled in the water. It is fuggested, however, that there fhould be an easier way of clearing the copper from dirt, which will, in fpite of washing, gradually collect at the bottom of it, without having the neceffity of breaking the mortared joint which connects it and the half-hoghead. Other modes of a fimilar nature, equally fimple and convenient, exist in many other places, which are found to answer perfectly well, where only small quantities of this fort of food are wanted to be prepared at a time.

The flameing of cattle-food is a practive which is yet probably but in its infancy, conseqently every discovery of a ready and cheap method of efrecting the butterknife is particularlly deferving of the farmer's attention, as well as the ascertaining of the improvements which different forts thereby undergo, for the purpofe of being applied in the different procéfles of feeding and fattening various kinds of animals of the farm fort.

STEAMING-House, a place properly fitted up for the purpofe of preparing roots by flame for the ufe of cattle. See the preceding article.

STEATITE, in Mineralogy, a mineral particularly diftinguifhed for its uctuous feel, refembling that of soap. That variety which is found in Cornwall differs from common flate by the abfence of alumine in its composition, and is commonly called foap-flone. See SOAP-Stone.

Steatite is of various shades of white, grey, yellow, and red. It occurs mafive, and forming fucrations; it is fometimes cryftallized; but mineralogifts are not agreed regarding the cryftals; fome confidering them as true cryftals, others as falfie ones, formed in the cavities made by pre-existing cryftals. The fix-foided prism, the rhomb, and fix-fided pyramid, are confidered by Mr. Jamefon as falfie cryftals; the prism originating from rock-cryftal; the rhomb from brown flate; and the fix-foided pyramid from calcareous flate.

Steatite is soft, yielding to the nail, but does not adhere to the tongue; the fracture is splinterly: it is more or lefs tranquilent on the edges, and bears a great reemblance to perfentine; but is much softer than that rock, to which, however, it is nearly allied, being commonly found traversing it in veins.

Steatite also occurs in metalled veins, with the ores of copper, lead, zinc, silver, and tin, mingled with albite, mica, and quartz. This mineral sometimes forms beds in primitive mountains. It is infufible by the blowpipe, but changes its colour, and becomes black. According to Klaper, the flate of Barenth contains

| Silex | - | 49.50 |
| Magnesia | - | 39. |
| Iron | - | 2.50 |
| Water | - | 5.50 |

According to Vaquelin, the flate of Monte Ramuzo contains

| Silex | - | 44. |
| Magnesia | - | 44. |
| Alunine | - | 2. |
| Iron | - | 7. |
| Manganese | - | 1.50 |
| Chrome | - | 2. |

...with a trace of lime and muriatic acid.

Steatite has been employed in various countries to anfwer the purpofes of soap and fuller's-earth. The white variety is much valued in the manufacture of porceain.

The inhabitants of New Caledonia are faid to eat confiderable quantities of flateite. Humboldt fates also, that the Otosacks, a favage race on the banks of the Oronoce, live for nearly three months in the year principally on flateite, which they fift, bake flightly, and then fotten with water. Mr. Goldbery fays, that the negroes on the banks of the Senegal mix their rice with white flateite, and eat it without inconvenience. Very recently, confiderable alarm was exicted in the county of Cornwall, on the discovery that it had been the practive of a fraudulent miller in that county to mix a confiderable quantity of ground flateite with his flour.

Steatite hardens in the fire, and has been successfully employed in imitating engraved gems, by Mr. Vidalot, an artifl in the vicinity of Liege. The subjécts to be repreffed are engraved on it with great ease; it is then expofed to a frong heat. It is afterwards polished, and may be coloured by metallic solutions. A variety of flateite found at Aragon, in Spain, is used by artifls under the name of Spanifh chalk; when gently burned, it is fometimes used as the basis of rouge.

Steatite occurs in Cornwall, in Angleafe, at Portjoy, Icolm-kil, and various parts of Scotland; and in Norway, Sweden, Germany, Switzerland, &c.; and we believe, in all districts where perpontine abounds. Some mineralogifts fuppofe that flateite is formed from the decomposition of felfpar and mica; others, that it is nothing more than decomposed perpontine. See Serpentifne.

STEATOCELE, from steat, fat, and ko, a tumour, a fwellling of the fcrotum, containing fat.

STEATOMA, a wen, or encyctled tumour, composed of a fhulace like fult.

STECKBORN, in Geography. See STEKKOREN.

STECKEM, a town of Flanders; 5 miles S. of Hulit.

STECKEN, a town of Bohemia, in the circle of Czlow, 4 miles W. of Polna.

STECKENITZ,
STECKENITZ, a river which rises in the territory of Lubeck, and runs into the Elbe at Lauenburg.

STECZICA, a town of Poland, in the patrinate of Sandomierz, on the Wieprz, near its union with the Vilula; 20 miles W. of Radom.

STEE, a provincial term applied to a ladder.

STEEBERG, in Geography, a town of the duchy of Carniola; 11 miles E.S.E. of Cirknitz.

STEEGE, a sea-port town of Denmark, on the W. coast of the island of Moen; formerly a place of great strength, with a castle, which has been since destroyed; 38 miles S.S.W. of Copenhagen. N. lat. 52° 3'; E. long. 15° 26'.

STEEL, in the Arts, a most valuable metal, consisting of iron combined with carbon. It is chiefly used for edge-tools, and other cutting instruments, and from its fine polish is used in ornaments of various kinds.

In chemistry it is called a carburet of iron.

Its hardness is greater than that of iron; and its most valuable property is, that it can be made harder than any other metal, by suddenly cooling it when heated to redness; also, if it is heated to a lower temperature, and suddenly cooled, it becomes the most elatic of all the metals. It is of a darker colour when polished, and retains its polish much longer, than is liable to oxidate.

The specific gravity of steel is greater than that of iron: thus, the specific grav. of cast-iron is .72070; malleable iron, .77880; steel in its solid state, .78404; hardened steel, .78180.

Steel is manufactured by two processes, one in which the steel is made from pig-iron at once in the furnace: this is practised in Germany, and is called natural steel. Cemented steel is formed by stratifying bars of iron with powdered charcoal in a close vessel, and by keeping the mass at a brisk red heat for a longer or shorter time, depending upon the size of the bars. This process is called concræfön. The test of the conversion being complete is its blitfered appearance, from which it has been called blitfered steel. As the steel in this change does not undergo fusion, all the imperfections in the mechanical texture of the iron will still be found to exist in the steel. A drawing of the furnace employed for this process is given in Plate VII. Iron Manufacture; for the references to which, as well as the mill for tilting steel, see Tilting of Steel. It is from blitfered steel that all the different kinds of steel are manufactured. These are principally of two varieties, viz., cast-steel and wrought-steel.

Cast-steel is blitfered steel fused and cast into ingots, which are afterwards drawn into rods by the hammer, or by rolling. By this change the steel becomes much harder, and of course entirely free from those flaws and other defects which exist in the blitfered steel: this is what renders cast-steel so much better for polished goods: for when blitfered steel is attempted to be polished, the surface is seen to abound with numerous spots, arising from mechanical defects in the bars previous to conversion.

Cast-steel works much harder under the hammer, and will not bear much more than a red heat, without breaking in pieces under it. This, however, is more especially confined to that commonly made; since cast-steel may be made which will bear a white and even a welding heat; but it requires a much greater heat for its fusion, and would in consequence be sold at a higher price.

The refuse of blitfered or common steel is generally melted into cast-steel; but this is not of the best quality. The best cast-steel is made by melting the bars of blitfered steel, which, for this purpose, are a little more converted than for ordinary purposes, in order to give the steel a little more carbon than if it were used in the state of blitfered steel. The bars are broken into small pieces, for the purpose of lowering the greatest quantity in the crucible.

The furnace employed for melting steel is the best constructed air-furnace, and is similar in form to those used by brails and iron-founders in the small way, where the crucible is employed. That part of the furnace containing the crucible and the fuel is of a prismatic form, about twelve inches square, and two feet in length from the grate to the top where the cover is placed. About three inches below the cover is a horizontal opening, called the throat of the furnace, which leads directly into the chimney. This opening is about three inches by six, and must never be less than the open part of the grate. In some manufactories, ten or twelve of these furnaces are at work at one time. The mouths of the furnaces are level with the floor of the room where the calling is performed. These are arranged along the two opposite walls, each containing a stack of high chimney. The ash-pits of these furnaces terminate in a cellar below, which is well supplied with air. The crucibles in which the metal is melted are made on the spot. The material is Stourbridge clay, to which a little coke-dust is added. They are formed in a mould of cast-iron of the form of the crucible of the crucible. The proper quantity of tempered clay is first put into this mould, and then a wooden plug is driven in to form the inside of the crucible. They are then gradually dried, and slightly baked, at a much less heat than is given to the softest pottery. The crucible is generally removed from the baking fire to the furnace, which would be liable to crack if put into the fire cold. The crucible is placed upon a fland about four inches high, which is also placed upon the middle of the grate. The base of this fland is less in diameter than the upper part, in order to intercept the air the least possible. Each crucible is also provided with a cover, made very true on the under side, so as to fit. It is a little larger than the top of the crucible, in order to be cally removed with tongs. The cover is generally made of fire-clay a little more fusible than that of the crucibles. This admits of as much vitrification between the cover and the crucible, before the melting of the steel, as serves to keep out the air, which, at this high temperature, would injure the quality of the steel, by first destroying its carbon, and then oxidating the iron. In order, however, to guard more completely against this evil, some make use of what is termed a flux. This consists of some vitrifying substance, such as bottle-glass, in very small quantity. The substance now employed is the blast-furnace cinder.

The fuel used for melting steel is the coke of pit-coal, very highly baked in kilns used for the purpose. The fracture of these coals is white and brilliant. They are so hard as to be porous; and their specific gravity is much greater than ordinary coals. This coke, being broken into pieces about the size of an egg, is made to surround the crucible closely on all sides, and a few inches above the flame. The heat required to melt steel is so intense, that if the furnace were not firm and dense, the fire would not last till the steel took place. This would require a supply of cold fuel, which would not only endanger the crucible, but occasion great delay. When the steel is thoroughly fused, the crucible is withdrawn with a pair of large tongs, opening with two concave jaws to fit the cylindrical form of the crucible. The tongs are not removed till the metal is poured. Immediately on bringing it out of the fire, previous to which the cover is removed, some fooria, or refuse arising from the flux, is first removed. This expels the steel to the action of the oxygen of the atmosphere. Particles of the metal are now seen to dart out of the crucible in bright corruptions, and their continue all the time the metal is pouring into the mould, causing a grand and interlinge appearance. The mould is
of cast iron, giving an octagonal shape to the ingot. These moulds are of various forms. Those used for fleel-plate are in the form of parallelograms; and those for making large faws are smaller at each end, in order to roll out into a plate nearly of the form of the faw.

The fleel known by the name of shear-fleel, has been fo called from its application to the cutting part of sheef or wool fhears. It was formerly manufactured at Newcastle-upon-Tyne, and has been called Newcastle fleel. From being subjected to a similar process to the natural fleel made in Germany, it has also been termed German fleel.

We have before obferved, that the bar-iron of which fleel is made, contains many defects in its mechanical texture. In this fleel, it is faid by the workmen to be baffe, and is more or lefs So, as depending upon the management of the bar-steel-forger. The manufacture of shear-fleel confists in removing these defects, and at the fame time giving it what is called increased fibre by the operation of hammering.

The prefent preparation is to lay a number of bars of blistered fleel together, and bind them with iron rings at one end, fo that the bars which are put in the fire may not be difplaced. A portion of these united bars is now to be heated to a full welding heat, keeping the surface well defended by throwing powdered fand upon it from time to time. This fufes with the oxyd of iron, forming a liquid coating, which defends the surface from the action of the air. If this precaufion is not obferved, the fleel, when heated to the degree of welding, would become what is termed burnt, and its malleability be impaired. In the welding fleel it is placed under a forge-hammer, working by water or a foom-engine; when the bars become firmly united, and all the loose parts previously exifting in the malleable iron are at the fame time made found. When a little more than half the length of the bars is treated in this way, the iron rings are removed, and the other end heated and hammer ed in a fimilar way. The welded mafs is now drawn down into small bars about an inch and a quarter broad, and three-eighths or half an inch in thickness. In this fleel it is fold to the consumer, who afterwards has it reduced to different fixed rods by the tilt-hammer. The fleel is rendered fo compact in texture by the welding and hammering, as to become fufceptible of a much better working than the bar-iron. In this fleel is placed at the fame time that its tenacity and malleability are much improved. The former improvement highly fuits it for table-knives; the latter makes it valuable for Springs of various kinds, particularly thofe of gun-locks.

The process by which this fleel is formed has another advantage besides rendering it found and more malleable. It is found fouter and more kind than the blistered fleel from which it is formed, and is much more uniform in its quality. This may be explained by the fad, that a quantity of the carbon of the blistered fleel is diffipated in the form of carbonic acid during the welding and hammering, by which a fleel is obtained, having a lefs than ordinary proportion of carbon, and is in confquence ftruck liable to break in bending, and at the fame time fouter and more flexible. Indeed, if the process of welding and hammering were repeated feveral times, the fleel would lofe the whole of its carbon, and become pure iron.

Blistered fleel fhou Id not be used but for the commo nfeil purpofes, where great tenacity of polifh is not an obje pt. For all nice purpofes, where great tenacity and foun dnefs are neceffary, shear-fleel fhould be employed; and where a fine polifh or great hardnefs is wanted, cat-fleel is indifpenfable. See Iron and Cutlery.

Steel. Annealing, or Neafeling of, is for the foftening it, in order to make it work eafier; which is ufually done by giving it a blood-red heat in the fire, and then taking it out, and letting it cool of itself.

Some have pretended to fecrets in annealing, by which they could bring down iron or fleel to the temper of lead; this was to be done by often heating the metal in melted lead, and letting it cool again out of the lead. But this method has no other effe ft than what is obtained from the former, when the cooling is very gradual.

Steel may indeed be made a little fouter than in the common way, by covering it with coarse powders of cow-horn, or hoofs: thus inclining it in a loam, heating the whole in a wood-fire till it be red-hot, and then leaving the fire to go out of itfelf, and the fleel to cool, which it will do foonly from being infecled. See Tempering, and Steel, fuper.

For the expansion of fleel by heat, see Pyrometer.

Steel-glafler, a name given by fome authors to the metaline fpheres used in optics. Thofe, accord ing to Cardan, are made of three parts of brifts, one part of tin, and one of filver, with an eighteenth part of antimony; but fomewhat entirely lefs than this proportion, and many of the other methods, directed by feveral authors, but most rife arsenic and tartar, mixed with the metals. These are afterwards to be polished with emery, rotten-flone, putty, and the like.

Steel-ore, is used to fignify a particular kind of lead-ore.

Steel-powder. See Powder.

Steel, Satl of. See Salt of Steel.

Steel-Waters. See Mineral Waters.

Steel, Damascus. See Damascus.

Steel, Engraving on. See Engraving.

Steel, Faggot of. See Faggot.

Steel-Wine. See Wine.

Steel Plate, in Geography, a cape on the E. coast of Labrador. N. lat. 58° 40'. W. long. 62°.

Steele, Sir Richard, in Biography, a political and miscellaneous writer of considerable note, was born at Dublin, either in 1671 or 1676. His father, who was of English extraction, had been for some time private secretary to the first Duke of Ormond, through whose influence the son was sent, at an early age, to England, and placed at the Charter-Houfe for education. In 1691 he was entered of Merton college, Oxford. Of his academical life little or nothing is known, except that he composed a comedy during his residence, which, by the advice of a fellow-collegian, he suppressed. He left the university without a degree, and feeling a strong inclination for the army, he entered himself as a private in the horfe-guards, but his friends soon after procured for him an ensign's commission. Feeling that he might not be able effectually to refit the temptations incident to his age and situation, he drew up a little treatife for his own admonition, and which is well known even now, entitled "The Christian Hero; " this was printed in the year 1701, at which time the author was secretary to lord Cutts, and had, by his means, obtained a company in a regiment of fifileers. The seriousnefs of the work exposèd him to fome ridicule among his companions, and the more fo, as it failed in producing the correponding good effect in regulating his own morals; he therefore, "to calvien his character," as he fays of himfelf, brought out a comedy, entitled the " Funeral, or Grief à-la-mode." This piece proved fucciffeful: it had the merit of uniting entertainment with the more direct purpofe of moral improvement, than was usual among dramatics at that time. Either on this or on other accounts he attracted the notice of king William, who meant to have R
betrothed upon him some mark of the royal favour, but he did not live to effect his intention. He obtained the very humble office of gazette-writer under queen Anne; but he now purfued his career as a writer, and in 1704 brought out his comedy of "The Tender Husband," which was acted with great success. This was followed by "The Lying Lover," which was not well received.

In 1709, Steele began a series of periodical papers, which, more than any of his other exertions, has contributed to establish his fame. The "Tatler," with which it began, was formed upon a plan which included the political information of a common newspaper. Its main object was, however, to improve the morals and manners, by holding up to ridicule fashionable follies and vices of every kind, and inculcating just and liberal sentiments on common topics, with a general regard to the proper decorum of social life. The author was fully qualified for this task by a knowledge of the world, acquired in free converse with it, by natural humour and vivacity, and by a generous and benevolent way of thinking. He had likewise the felicity of being able to engage coadjutors of considerable talents, among whom were Addison and Swift. The Tatler was extensively circulated, and as, in its politics, it fided with the minister, Steele obtained the reward of a place among the commissioners of the stamp-duities, which he retained after the dismissal of the ministers who had granted it. In 1711 this paper was succeeded by the more celebrated "Spectator," in which the plan was matured, the politics of the day were rejected, and the affiance of Addison and other eminent writers was more constant, though Steele continued his own most active services. This work was brought to a close, and the "Guardian" commenced in 1713, and was terminated in the same year. He afterwards engaged in other periodical works, but being subordinated to more political purposes, they have all been long since forgotten.

On taking a decided political character against the government, he resigned his post in the stamp-office, and likewise his pension, which he had hitherto received, as having belonged to the household of the late prince, George of Denmark. He was now returned member of parliament for the borough of Stockbridge. He had not taken his seat long before he was expelled as the author of certain publications to which his name was prefixed, and which the house, in its great majesty, voted to be feditious and scandalous libels. The most noted of these, entitled "The Crifi," was not written by Steele, but by a friend and political coadjutor. The charge brought against him, that the libels, as they were called, contained many expressions highly reflecting upon her majesty, &c. maliciously insinuating that the Protestant succession in the house of Hanover is in danger under her majesty's administration. Steele met with very able as well as zealous defenders in Addison, the Walpoles, lords Finch, Lumley, and Hinchinbrooke; but the party in power was determined on the sacrifice, and the charge against him was affirmed by a majority of nearly two to one. After his expulsion he engaged in some literary undertakings; but on the accession of George I. he was taken into favour, and was presented with a small appointment under government.

Having procured a licence to be chief manager of the royal company of comedians, he had interest enough to get this licence exchanged for a patent for life as governor of that company. In the first parliament of the new reign he re-entered the house as member for Boroughbridge, in Yorkshire; and in April 1715, he received the honour of knighthood, on presenting an address; and about the same time, the more substantial reward of 500l. was given him by fir

Robert Walpole, for special service. Thus encouraged, his fertile pen produced a variety of political tracts in favour of that cause which seemed at all times to be near his heart, as well in its depressed as in its triumphant state. Having been appointed, in 1717, one of the commissioners for enquiring into the estates forfeited by the late rebellion in Scotland, he went to that country, and was treated in it with great respect, notwithstanding the unwelcomeness of the errand on which he was sent. It was on this occasion that he conceived the project of forming an union between the Scotch and English churches, and had several conferences with the Presbyterian ministers respecting the restoration of episcopacy; but his zeal, it is said, was not directed by judgment. He obtained, and with much justice, the character of a projector, which was both the effect and cause of that perpetual embarrassment under which he laboured, and which was principally owing to a radical want of economy, and a strange inclination to expenses. He was twice married, and with each wife he had a good fortune; yet he seems to have been always necessitous. In 1718 he had a project for conveying fish to market alive, for which he obtained a patent, which, instead of mending his circumstances, only involved him full deeper in difficulties. His biographers observe, that "it were to be wished that his difficulties had occasioned no other fardicencies than that of money; but there is reason to suppose that they sometimes interfered with the dictates of conscience." Whilton says, that once having met with Steele after a vote in parliament contrary to his former declarations, with which he lightly upbraided him, the knight replied, "Mr. Whilton, you can walk on foot, but I cannot." Steele's spirit was not, however, formed for implicit submission, and for his opposition to the peerage-bill in 1719, he was deprived of his theatrical patent. He appealed to the public, and was restored in the following year. He pleaded the cause of the nation by a pamphlet against the South-sea scheme. In 1722 he brought forward his comedy of "The Confeious Lovers," which was received with great applause. He dedicated it to the king, and was remunerated with 500l.; but his embarrassments pressed upon him; and in addition to his other misfortunes, he engaged in an unsuccessful law-suit. Broken in fortune and constitution, he retired to an estate in Wales, where he died in 1729.

He appears to have been much beloved for the benevolence and warmth of his heart: in understanding, he has been characterized as a man of parts rather than of genius; his productions are lively, but they display neither the great, nor the accurate. His style and train of thinking are equally lax and incorrect. He was a lover of virtue, and frequently painted it in pleasing and attractive colours. His reputation as a writer seems to have been much indebted to the partnerships which he formed; and his name is fearlessly entitled to a place among those which throw peculiar luster upon the period of English literature. Biog. Brit.

Sir Richard Steele, without much taste or science in the art, was a musical critic and poet. His elegies on Nicollini, in the Tatler, No. 115, would have done his taste and judgment honour, if he had not afterwards treated operas in general, when they clashed with his interest in the playhouse, with the utmost contempt. He joined with Clayton, Haym, and Duport, in a concert at York-buildings, against the opera; and afterwards employed Hughes to alter Dryden's Ode on St. Cecilia's Day for music, to set which he employed Clayton! but the plan failed. And he had the room in York-buildings afterwards fitted up at a considerable expense, and a roof erected for himself to read lectures in, on the drama and other subjects. We have heard, 8
Sir Richard Steele was certainly a man of wit and humour, and in some of his sermons there were good intentions; but he seems to have been (says Dr. Burney) an unprincipled politician, an occasional Christian, and a prentice, self-interested and ignorant musical critic.

STEELING, in Ship-Building, a name given to the foremost or aftermost plank, in a strake which drops short of the flume and flern-poll, and of which the end or butt nearest the rabbot is wrought very narrow, and well forward or aft. Its use is to take out the fusing-edge occasioned by a full bow, or sudden circular buttock.

STEELING, in Cutlery, the laying on a piece of flesh upon a larger mass of iron, to make that part which is to receive the edge harder than the rest. The body of an axe may very well be of iron, as it never comes into use to cut with, and perhaps is stronger, and less liable to break, than if of flesh; but it must have a quantity of flesh at that part where the edge is to be made.

STEELYARD, or STYLLARD, in Mechanics, a kind of balance, called also flattera Romana, or the Roman balance; by means of which the gravities of different bodies are found by the use of one single weight.

STEELYARD, Confinication of the. It consists of an iron beam A B (Plate XXXVIII. Mechanics, fig. 6.) in which a point is assumed at pleasure, as C, and, on this, a perpendicular raised, C D. On the shorter arm, A C, is hung a scale or bason to receive the bodies weighed; the weight I is shifted this and that way on the beam, till it be a counterbalance to one, two, three, four, &c. pounds placed in the scale; and the points are noted in which I weighs as one, two, three, four, &c. pounds. From this construction of the steeleyard, the manner of using it is apparent. But the instrument, being very liable to deceit, is therefore not to be countenanced in commerce.

STEELYARD, Spring, is a kind of portable balance, serving to weigh any matter, from about one to forty pounds.

It is composed of a brafs tube, into which goes a rod, and about that is wound a spring of tempered steel in a spiral form. On this rod are the divisions of pounds and parts of pounds, which are made by succesively hanging on to an hook fastened to the other end, one, two, three, four, &c. pounds placed in the scale; and the points are noted in which I weighs as one, two, three, four, &c. pounds. From this construction of the steeleyard, the manner of using it is apparent. But the instrument, being very liable to deceit, is therefore not to be countenanced in commerce.

The beam, or yard, is a small rod of wood or ivory, about a foot in length; upon this are three rules of meafure, made of a fine silver-fuddled work; they all begin from the end of the beam, whence the first is extended eight inches, the second fix and a half, the third eight and a half. The first is the European meafure, the other two seem to be China meafure. At the other end of the yard hangs a round scale, and at three several distances from this end are fastened so many finer strings, as different points of suspension. The first distance makes eight-fifths of an inch, the second is double to the first, and the third four inches and four-fifths. When they weigh any things, they hold up the yard by some of these strings, and hang a sealed weight, of about one ounce and one-fourth Troy weight, upon the respective divisions of the rule, as the thing requires.

STEELYARD-SWING. In the Philosophical Transactions (No. 452, fept. 5.) we have an account of the steeleyard-swifg, proposed as a mechanical method for affilling children labouring under deformities, owing to the contraction of the muscles on one side of the body. The crooked person is suspended with cords under his arm, and these are placed at equal distances from the centre of the beam. It is supposed that the gravity of the body will affect the contracted side, so as to put the muscles upon the stretch; and hence by degrees the defect may be remedied.

STEEN, JAN, in Biography, one of the brightest ornaments of the Flemifh school of painting, was born at Leyden in 1636. His father was a brewer in that city, who perceiving an inclination in his fon for painting, placed him as a pupil with N. Knuffer, an historical painter at Utrecht.

That he might not be entirely dependent upon his talents as an artist, his father established him in a brewhoufe at Delft; but this kindnefs, which might have secured him comfort, only afforded him the means of fentimental indulgence, to which he was prone, and which, in a short time, led to the ruin of the concern; and his father finding him irreclaimably bent on difpaffion, at length abandoned him. He afterwards became a keeper of a tavern; but this was a more ruinous occupation than the former, and soon brought on the calamities his conduct merited; as he was faid to be a more active consumer of his own fiores than any of his customers.

Amidst the interruptions of indulgence and of bufinefs, he continued conftantly to prattife the art he had acquired; prefenting generally the features and fubjefts in which he paffed his time and were molt congenial to him. The felivity, frolic, and fun of low life in the alchonie or other places of public refort, he treated with the cleareft expreffion and character; and executed them with a pure tone of colour, and a freedom of touch peculiarly his own. Sometimes, however, he feared somewhat higher, and entering the domestic circles of his friends, perpetuated with the greatest felicity the diversities of character and anfufements which prefented themselves to his obfervant and intuitive eye. In no man's pictures is another more amufed with variety than in Jan Steen's; or more entertained by wit and humour, unless it be in thofe of our own Hogarth. His drawing and composition are in general very good, and his colour admirable, particularly in parts; but oftentimes his management of chiaro-feuro is deficient, and his pictures want air. While he lived, his works were not in much effimation; perhaps his vulgar and disorderly habits prevented them from being known: but since his death, and particularly since Sir Joshua Reynolds evinced an affimilation of them, they have rifen in value, and are now fold, when of fuc quality, at very R 2 great
great prices, and fought with avidity. He died in 1669, at the age of fifty-three.

STEN, in Geography, a town of Norway, in the province of Aggerhuss; 15 miles N. of Christiania.

STEENBERGEN, a town of Brabant, formerly a place of confederation, on the sea-side, with a convenient harbour, but now, in consequence of the reefs of the sea, a league from it; and by this circumstance, as well as the calamities of war, reduced to as to have scarcely the appearance of a town; 25 miles N. of Antwerp. N. lat. 51° 37'. E. long. 4° 11'.—Also, a mountain of Africa, near the Cape of Good Hope.

STEENSEHOUSE, a town of Scotland, in the island of Pomona; 7 miles W. of Kirkwall.

STEENKIRK, or STEENKERQUE, a village of France, in the department of Nord, situated on the river Somme, where a bloody battle was fought by the allies commanded by William III. king of England, with the French under the duke of Luxemburg, July the 24th, 1692, in which the latter were victorious; 13 miles N. of Mons.

STEENKIRK, Steenvre, or Steenkerch, a town of Flanders; 8 miles W. of Dixmude.

STEENPLAAT, a town on the W. coast of the island of Giljo. N. lat. 1° 20'. E. long. 127° 21'.

STEENWORDE, a town of France, in the department of the North, and chief place of a canton, in the district of Hazebrouck; 4 miles E. of Cassel. The town contains 3414, and the canton 23650 inhabitants, on a territory of 132 kilometres, in 9 communes.

STEENWYCK, Henry, in Biography, was born at Steenwyck in 1550. He was a scholar of John de Vries, a painter of perspective and architectural scenes. Steenwyck surpassed his master in the fame subjects, viz., interiors of churches and Gothic buildings, which he painted with great neatness and clearness. His colouring is rich and brilliant, but he injured his effects by painting the lights too much in lines, unblended and too sharp, which destroys the appearance of solidity. He died in 1603, and left a son, Henry Steenwyck, born in 1589 at Antwerp, who excelled him in the same line, and married to the last he painted on a larger scale than his father. Vandek, with whom he lived in intimacy, recommended him to Charles I., who invited him to England, where he resided several years, and died in London. The pictures of both these painters were emblazoned with figures by friendly artists, as old Franck, Teniers, Breughel, Van Thulden, &c.

STEENWYCK, in Geography, a town of Holland, in the department of Overijssel, situated on the river Aa, in the country of Zallant, and on the confines of Friesland. It has three churches; 55 miles S.W. of Emden. N. lat. 52° 48'. E. long. 6°.

STEEP, in Agriculture, any kind of liquid or other preparation that is used for steeping any sorts of grain or feeds in, which are designed to be town for raising crops, in order to prevent disease taking place in them. That which is most highly esteemed by the farmer in common, is a very strong solution of common salt in water, such as will keep up a heavy egg upon its surface. Strong stale chamber-ley, in which common salt has been dissolved, is also much used by some farmers in different situations. And there are other sorts of preparations which have been long tried with this view both for feed-grain and small feeds, without some effect in preventing the danger from disease, as well as from the attacks and ravages of different sorts of insects in the infant state of vegetation and growth in the different kinds of plants as crops.

Several different sorts of preparations, contrived expressly for the purpose of being applied in this way, are given under our articles Pickle, Steeping of Seed-Grain and Seeds, and Turnip-Fly.

STEEP, in Rural Economy, a term sometimes employed to signify the prepared mash, bag, or吩咐, of a calf which is killed when suckling. Those in which the calf is perfectly healthy, when killed, has been wholly supported with the milk of the cow, and in which there is found a white curdly matter to be present, are the best for the purpose, when well prepared by proper salting and steeping in pickles. See DAIRING and RENNED.

STEEP, Island, in Geography, a small island in the Mergui Archipelago. N. lat. 16° 43'.

STEEP ROCKS, a ledge of perpendicular shelly rocks, forming, with some interruptions, the W. bank of Hudson's river, for 12 or 13 miles from the Tappan Zoe, to within 11 miles of the city of New York. Some of these rocks are from 150 to 200 feet high.

STEEP POINT, a cape on the S. coast of the island of Java. S. lat. 7° 34'. E. long. 109° 3'.

STEEPHOLM, a small island in the Bristol Channel, about midway between the coasts of England and Wales. N. lat. 51° 16'. W. long. 3° 7'.

STEEPING of Seed-Grain and Seeds, in Agriculture, the practice of preparing wheat, barley, and other sorts of seeds, before putting them into the ground, by means of steep, in order to prevent disease. It is observed by Mr. A. Young, who has made a great number of interesting experiments in this way, that the modes of steeping, brining, and liming feed-wheat, are inapplicable, and all equally intended against the fmut. From his experiments it appeared that steeping from twelve to twenty-four hours in a loy of wood-ashes, in lime-water, and in a solution of arsenic, gave clean crops from extremely smutty seed, but that a short time in these mixtures had a much less effect.

In the northern districts, the practice of steeping is almost in general use with steep of the chamber-ley and flock kinds with lime, and the following are the practices in two of the principal grain districts in the southern part of the kingdom. It is stated in the Agricultural Survey of Norfolk, that Mr. Robinson, of Watton, for many years has had no other fmut on his farm, than what has been caused by accidentally fowing a headland, or finishing a corner of a field with dry feed; but if steeped, the prevention is im-possible. His method is, to steep it in a brine made with common salt, of strength to bear an egg, for twelve hours, and then to dry with lime. Mr. Dover, of Hookham, had great plenty of pheasants, but loll them all by using arsenic in steeping his wheat-feed. Mr. Salt, of Winborough, however, dresseth with salt and lime without steeping, and never has the fmut; it is only to be concluded, that he has always fown clean feed. And Mr. M. Hill makes the lime with salt, dissolved in a small quantity of water; dips the wheat in a steep in plain water only; lays it on the floor, and incorporates it with salt and lime, and then dries it with lime. Mr. Overman thrives his feed well in pump-water, then lays it in a heap to drain, and adds half a pound of salt to every bushel, flits it well together, and dries with lime; this he finds sufficient against the fmut. Whence the writer concludes that he's feed is always free from that dissembler, or assuredly he would find the process to fail, for he does not leave it any time limed.

The falt is dissolved in a very small quantity of water; with this salt and water the lime is flaked, and with this fa-
line preparation in its hottell rate the wheat becomes candied, having previously been moistened for the purpose with pure water.

Also in Hertfordshire, Mr. Bye brines his wheat; he swins it, but takes it out directly and limes it. And about Beachwood they make a brine with salt, which will swin a new-laid egge. They leave the feed from two to four hours long in this brine, and lir and dicem it; they lume it over night, and then row it next morning, but if it be kept a week it will receive no injury; they are however not free from smut, and have occasionally much over the whole country, even from Watford. A steeping of one hour is trusted to at King's Waldon. If chamber-ley be added or thrown on the feed after brining, it kills the wheat. Mr. Leach has bought smutty wheat to sow for curiosity, and even the worst which he could find; he steeped it six hours in a verystrong brine, made to swin a large egg; he dreed it with hot lime and fowed it directly, and had no smut. He has tried this several times, always with success. He steep clean wheat but three hours. But Mr. S. d'Gwick steep his feed in brine above six hours, then dries it, with lime and fows it directly, and he never has any smut; he omitted it three or four years, and suffered severely by such omission.

In the Appendix to the Inquiry concerning the Nature and Causes of the Blight, &c. some useful practical observations have been inferred from Mr. Blackie, the bailiff of the earl of Chesterfield, on the farm at Bradley Hall, in Derbyshire. It is there rated that it has been found by experience, and is pretty generally known, that smutty-feed-grain of the wheat kind will produce smutty crops; but it is believed, that it is not generally understood, that the molt smutty feed, by being properly cleaned, will produce clean crops; such, however, is the fact, it is said; and it has been found that the pure feed will, by being exposed to, or inoculated, as it is called, with the diseased, produce smutty wheat-crops. It is for the naturalist, it is supposed, to affign a cause why the disafe should be infectious; but it is sufficient for the practical farmer to know that the fact is indisputably established, and that it is in every one's power to satisfy himself on the point.

It is noticed farther, that many farmers have felt themselves disappointed in not having their wheat-crops clear of smut, after having been at the trouble and expense of changing the feed, and even washing and steeping or bringing that feed, not being aware of the infectious nature of this; which, however, is the fact, it is said; and it has been found that the very means they were taking to clean the feed, were also perhaps the means of inoculating, impregnating, or infecting it with the smutty matter. For after the operation of steeping or pickling is performed, the feed is generally spread out on the barn-floor to drain, and probably on the very same floor where smutty wheat had previously been threshed out; or perhaps the feed is put up into sacks in which had been smutty wheat but a short time before. The inoculation or infection is then, it is said, complete; the feed is fown; the produce will inevitably and invariably prove smutted; and the farmer naturally feels himself disappointed, after all his attention, trouble, and expenditure. It would also, it is said, be prudent in every farmer to see to the washing and steeping or pickling the feed himself, for if he trust that operation to ferrants, he will generally find himself disappointed.

It has been known that some farmers sow the same wheat for a succession of years, and with very little preparation or cleaning of the feed, yet have no smut in their crops; and so they may with safety continue to do, so long as they keep clear of the infection, by not borrowing or lending sacks, by change of barn, or implements, or of other things employed about it. It is suggested, that the infection is also sometimes probably carried from the barn-door, when the dung is taken green to the fields, without being properly turned and fermented. It is likely too, it is said, that there are various other ways by which the infection is communicated, but which the careful farmer will guard against, when he becomes more sensible of the contagious nature of the disease.

In the result of two experimental trials, which were made in the years 1807 and 1808, on the same farm, under the patronage and inspection of the noble owner, there is much certainty and satisfaction afforded on this important and interesting subject.

In the first trial, it is said that in the autumn of the preceding year, his lordship bought a peck of very smutty diseased wheat from a neighbouring farmer, who had that year great loss in his crop from smut. A piece of land was then let apart for the trial; one half of the wheat was sown in the latter in which it was bought, and the result proved, it is said, as might be expected, two-thirds of the produce being smut. The other half peck was washed as clean as possible, changing the water three times, and then put into a brine or steep strong enough to carry a new-laid egg, in which it remained two hours, being floured twice in the course of that time; when taken out it was dried over with quick-lime, and sown on the other half piece of land: the result, it is said, proved entirely satisfactory, as it produced a full crop of clean wheat, without a single ear of smut.

In the second trial, in the preceding autumn also, his lordship, by way of change in the feed-grain, had the whole of his feed-wheat from Dunstable: it was fine, it is said, and perfectly free from smut. Six ears of the smutty kind were fowed from the crop of the preceding year's trial; they were put into a small bag, and rubbed therein; the smutty grain was then carefully shook out of the bag, so that there only remained the black dust: a quart of Dunstable wheat was then taken, and although perfectly clean at the time, was washed in three waters, and then put into the smutty bag for the purpose of inoculation, or being impregnated with the infection; it was shook in the bag, in which it remained two days, and was afterwards sown. The result is stated to have been highly satisfactory in proving the effect of inoculation, as a very great proportion of the produce was entirely smut; while out of twenty acres sown with the same feed-grain not inoculated or infected by the smutty matter, not one smutty ear was produced, although carefully examined expressly for that purpose.

These trials are said to be known, and to have been seen by many farmers and other persons in the neighbourhood. And that the inoculated wheat, on being cut and carefully threshed out, was kept for the purpose of being shewn to any person who might think it worth while to examine it. It is further noticed, that since the advance in the price of salt, the expense of good brine for steeping or pickling feed-wheat has become a consideration to farmers, and that in consequence, various substitutes have been adopted, frequently not efficacious.

It is thought too, that it would be very advisable, in addition to all other precautions, that the feed should be well washed, and all the refuse scummed off from the surface of the liquid made use of for that purpose.

The above observations and results are strongly enforced, and shewn to be correct by the following statement. In the autumn of 1805, after having finished the wheat-feeding on the above farm, a neighbouring farmer was advised to send for the steep or pickle which was left. He has suffered much
much in former years from the smut, and previous to his
farming for the pickled, had that year sown half of his wheat
feed brined or steeped in his usual way; the remainder of the
feed was well washed, was steeped or pickled, and proper
precautions taken in the manner directed above; the result
was quite satisfactory, as the crop from the first sown feed
proved full of smut; whereas there was not one smutty ear
to be found among that of the latter sown feed.

On the nature and causes of the disease there are too many
notions and opinions, that, it is said, one farmer fits down
contented with his crop of diseased wheat, under the idea
that it has been caused by something pernicious in the at-
mosphere; another thinks that it is owing to the nature of
the soil, which he concludes to have always grown smutty
wheat; and a third, who is better informed on the matter,
conceives that it proceeds from the feed, which, though
brought from a distant district for the sake of change, and
appearing to be pure feed, yet was the means of affording
the smut, contends that it is of no use to change the feed,
as he is still liable to get smutty wheat: various other causes
of the disease also maintained by others, which need not
be here noticed.

It is condescendingly concluded, that it has surprised the
writer much, that lenible, practical farmers and agriculturists
should still remain so greatly prejudiced, even against
their own interests, as not to endeavour to eradicate or re-
move this pernicious disease, when it is certainly within their
power so to do. The means by which it is thought possible to
accomplish fo definable an object, arc, it is said, ficians to
impress on the minds of all such persons, that the disease
originates with the feed; secondly, that it is in a high degree
infectious; and, thirdly, that the same preventive and cure
are to be effected by proper care and attention to the esta-
blished practices of well washing, and brining, steeping, or
pickling the feed.

In short, there has been such a variety of contradictory
opinions and conclusions entertained in relation to the use
and efficacy or advantage of steeping and preparing feed-
grain, that nothing could hitherto feasibly be attempted or
established upon any thing like a satisfactory or scientific
basis; but the result of the whole of what has been flated
from the above experiments and trials would seem to direct
and lead to greater correctness and certainty in the principles
and practices which are to be pursued, as it shews, that the
disease to be guarded against by them is of a very infectious
kind, even when in the smallest and most minute portions
of the feed-grain, and probably that the infection lies in the
black powdery matter which adheres to the grain; conse-
quently that every sort of washing, steeping, and perhaps
rubbing, may be of some benefit, but especially the two
first, when performed with sufficient care, attention, and
cautions in every way, and for a proper length of time.
When, in spite of all such care and precaution, some ears of
a crop may become diseased, it must be the consequence of
some minute particles of this black powdery material still
adhering, in defiance of every effort for their removal, to the
feed-grain.

The accidental occurrence of the disease in such cases,
may, however, as has been feen, sometimes originate from
infection and the imperfect execution of the means which
are made use of for the purpose, in the barns or other simi-
lar places, as well as from slight portions of the powdery
substance being inadvertently carried or conveyed into the
fields in a variety of different ways, as by the facks with
the grain, the hoppers, the feed-lips, and numerous other
modes.

In regard to the use of steeping feeds of the turnip and
other small field kinds, it has been noticed by a late writer
on agricultural chemistry, that there are different prepara-
tions and menstrua of the chemical kind which render the
process of sproting or germination much more rapid than
usual, when the feeds have been steeped in them. As in
these cases the feed-leaves are quickly protruded and pro-
duced, and more speedy perform their functions, it was
proposed as a subject of experiment to examine whether
such menstrua and preparations might not be useful in raif-
ing the turnip in a more speedy manner to that state in which
it would be secure against the attacks of insects, especially
the fly, which is so destructive to it; the result, however, it
is said, proved that the practice was inadmissible; as feeds so
reated, though they germinated much quicker, did not pro-
duce healthy plants, and often died soon after sproting.

In the month of September 1807, radish-feeds were
steeped for twelve hours in a solution of chloride, and simi-
lar feeds in very diluted nitric acid, in very diluted sulphuric
acid, in weak solution of oxysulphate of iron, and inome
in common water. The feeds steeped in solutions of chlo-
rine and oxysulphate of iron, threw out the germ in two
days; those in nitric acid in three days, in sulphuric acid in
five days, and those in common water in seven days. But,
if it is said, in the case of premature germination, though
the plume was very vigorous for a short time, yet it became
at the end of a fortnight weak and sickly; and at that period
left vigorous in its growth than the sprouts which had been
naturally developed, so that there can be scarcely, it is
thought, any useful application of these experimental tri-
als. Too rapid growth and premature decay seem invariably,
it is supposed, connected in organized structures; and that
it is only by following the slow operations of natural causes,
that we are capable of making improvements. See Turnip-
Fry.

However, if the result of these trials should be confirmed
by farther ones, and more full and complete experience,
even though steeping feeds of these kinds in these sorts of
preparations may not be capable of being usefully had recourse
to in the above intention, it may often be beneficial for pro-
moting the healthy sproting and early growth of thefe
and many other sorts of small feeds in very dry times and
hot parching feasons, as well as, in common water, for
clearing them of various sorts of extraneous matters and
light imperfect feeds. Many of the preceding observations
may be applied with advantage by the gardener, in steeping
peas and beans, &c. as well as the nuts, kernels, and items
of many different sorts of plants and fruits.

STEERAGE, an appendage generally raised on the western
end of a church to hold the bells.

Steeples are denominated from their form, either spires, or
towers. The spire are such as ascend continually, dimin-
ishing either conically or pyramidically.

The latter are mere parallelipiped, and are covered at top,
platform like.

In each kind, there is usually a sort of windows, or aper-
tures, to let out the round; and so contrived, at the same
time, as to drive it down.

Maltese, in his treatise of bells, treats likewise of steeples.
The most remarkable in the world is that at Pisa, which
leans all to one side, and appears every moment ready to fall;
yet is in no danger. This odd disposition, he observes, is
not owing to a shock of an earthquake, as is generally
imagined; but was contrived so at first by the architect; as
is evident from the ceilings, windows, doors, &c. which are
all in the level.

STEER. Hog-fret. See Hoo and Ox.

STEERAGE, in a Ship, that part of the ship abaft where
where the tiller traverses between decks. In merchant-ships, it is the term between the companion-ladder and captain's cabin. In large ships of war, it is used as a hall, through which it is necessary to pass to or from the great cabin. In merchant-ships, it is generally the habitation of the inferior officers and ship's crew.

STEEVAGE, in Sea Language, is also used to express the effort of the helm; and hence

Steevage-way is that degree of progressive motion communicated to a ship, by which the becomes susceptible of the effect of the helm to govern her course.

STEERING, in Navigation, the art of directing a ship's way from one place to another, by means of the helm and rudder, or of applying the efforts of the helm to regulate her course when the advances.

He is held the bell steerman, who uses the leaf motion in putting the helm over to and again, and who keeps the ship's bell from making yaws; that is, from running in and out.

For this purpose the helmsman should diligently watch the movements of the head by the land, clouds, moon, or stars; because, although the course is in general regulated by compass, yet the vibrations of the needle are not so quickly perceived, as the failies of the ship's head to the right or left, which, if not immediately refrained, will acquire additional velocity in every instant of their motion, and demand a more powerful impulse of the helm to reduce them; the application of which will operate to turn her head as far on the contrary side of her course.

The phrases used in steering a ship, vary according to the relation of the wind to her course. Thus, if the wind is fair or large, the phrases used by the pilot or officer who superintends the steerage, are port, starboard, and finely; which see respectively. The first is intended to direct the ship's course farther to the right; the second is to guide her farther to the left; and the last is designed to keep her exactly in the line upon which she advances, according to her preferred course. The excess of the first and second movement is called hard-a-port, and hard-a-starboard; the former of which gives the greatest possible inclination to the right, and the latter an equal tendency to the left.

In a ship of war, the exercise of steering a ship is usually divided amongst a number of the most expert sailors, who attend the helm in their turns; and are accordingly called timoners, from the French term timonier, which signifies helmsman.

The steerage is constantly supervised by the quarter-masters, who also attend the helm by rotation. In merchant-ships, every seaman takes his turn in this service, being directed therein by the mate of the watch, or some other officer. Falconer.

For the theory and effect of steering, see Sailing, Course, &c.

STEERING-Wheel, in Ship-Building, the wheel on the quarter-deck, to which the tiller-rope is connected by a sufficient number of turns round its barrel, by turning of which the helm is moved from one side to the other with the greatest exactness.

STEERISH, in Rural Economy, a term applied to young growing oxen, in contradistinction to oxen.

STEEVENS, GEORGE, in Biography, the most successful of all the editors and commentators of Shakspeare, born at Poplar in the year 1735 or 1736, was the son of an East Indie captain, afterwards a director of the company. The subject of this article received the elements of his education at King's-upon-Thames, and he had Gibbon, the celebrated historian, for his school-fellow. From hence he went to Eton, and in a few years was admitted a fellow commoner of King's college Cambridge, and having acquired a large portion of classical literature, with a general taste for learned pursuits, he devoted his time and fortune to the study and collection of books.

On the first establishment of the Efsex militia he accepted a commision, but he spent the concluding years of his life in almost total seclusion from the world, seldom mingling with society, but was found either in the shops of book-sellers, in the Shakspeare gallery, or in the morning conversations of sir Joseph Banks.

Although not an original writer, he devotes a place among the chief literary characters of the age, considering the works which he illustrated, and the learning, sagacity, taste, and general knowledge which he constantly exhibited in his writings. With a great versatility of talents, he was eminent both by his pen and pencil; but his chief excellence lay in his critical knowledge of an author's text; and the bell specimen which he gave of his great talents is his edition of the works of Shakspeare, in which he is said to have left all competitors far behind him. He had studied the age of Shakspeare, and employed a very large portion of his life in becoming acquainted with the writings, manners, and laws of that period, as well as the provincial peculiarities, whether of language or customs, which prevailed in different parts of the kingdom, but more particularly in those in which Shakspeare passed the early years of his life. He was continually increasing this store of knowledge by the acquisition of the obsolete publications of a former age, to obtain which he spared no expense.

His critical sagacity and observation were constantly employed in calling forth the hidden meanings of the dramatic bard. In preparing his last edition for the press, he gave a very singular example of diligence and perseverance. To this work he exclusively devoted a period of full eighteen months, during which he kept his house at Hampstead every morning at one o'clock, and coming to London, without any regard to the weather, or the season of the year, he found a proof-sheet of Shakspeare ready for his perusal and correction. Thus, while the printers slept he was awake, by which means he completed in about the time already mentioned his splendid edition of the works of Shakspeare, in 15 vols. octavo.

Mr. Steevens died in the year 1805, at the age of about 65 years. He bequeathed his valuable copy of Shakspeare, illustrated with 1500 prints, to lord Spencer; his Hogarth, which was perfect, with the exception of two prints, he bequeathed to Mr. Windham; and his corrected copy of Shakspeare, with 200 guineas, he left to Mr. Read, at whose chamber he always corrected the proofs of his work in the silence of night.

Mr. Steevens was a man of great wit, and indulged his propensity freely, not only in conversation, but in various other modes in which he threw ridicule upon some of his antiquarian friends, whom he was fond of leading into errors. "His satire was severe and not without malignity, and his character seems to have been far from amiable, though he is said to have been courteous, on many occasions, to persons in distress." He was indefatigable in every thing which he undertook, but subject to caprice in his habits and attachments.

STEEVING, or Stiving, in Sea Language, denotes the
the elevation of a ship's cathedral or bowprit above the item, or the angle which either makes with the horizon.

STEVING, in Merchand Ships, is used for the flowing of cotton or wool, by means of torcers, to force it close together.

STEFANO, called Il Fiorentino, in Biography, is the only one of Giotto's scholars who aimed at something beyond the mere imitation of his master, whom, according to Vafari, he surpassed. He was born at Florence in 1301, and was the grandson of Giotto, by a daughter called Caterina. He was the first who attempted foreshortening; and if he failed of complete luminous, he certainly corrected perspective, and gave more varied turns, more character, and greater vivacity to heads. His most accredited works in the church of Alz Colet at Rome, Sta. Spira at Florence, and elsewhere, are no more. No authentic work of his remains, unless we except a Madonna in the Campo Santo at Pisa, undoubtedly in a greater style than the works of his master, but retouched. He died in 1352, aged 49. Tuceli.

STEFANO, Tomaso, according to Baldinucci, was the son and disciple of the foregoing artist, and born at Florence in 1324. He acquired the name of N Giotto, from the great resemblance of his works to those of Giotto. A Pieta, which still remains of him at S. Remigio at Florence, and some frescoes at Affili, bear indistinguishable marks of that style. He died at Florence, at the age of 22.

STEFANI, Agostino, a disciple of the elder Bernabei, was born in 1655. Though Walther and most of the Germans, who wish to rank him among their countrymen, say that Leipsig was the place of his birth; yet Handel and the Italians make him a native of Caffello Franco, in the Venetian state. He was a chorister at St. Mark's during his youth, where his voice was so much admired by a German nobleman, that, obtaining his dismission, he took him to Munich in Bavaria, and had him educated, not only in music under the celebrated Ercole Bernabei, but in literature and theology sufficient for priest's orders; in consequence of which, after ordination, he was diisguised by the title of abate, or abbot, which he retained till late in life, when he was elected bishop of Spiga. In 1674, at the age of 19, he published his "Psalms," in eight parts. He likewise published "Sonate et Stro-menti" but his chamber duets are the most celebrated of his works, and, indeed, of that species of writing. In his little tract, "Della certezza Dei principij della Musica," he has treated of the subject of musical imitation and expression, according to P. Martini, like a philosopher, and agreeable to mathematicall principles. This work, written in Latin, which we have never seen, was held in such high estimation in Germany, that it was translated into the language of that country, and reprinted eight several times. Walther and Marpurg have given the following list of Italian musical dramas or operas, which the admirable Stefani let for the court of Hanover, where he resided many years as maestro di capella: "Alessandro," "Orlando," "Enrico," "Alcide," "Alcibiade," "Atalanta," and "Il Triunfo del Fato," which were afterwards translated into German, and performed to his music, between the years 1695 and 1699, at Hamburg. About the year 1724 he quitted the court of Hanover, when he is said to have resigned his office as maestro di capella in favour of Handel. He was elected honorary president of the Academy of Ancient Music in London. In 1729 he went into Italy, to see his native country and relations, but returned the next year to Hanover. However, soon after, having some business to transact at Frankfort, he was there seized with an indif-
STEIGNACH, a river of Wurttemberg, which rises S. of Neften, and runs into the Neckar, near Nürtingen.—Alfo, a river which runs into the Maine, 1 mile S. of Zeulen, in the bishopric of Bamberg.

STEIGNACH, Markt, a town of the duchy of Wurzburg; 3 miles E.N.E. of Schweinfurt.

STEINNAKIRCHEN, a town of Austria, on the Little Erlapf; 10 miles S. of Ips.

STEINAM AXGER, or Szambath Hely, a town of Hungary, built on the ruins of an ancient Roman town, called "Sabaria;" 48 miles S. of Vienna. N. lat. 45° 30'. E. long. 16° 50'.

STEINAU, a town of Silefia, and capital of a circle, in the principality of Wohlan, on a small river near the well side of the Oder; containing two churches, and forge manufactures of cloth. It has had the misfortune of being fenced and burned in several successive wars; 80 miles W.N.W. of Wohlan. N. lat. 51° 22'. E. long. 16° 25'.

STEINAU, or Strymawa, a town of Silefia, in the principality of Oppeln; 22 miles S.S.W. of Oppeln. N. lat. 50° 18'. E. long. 27° 18'.

STEINACH, a town of Germany, in the county of Hanau; 16 miles S.W. of Palms. —Alfo, a town of Germany, in the duchy of Bremen; 24 miles N.E. of Carlburg.—Alfo, a river of Silefia, which runs into the Neyelle, opposite to Lowin.

STEINACH, a town of Germany, in the lordship of Schwarzenberg; 3 miles E. of Schainfeld.—Alfo, a town of Germany, in the county of Henneberg; 5 miles E. of Smalkalden.—Alfo, a town of Austria; 6 miles S. of Steyr.

Alfo, a town of Germany, in the principality of Nassau; 16 miles N.W. of Dillenburg.—Alfo, a town of Germany, in the duchy of Bremen; 5 miles W.S.W. of Gerfchach.

STEINACH, Langen, a town of the duchy of Bamberg; 3 miles W.N. of Baden.

STEINBACH, a town of Pruffia, in Natangen; 24 miles S. of Brandenburg.

STEINBERG, a town of Bavaria, in the bishopric of Bamberg; 3 miles N. of Cronach.—Alfo, a town of Welfphalia, in the county of Lippe; 10 miles E.N.E. of Lemgow.—Alfo, a mountain of Welfphalia, in the principality of Calenburg, near Minden.—Alfo, a town of Saxony, in the circle of Ercegeberg; 14 miles S.E. of Freyberg.—Alfo, a town of Germany, in the county of Henneberg; 3 miles E. of Romhild.

STEINBERGEN. See Steenbergen.

STEINBIZA, in Ichtyology, a name given by Hildegard, and some other writers, to that small species of cebites, called by others cebitis acutata, and tenia corona. It is the cebitis with a forked spine under each eye, described by Armed.

STEINEA, in Geography, a town of Switzerland, belonging to the canton of Zurich, in the Thurgau; 4 miles N.E. of St. Gal.

STEINFURT, or Burg Steinfurt, a town of Germany, and capital of a county, to which it gives name, on the Aa; 17 miles N.W. of Munften. N. lat. 52° 15'. E. long. 7° 15'.

STEINFURT, a town of the duchy of Wurzburg; 3 miles W.S.W. of Hafurt.—Alfo, a county and principality of Germany, surrounded by the bishopric of Munfter, about 25 miles in length, and from five to eight in breadth; raised to be a principality of the empire in the year 1495. Part of the territories belonged to the bishop of Munfter, and part to the count of Bentheim. To a Roman month it contributed 7 florins 32 krueters, and it was taxed to the imperial chamber 40 rixdollars 42 krueters.

STEINFURT, or Dreischenfurt, a town of Germany, in the
the bishopric of Munster; 11 miles S. of Munster. N. lat. 51° 48'. E. long. 8° 32'.

STEINHARD, a town of Germany, in the principality of Anspach; 5 miles S.S.E. of Wafflertudingen.

STEINHAUS, a town of the duchy of Sthiri; 4 miles N.E. of Muensterichberg.

STEINHAUSEN, a town of Switzerland, in the canton of Zug, on the north end of the lake of Zug; 2 miles N.W. of Zug.

STEINHEID, a town of Germany, in the principality of Coburg; 9 miles N.N.E. of Coburg.

STEINHEIM, or Oker Steinheim, a town of Germany, in the circle of the Lower Rhine, on the Main; 2 miles S. of Hanau.

STEINHEIM, a town of Weilhalla, in the bishopric of Paderborn; 14 miles N.N.E. of Paderborn. N. lat. 51° 45'. E. long. 9° 51'.

STEINHEIM am Muhir, a town of Wurttemberg; 10 miles N. of Stuttgart.

STEINHOF, a town of the Helvetic republic, in the canton of Bern; 16 miles N. of Bern.

STEINHÜDE, a town of Germany, in the county of Schauenburg, on the south side of the Steinhuder Meer; 13 miles N.W. of Hanover.

STEINHÜDER MEER, a lake of Germany, in the county of Schauenburg, six miles long and two broad; 14 miles N.W. of Hanover.

STEINHUN, Stone-hen, in Ornithology, a name given by the Germans to a bird of the lagopus kind, more commonly known by the name of otomo, and in some places by that of colomfre.

It seems not to differ from the lagopus in any thing but colour, and that bird being known to change its colour in the summer months, it is probably no other species.

STEINHURST, in Geography, a town of the duchy of Holstein, with a castle; 25 miles E.N.E. of Hamburg.

STEINING, a term used for the lining of stone or bricks to a well, shaft, or tunnel pit.

STEINISNAK, in Geography, a town of Croatia; 10 miles E.S.E. of Carltad.

STEINKIRCHEN, a town of the duchy of Bremen; 10 miles S.E. of Stade.

STEINORT, a town of Prufia, in Nantangue; 52 miles S.E. of Königsberg.

STEINPLEISZ, a town of Saxony, in the circle of Frezzeberg; 5 miles W.S.W. of Zwickan.

STEINSDORF, a town of Saxony, in the circle of Neudorf; 3 miles S. of Weyda.

STEINSTADT, a town of the duchy of Baden. In October, 1756, the French were defeated here by the Autrians; 16 miles S. of Fruburg.

STEISBEL, a mountain of Hungary; 4 miles N. of Kemnitz.

STEITZ, a town of Germany, in the principality of Anhalt Zerbit; 6 miles S. of Zerbit.

STEKAN, in Commerce, a liquid measure in Holland. Rhine and Moeil wine, and also spirits distilled from corn, are sold by the aam, which contains 4 ankers, 8 fleksans, 21 viertels, 64 florins, 128 mingels, 256 pints, or 1324 miles; and which holds 8666 Dutch, 7205 French, or 9351 English cubic inches, or about 404 English wine gallons. Linseed and rape-feed oil is sold in aams of 7 1/2 fleksans, or 120 mingels, weighing about 286 lbs. avoirdupois. Train-oil is sold in quartels of 18 or 21 fleksans; also in vats of 12 fleksans, or 192 mingels. The mingel of 2 pints, or 8 mufes of rain-water, weighs about 2 lbs. 43 oz. Amsterdam weight; 19 mingels = 6 English wine-gallons, and 27 mingels = 7 English beer-gallons. A vat of oil of olives contains 717 mingels, and weighs 1730 lbs. avoirdupois: 19.82 fleksans of Amsterdam = 100 English gallons, and each flekan = 1165 cubic inches.

STEKBOREN, in Geography, a town of Switzerland, in the Thurgau, on the south side of the lake of Zell; 7 miles W. of Constance.

STEKEN. See STEKKEEN.

STEKENZIT. See STEKKEENZIT.

STELE, in Ancient Geography, the name of a town in the island of Crete, near Paros. Steph. Byz.

STELE, Etruscan, in Antiquity, a kind of punishment, being a pillar wherein a criminal was exposed, and on which was engraved an account of his crime.

The perils thus exposed to the laughter and reproaches of the people, were called felpis. Potter, Archzolel. Græc. lib. 1. cap. 25. tom. 1. p. 130.

STELECHEIA, a word used by some authors to express the vena portae.

STELECHITES, in the Materia Medica, a name given by Dioscorides, and some other of the Greek writers, to a peculiar kind of florax. It was the same with the calamite, only that this name was given to the larger, and the name calamite to the smaller or slenderer pieces.

Pliny, Strabo, and many others, join in telling us, that the wood of the florax-tree, on account of its softness and sweet taste, was the most subject to be eaten by worms of that of any tree in the world.

When the worms attacked the body of the tree, the ducts they made by their erosion formed a hillock or heap round the tree, or at its foot, and the extravasated balsam running amongst this duct, made a mias that was called the cynnatus florax at that time, and was the same with the common florax now in use.

STEL娌ES, Sthili Facis, in Natural History, a very uncouth name given by Aldrovandus, and some others, to the entrochi. He gave them this name from the resemblance of some of the elongated pieces to fragments of the trunks of trees, the arms parting out from the sides of these main branches, the rudiments of which are very frequent in many of the entrochi, passing for the remains of boughs, and the hollow in the middle, for the cavity where the pith of the tree was. The addition of Stili facis was only from the observing that the top and bottom were radiated, or frirated, from the central hole to the circumference, in the manner of antimony. These are truly no vegetable remains, but parts of the arme of that strange fished called fela arboreus. See Sthili-Fish.

STELENCHIS, a fritill, or an instrument used in the baths to rub off the sweat from the skin.

STELENDENIA, in Ancient Geography, a country of Affia, in Syria, near the deferts of Palmyra. Pliny.

STELHOVEN, in Geography, a town of Holland; 3 miles S.W. of Gertrudenburg.

Gen. Ch. reformed. Col. Perianth of three equal, ovalate, keeled, somewhat concave leaves, cohering at the base. Cer. Petals two, distinct, much smaller than the calyx, obtuse, concave, vauled over the column. Nectary a lip without any spur, of the size, and nearly the shape of the petals, somewhat emarginate, inflexed at the edge. Stam. Another a vertical moveable deciduous lid, of two cells; mallets of pollen globular, at length waxy, solitary. Fyl. German inferior,
STELIS.

inferior, ovate; fiolet very short, dilated, hollowed, with three teeth, at the summit; stigma in front, near the anther, convex. Peric. Capsule oval, with three angles and three furrows, one cell and three valves; the uppermost furrow keeled.

Section 1. Inflorescence terminal.

1. S. ophioglossa. Adder's-tongue Stelis. Swartz Ind. Occ. 1557. Willd. n. 2. Alt. n. 1. (Epipedium ophioglossa; Lindl. Sp. Pl. 1553. Jacq. Amer. 225. t. 125.)—Stem with a solitary, lanceolate leaf, shorter than the spike. Cloved flowers three-fidged. This grows on the trees and branches of trees, in the mountains of Jamaica, and other islands of the West Indies, flowering in July and August. The perennial root consists of numerous long, simple, zigzag, whitish fibres. Stems several, two or three inches high, simple, clothed with compressed, oblique, tubular, membranous sheaths, and bearing at the top one coriaceous, ribbed, blunted, nearly elliptical leaf, two or three inches long, on a short twisted footstalk. Spike generally solitary, axillary, falked, erect, slender, simple, rather taller than the leaf, bearing numerous, alternate, small, ovate, acute bracteas. Flowers very minute, nearly or quite sessile, flat at the base; when closed perfectly triangular. Calyx pale green. Petals light red. Lip dark purple. Anther purple.

2. S. micrantha. Small-flowered Stelis. Swartz Ind. Occ. 1553. Willd. n. 2. Alt. n. 2. Sm. Exot. Bot. v. 31. t. 75. (Epipedium micranthum; Swartz Prodr. 125.)—Stem with a solitary, lanceolate leaf, shorter than the spike. Cloved flowers five-fidged. Found on trees, and on the sides of rocks, on the lofty mountains of Jamaica. The marquis of Blundford received it from thence in 1805, and it flowered in his lordship's hothouse in November 1806. This has the habit of the preceding, but is rather larger, with a longer, though narrower, leaf. The flowers are numerous, revered in their position, but we know not whether this character be proper to the whole genus. When closed, they form a roundish five-fidged figure. Calyx green. Petals and lip, as well as the column and anther, of a dark brownish-purple.

3. S. acutiflora. Sharp-flowered Stelis. Willd. n. 3.—"Stem very short, with one lanceolate, abrupt leaf, shorter than the spike; tapering and sheathed at the base."—Native of Peru, on the trunks of trees. Described by Willdenow, from a dried specimen, gathered by Ruiz and Pavon, as are all the following, except our tenth species.

4. S. lanceolata. Lanceolate Stelis. Willd. n. 4.—"Stem elongated, with one oblong-lanceolate, abrupt leaf, equal to the spike. Bracteas membranous, the length of the flowers."—From Peru.

5. S. polyphylla. Many-spiked Stelis. Willd. n. 5.—"Stem elongated, with one lanceolate-elliptical, abrupt leaf. Spikes two or three together, longer than the leaf."—From the same country.

6. S. oblonga. Long-leaved Stelis. Willd. n. 6.—"Stem elongated, with one lanceolate-elliptical, pointed leaf, longer than the twin spikes."—Native of Peru. The back of the leaf is purple.

7. S. parviceps. Purple-leaved Stelis. Willd. n. 7.—"Stem elongated, with one elliptical, slightly pointed leaf; coloured underneath. Spikes two, longer than the leaf."—Native of Peru.

8. S. revoluta. Revolute Stelis. Willd. n. 8.—"Stem elongated, with one ovato-lanceolate, coriaceous leaf, scarcely longer than the spike."—Native of Peru.

9. S. cordata. Heart-shaped Stelis. Willd. n. 9.—"Stem elongated, with one ovate, somewhat heart-shaped, pointed, coriaceous leaf. Flowers aggregate, in the bosom of the leaf."—This, like the six preceding species, grows parasitically on trees in Peru. They constitute the genus Humboldti of the learned authors of the Flora Peruana, notice of which has, as yet, appeared in their Prodrorum only.

Section 2. Inflorescence radical. Leaf from a bulbous base.

10. S. racemosa. Yellow Racemose Stelis. —Leaf lanceolate, emarginate, on a short stalk. Flower radical, nearly sessile, deflexed.—Found by Dr. F. Buchanan, on trees in Upper Nepal. The root is thread-shaped, creeping, fixing itself at intervals by means of tufts of numerous fibres, from whose crown proceeds a green ovate bulb, an inch long, bearing an erect leaf; measuring, with its short stalk, four or five inches. Cloths solitary from the bases of some of the bulbs, each four inches long, pendulous, on a short stalk, enveloped in membranous sheaths. Flowers about ten, rather distant, red, each on a very short partial stalk, accompanied by a lanceolate membranous bracteas, equal to the germen, or longer. Calyx-leaves yellowish-green, about half an inch long, equal, lanceolate, erect; one of them gibbous at the base. Petals very short, obtuse, of the same hue. Lip short, ovate, thick, entire, revolute.

11. S. hirta. Hairy-flowered Stelis. —Leaf radical, cylindrical, on a long stalk, drooping. Calyx hairy. —Gathered by Dr. Buchanan, on mossy rocks in Upper Nepal, flowering in January. The inhabitants call it Suni-pang, whence Dr. Buchanan named all the species of this section Sunipia, as composing a new genus. The difference of their habit from the original Stelides counterbalances this measure, but we are not distinctly enough acquainted with the precise structure of their flowers, to deduce a character from thence. The species before us has a creeping root, with crowded ovate bulbs. Of its leaves nothing is known. The flower-stalks are solitary, from the base of each bulb, erect, a span high, with a few scattered sheaths; and each bears a dense drooping spike, nearly its own length, of very numerous, whitish, highly fragrant, crowded flowers, of the size and shape of the leaf, but remarkable for their calyx being all ever finely hairy on both sides.

12. S. odoratissima. Capitate Fragrant Stelis.—Leaves elliptical, obtuse, sessile. Flowers capitate.—Native of mossy rocks, in Upper Nepal. Buchanan. The root creeps, bearing distant oblong bulbs, on each of which stands a fleshy leaf, near two inches in length, and somewhat emarginate. Flower-stalks erect, from the base of each bulb, and as tall as the leaf, each bearing a round drooping head of several white highly fragrant flowers, the points of the calyx yellow.

13. S. biflora. Two-flowered Stelis.—Leaves ovate, obtuse, on long footstalks. Bulbs nearly globose. Stalks about two-flowered.—On the mossy rocks of Upper Nepal. Buchanan. The branching creeping roots bear fleshy globose bulbs, not an inch in diameter. The footstalk of each leaf is an inch and a half long, erect. Leaf two inches, or more. Flower-stalks a little remote from each bulb, hardly to long as the leaf, bearing usually two yellowish flowers, larger than any of the foregoing; their partial filaments an inch long, gradually swelling upwards. Petals pointed, much smaller than the ovate calyx-leaf. Lip ovate, revolute, entire, falked, as long as the calyx.

We find among Dr. Buchanan's drawings and descriptions several more species, referred to his genus Sunipia, whose habit agrees exactly with our four last described. The parts of the flower however appear more unequal, or irregular, than properly belongs to Stelis, as is somewhat the case with our biflora. We leave them therefore, having no specimens,
STELLA, Jacques, in Biography, an eminent French painter, was born at Lyons in 1596. He was the son of an artist of that name, originally of Flanders, but who had settled at Lyons on his return from Italy. His father taught him the rudiments of design, but he was deprived of his instructor when only nine years old. He had however already imbied sufficient taste to proceed by himself, without the help of another master. In his twentieth year he travelled to Italy, intending to proceed to Rome to fulfil his studies; but was detained in his progress at Florence, by Coloma de Medici, to assist in the decorations preparing for the marriage of his son Ferdinand. The grand duke retained him in his service, and gave him a pension, with apartments; and he remained there seven years. At the end of that time he continued his intended journey, and at Rome he studied with unlimited attention the works of Raphael, in company with Nicola Poussin, with whom he lived in intimacy and friendship.

He had received repeated invitations from the court of Spain, and at last set out from Italy with an intention of going there, but was again interrupted in his journeyings by the solicitations of cardinal Richelieu, who recommended him to Louis XIV., and procured him a pension of a thousand livres, together with the employment of state painter, and an apartment in the Louvre; and, before all these advantages, the order of St. Michael was conferred upon him, as a particular mark of the king's favour.

Stella had considerable genius, but wanted a pure taste; his knowledge of Raphael and the Italian schools had not given that blest odour to his works. His invention was ready, his execution agreeable; the attitudes of his figures, however, exhibit the study and the lamp; and nature is less frequently the guide of their expressions than art. His colouring is completely artificial; and yet with these defects, there is an agreeable air in their effect; the parts are well balanced, and life and activity reign in them. He was most successful in his smaller productions. He died at Paris in 1647, aged 51.

Stella, Francis, was the younger brother of Jacques, and born in 1601. Though he lived very much with his brother, he never arrived at such eminence. There are many of his pictures in the churches in Paris.

Stella, Giuseppe Maria, an Italian ecclesiastic, author of a tract entitled "Breve Instruzione Alli Giovani, per imparare con ogni facilita il Canto Fermo," or short rules for young students to learn with the utmost facility, canto fermo, divided into two parts. In Roma, 1665, 4to.

This is an elaborate tretise on the subject, probably intended for the instruction of young persons intended for holy orders in the Roman church. The notes are taught by the Guidonian hand. The clefs and hexachords are explained in a clear manner, and the service of the whole year is given in Gregorian notes, on four lines only.

Stella, the name of a bandage in Surgery, resembling a tar, by the numerous croffings which it makes. It is employed after arteriotomy in the temple.

Stella. See Pseud-Stella.

Stella Grinita, in Natural History, a name given by Linkius to a genus of star-fish, the characters of which are these: that they have more than five rays, and from these have several other lateral proceffes, which are covered with a line down or hair.

Stella Lapis, in the Materia Medica, the name of a stone which has been very differently interpreted by different writers. Some have supposed it the asteria of Pliny, and some the common coralloid substitute; but Mulfre explains it to be the lapis lauiul.

Stella Marina, in Natural History. See Star-Fish.

Stella Arterioidea. See Basket-Fish, and Star-Fish.

Stella Occidentalis, a word used by some of the chemical writers to express salt ammoniac.

Stella Scapopendi, a name given by Linkius to a kind of star-fish with an indivited body, and five rays, resembling the bodies of the scapopodiæ, as those of the more usual kind, called Stella lumbricales, do the bodies of the common earth-worms.

Stella Verniformis, a name given by Linkius, and other authors, to a common kind of star-fish, which has five rays parting from the body, each somewhat resembling the body of a large worm.

Stella, in Geography, a river of Friuli, which runs into the gulf of Venice, 4 miles S.S.E. of Prifenis.—Alfo, a small island of Italy, in the lake of Garda; 14 miles N.W. of Verona.—Alfo, a mountain of Naples, in Principato Citra, on the coast, near Cape Licola.—Alfo, a town of Italy; 12 miles N. of Friuli.—Alfo, a mountain of the Grifoni; 15 miles S.W. of Tullis.

Stella, La, a town of Naples, in Principato Citra; 27 miles S.W. of Cangiano.

Stellarium, See Inter-Stellar.

STELTE
STELLARIA.

decisive mark, under all its numerous varieties, it may be known at once from every plant of its natural order, except *S. camphyloides* but particularly from *Ceratium aquatica*. *Leaves opposite, ovate, entire, smooth, on fringed stalks.* *Flowers white, inconspicuous, on solitary, axillary, or terminal stalks, which are hairy on one side.*

"It is a good vegetable boil-d like Spinach. Small birds eat the whole herb, as do young poultry."

3. *S. dichotoma.* Forked Stitchwort. Linn. Sp. Pl. 603. Sm. Pl. 1c. t. 14.—Leaves ovate, acute, stem forked. *Flowers solitary. Stalks when bearing fruit reflexed.*—Native of Siberia, whence it was sent by Gmelin to Linneaus. It flowers in July. *Root annual. Stem round, downy, much branched, and spreading on all sides, remarkably forked, leafy, manyflowered. Leaves two at each division of the stem, opposite, acute, stem, downy. *Flowers solitary, on round, downy stalks, which are upright at first, but bent back, as if broken, when the flower is ripened.*

4. *S. radians.* Radiated Stitchwort. Linn. Sp. Pl. 603. Willd. n. 3. (Alfina laxatlis, angular et oblongo falciis folio, flore albo, tenuifiae laciniae; Amm. Ruth. 64. t. 192.)—Leaves with small teeth, deeply five-cleft.—Native of Siberia, in swampy ground. *Root yellowish, jointed. Stems at the radical joints, about an span high, slender, upright. *Leaves opposite, pale green, hairy, veined, like those of a willow. *Flowers terminal, solitary, white, on slender stalks, with much divided or jagged petals, in which respect it differs from all the other species.*

"This herb has so much of a grasy appearance, that old botanists have named it the white-flowering grasf."

7. *S. graminia.* Sheifer Stitchwort. Linn. Sp. Pl. 604. Engll. Bot. t. 833.—Leaves linear-lanceolate, entire. *Pedicile terminal, spreading. *Calyx three-nerved, about equal to the petals.—Common among furze-bushes, heath, and low broom, on a gravelly or sandy soil, principally observ- able in the early summer months. *Root perennial, creeping. *Stems and flower-stalks perfectly smooth. *Leaves entire, scarcely ever rough at the margin. *Flowers in a dichotomous panicle, extremely elegant, white, baskinggurar furze-bushes and other shrubs, which so conceal the herbage as to make the flowers seem suspended in the air. *The calyx-leaves are remarkable for having three, acute, green ribs. The whole habit of this greatly resembles that of the last species, but its size is smaller, and the colour a grays-green, not glaucous."

8. *S. glauca.* Glaucous Marsh Stitchwort. Sm. Fl. Brit. 475. Engll. Bot. t. 825. (S. palustris; Willd. n. 7.)—Leaves linear-lanceolate, entire, glaucous. *Flower-stalks erect. Calyx three-nerved, shorter than the petals.—Found occasionally in a moist, gravelly soil, on meadows or in ditches, in many parts of Great Britain, flowering from June to August. Very nearly allied to the preceding species in habit, but perfectly distinct. *It has glaucous colour, perfectly smoothness of the edges of the leaves as well as of the stem, and larger flowers, the petals being twice as long as the calyx; to which may be added that the flower-stalks are more univerally lateral and foliary, much less collected into a panicle, and the three nerves of the calyx less sharply prominent; all these circumstances help to distinguish it from the former. In colour, size, and general habit, it rather approaches the *S. holophylla,* but that is beautifully distinguished by the total want of nerves in its calyx, and the rough edges of its leaves and stem."

9. *S. uliginosa.* Bog Stitchwort. Sm. Pl. Brit. 476. Engll. Bot. t. 1074. Curt. Lond. facs. 6. t. 28. (S. uliginosa; Willd. n. 9.)—Leaves elliptic-lanceolate, entire, with a callous tip. *Flowers irregularly panicked, lateral. Petals shorter than the calyx.—Frequent in rivulets, and clear waters, in grass or rushes. *Flowers plentiful in June. *Root annual, fibrous, small. *Stems numerous, feeble, branched, square, smooth, leafy. *Leaves much veined, pale, glaucous, a little undulated at the margin, with a callous tip. *Flowers very small, yellowish, on axillary and terminal stalks, generally three in number, two of which are three-cleft and three-flowered, the remaining one single flowered, all furnished with membranous, lanceolate bracteas.* This species, like *S. camphylodes,* is remarkable for varying in the number of its styles, from three to five.

10. *S. saepigera.* Many-stalked Stitchwort. Willd. n. 17. Engll. Bot. t. 1260.—Stems shorter than the flower-stalks. *Leaves linear-lanceolate, rough-edged. Calyx three-nerved, the length of the petals.—Native of Scotland, where it was discovered by Mr. G. Don in 1794. *Root perennial. *Stems very short, (Wildonow incorrectly says, none,) tufted, thickly clothed with numerous, opposite, acute leaves, smooth except at the edges, turning red in decay, each having a single rib, very thick at the base, tapering and vanishing towards the point. *Flowers terminal, white, on long, mostly single stalks.*

three or four inches long. Leaves opposite, sessile. Flowers axillary and terminal, two or three together, on capillary, long-ridged stalks.

17. S. gruendlichiana. Greenland Stitchwort. Willd. n. 15. Retz. Prodr. Fl. Scand. 107.—Stems decumbent, generally two-flowered. Leaves linear, slightly fringed at the base. Petals emarginate. Fruit globose.—Native of Greenland. This delicate little herb is scarcely more than an inch in height, with very slender stems. Leaves a little flabby, and fringed at the margin with long hairs. Flowers white, large in proportion to the plant, with scarcely emarginate petals.

18. S. Arenaria. Sandwort Stitchwort. Linn. Sp. Pl. 604. Willd. n. 16.—Leaves fruticulose. Stem erect, bifid. Branches alternate. Petals emarginate.—Native of Spain. Root annual, fibrous. Stem erect, round, a span high, downy and rather glutinous, with spreading hairs. Branches alternate, nearly as long as the stem. Leaves sessile, smooth above, hairy at the margin, and beneath. Flowers white, large, one at the division of the branches, the leaf alternately from their axils.

19. S. pubera. Woolly Stitchwort. Michaux Boreal-Amer. v. i. 273. Pursh v. i. 317.—Leaves fruticulose, ovate, fringed. Flower-stalks erect. Petals longer than the calyx.—Native of sandy woods on a rich soil from Pennsylvania to Carolina, flowering in May. All that we know of this species is from the above quoted authors, the former of whom observe that the whole herb is remarkable for being clothed with a downy wool. The flowers are large and white. Calyx-leaves oval.

STELLARIA is also a name used by some authors for the carduius fellatus, or star-thistle. See CENTAUREA.

STELLARIS LAPIS, a name given by many authors to the various species of alstroemer, or star-lone. See STAR-Stone.

STELLATA, in Geography, a town of Italy, in the department of the Lower Po; 12 miles N.W. of Ferrara.

STELLATE PLANTS, such as have their leaves growing on the stalks, at certain distances, in the form of a star with rays; or such flowers as are star-like, or full of eyes resembling stars.

Mr. Ray makes the stellate plants, so called from the disposition of their leaves, the tenth genus of English plants; of which kind are croft-wort, mollugo, wild madder, apenora or woodruff, gallium, or ladies bed-flower, ajarine or cleavers, and rubia tinctorum or dyers' madder.

STELLENBOSCH, in Geography, a small town of Southern Africa, near the Cape of Good Hope. It consists of three long straight streets, running parallel to each other, and several crofs streets intercepting these at right angles. The houses are most of them, and substantially built, though only thatched with straw. Each street resembles an avenue, since, on both sides before the houses, are large shady oaks, which are almost as old as the place itself, which was built at the beginning of the former century, though it was wholly burnt down in 1710. In December, 1803, a small fire occurred, when the number of houses left standing was about 80. The church was built in 1722, and though not equal in size to the churches of Roodezant and Paarl, it is no way inferior to them in point of architecture. The number of inhabitants at Stellenbosch, including slaves and Hottentots, is estimated at 1000. Every person in this town carries on, with his trade, some portion of agriculture and horticulture; and as there are none who can be called actually poor, who labour for hire, they are obliged to have slaves, who do not pay the expense of keeping them.

Strangers, who in their long voyages make any stay at the Cape, never fail to visit Stellenbosch; and people of property at the Cape Town also, in the fine seafar of the year, often make parties of pleasure to this fertile spot. Hence houfes are fitted up here for the accommodation and entertainment of strangers.

STELLENBOSCH. See DRAGENSTEIN.

STELLENBOSCH, Draygely ef, one of the divisions of the Stellenbosch district, is a very handsome village, consisting of about twenty habitations, to most of which are attached offices, out-houses, and gardens, so that it occupies a very considerable space of ground. It is laid out into several streets or open fpaces, planted with oaks, which have here attained a greater growth than in any other part of the colony. This village, which is the residence of the landdroft, is delightfully situated at the feet of lofty mountains, on the banks of the Eerle, or Frift river, at the distance of twenty-six miles from Cape Town. In it is a small neat church, to which is annexed a parsonage-house, with a good garden, and very extensive vineyard. The clergyman has a salary from government of 120l. a-year, with this house, garden, and vineyard, free of all rent and taxes, in lieu of other emoluments received by the clergy of Cape Town. A popular clergyman is loaded with presents from day to day. Game of all kinds, fat lambs, fruit, wine, and other good things, are pouring in upon him occasionally. His outgoings are chiefly confined to the expense of clothing his family, and a little tea and sugar. The landdroft has a salary and emoluments that feldom fall short of 1500l. a-year; an excellent house, in a pleasant situation; and an extensive garden, orchard, and vineyard. The grounds in or near the village are mostly fuch as they call egendoms, or freeholds, though they are held by a small recognizance to government; but they are totally different from loan-farms, which are the usual kind of tenure in the colony. There are eight other small divisions, besides this droydy, which furround it, and lie between it and Faife bay. They consist chiefly of freehold eflates, and produce wine, brandy, fruit, fresh butter, poultry, and a variety of articles for the Cape market, and for the supply of ships whilst they continue
continue in Simou’s-bay. They yield also a small quantity of corn. Barrow’s Africa, vol. ii.

Obi. S. Pafflerina has eight ilamens. S. Chamaegaphus ten. Linneus and other authors inaccurately define the calyx as a corolla.

1. S. Pafflerina. Flax-leaved Stellera. Linn. Sp. Pl. 512. Jacq. lœc. Rar. v. t. 68.—Leaves linear. Flowers axillary, selflile, with a four-cleft calyx.—Native of dry, funny fields, in Germany, Switzerland, France, and Italy, flowering in July and August. In general appearance, this herb resembles Thesium alpinum. It is acrid, bitter, and purgative. Root annual, spindle-shaped, nearly smpfe, yellow on the outside, white within. Stem upright, about six inches in height, much branched from the very bottom. Leaves alternate, selflile, acute, entire, smooth, spreading, reflexed, shaped like a sparrow’s tongue, whence Linneus adopted its old generic name as a specific one. The flm and branches are terminated by long, loose, interrupted, leafy spikes. Flowers selflile, three, four, or five together, on the ends of the leaves, imbedded in wood at the base, greenish, with yellow tips.

2. S. Chamaegaphus. Siberian Stellera. Linn. Sp. Pl. 513. Gmel. Sib. v. 3. 27. (Chamaegaphus radice Mandragora; Amman. Ruth. 16. t. 2.)—Leaves lanceolate. Flowers terminal, clustered, naked, with a five-cleft calyx.—Native of Siberia, on the banks of rivers; flowering in June. Root externally brown, internally white, having a sweetish talle, and in its mode of growth greatly resembling the Mandrake root, divided generally into two parts, each furnished with numerous radicles. Sems numerous, slender, weak, reddish below, pale green at the summit. Leaves alternate, short, acute at each end, nervcd. Flowers white and purple, five-cleft.

STELLO, in Zoology, the name by which authors call the swift or spotted lizard. The spots which distinguish this kind are not, however, stellated, as might be supposed from the name, but round; some small, and featted irregularly all over the body; and others larger, and disposed in thirteen zones or semicircles. The spots are much more distinct and clear on the back than on the belly. It is common in Syria, and some other places. See Er and Lizard.

The stellio, named by the Greeks cordileos, is the most common species of lizard in all the islands of the Archipelago, in Crete, in the Morca, on the eal coast of Natelia, in Egypt, and in Syria. Olivier describes it as hav-

The body mixed with green, yellowish, and brown; the head and the back covered with scales, simple or tubercled, and pointed. The scales of the feet are more turned up, and more pointed, than those of the back. ‘The tail is verticelated, and covered with prickly scales. This lizard acquires ten or twelve inches in length. It lives on insects, and does no mischief. It seeks the sun in summer, in winter it keeps in holes, and there palls that seafon in a kind of torpor. STELLIO Adylica, an affected term used by some chemical writers for eimbar.
The term stem is also occasionally, in some district, made use of to signify the handle of any sort of tool of the fork kind.

Stem of a Ship, is a circular piece of timber, into which her two sides are united at the fore-end; the lower end of it is feared to the keel, and the bowprit rests upon its upper end.

The stem is formed of one or two pieces, according to the size of the vessel; and as it terminates the ship forward, the ends of the wales and planks of the sides and bottom are let into a groove or channel, in the middle of its surface, from the top to the bottom; which operation is usually called rabbleting.

The outside of the stem is usually marked with a scribe, or division of feet, according to its perpendicular height from the keel; the intention of which is to ascertain the draught of water at the fore-part, when the ship is in preparation for a sea-voyage, &c.

The stem, at its lower end, is of equal breadth and thickness with the keel, but it grows proportionately broader and thicker towards its upper extremity. Falconer. See Ship-building.

Stem, false, that fixed before the right one. When a ship's stem is too flat, so that she cannot keep a wind well, they put a false stem above, which makes her ride more way, and bear a better sail.

STEMMATA, in the History of Insects, are three smooth hemispherical dots, placed generally on the top of the head, as in most of the hymenoptera, and other classes. The name was first introduced by Linnæus. See Entomology.

STEMODIA, in Botany, derived from stemodium, a flamen, and his, double; each of the filaments bearing two anthers.

1. S. maritima. Sex Stemodia. Linn. Sp. Pl. 881. Swartz Obs. 242. (Scordium maritimunum ruticoformi, procumbens; Sloane Hiit. Jam. v. 1. t. 110. f. 2.)—Leaves opposite, half clasping the stem. Flowers sessile, solitary.—Native of the southern parts of Jamaica, on the east-shore. Root probably biennial, long, round, fibrous. Stem from one to three feet high, hairy, erect, or occa- sionally scandent, much branched. Leaves small, cellular, ovate-lanceolate, obtuse, ferrated, thickish, hairy, with smaller ones at the axis of the larger. Flowers few, axillary, among the terminal leaves, small, white or blue.

The whole herb has a pleasant aromatic smell, with a bitterish tinge.

2. S. duratifolia. Marth Stemodia. Willd. n. 2. Swartz Obs. 240. (Caparria duratifolia; Linn. Sp. Pl. 876. Veronica caule hexangulari, folia faterete ternis, terratis; Sloane Hiit. Jam. v. 1. t. 124. f. 2.)—Leaves three in a whorl, combined. Flowers two or three together, nearly sessile.—Native of Jamaica, in marshes on the shore, in clay. Stem herbaceous, a foot high, erect, branched, leafy, angular at the base, roundish upwards, hairy, clambilis. Leaves sessile, toothed or rather ferrated, spreading, nervcd, downy. Flowers on such short stamens as to be all but sessile, small, of a blue colour.

3. S. sijcofia. Vicid Stemodia. Mart. Mill. Dict. n. 4. Roxb. Coromandel. v. 2. 33. t. 163.—Leaves opposites, clasping the stem. Flowers on flsks, fully hariy. Native of Coromandel, in rice-fields after the crop has been cut. The Telingas call it Beda-sarum.—Stem herbaceous, two feet high, generally inclining to one side, branched from the base, square, hairy. Leaves linear, ferrated, clamby like the whole herb. Flowers axillary, small, violet-coloured. The plant has a pleasant aromatic fennel.

Vahl mentions a variety of S. camphorata, with narrower leaves, which, he says, may probably be Dodartia orientalis.

6. S. aquatica. Water Stemodia. Willd. n. 5. —Leaves three together; those imbermed doubly pinnate, capillary; those above water undivided, lanceolate, fertile. Spikes axillary. A native aquatic of the East Indies, found near Tranquebar. —Stem from six inches to two feet in height. Lower leaves doubly pinnate; upper three-nerved, smooth, deeply ferrated from the middle to the tip. Flowers alternate, fertile, in terminal spikes.

7. S. parviflora. Small-flowered Stemodia. Ait. n. 1. ("Erius verticillatus; Mill. Dict. ed. 8.")—Stem procumbent, much branched, downy. Leaves three together, on flsks, ovate, crenate.—Native of South America, flowering in July and August. First cultivated by Mr. Philip Miller in 1759. We know nothing further of this species than what is here extracted from the Hortus Kewensis.

STEMONA, was so denominated by Loureiro, from stemodium, a flamen, because of the remarkable form and connexion of those organs in its flower; which latter circumstance led him to refer the genus to the class Monadophila. His genus, however, proves by the description, and indeed by the synonym of Rumphius, to be no other than our's and Mr. Dryander's Roxburghia; see that article. We had not made this discovery when the said article was written. What would those who flackle for the mere right of priority of names, in spite of authority, use, utility, or taste, do in this case? Stemona is by far the oldest name, liable to little or no exception, and given by an able and learned botanist. Yet surely every one would retain Rox- burgia, for the sake of its author's authority. We cannot but contend for the occasional exercise of some disinterested power, when obviously for the good of science; however averse we may always be to alterations of established and received names, though perhaps for the better.

STEMPHYLA,
STEMPHYLAL, a word used by the ancients to express the buds of grapes, or the remains of the preflings of wine. The same word is also used by some to express the remaining mats of the olives, after the oil is pressed out.

STEMPHYLITES, a name given by the ancients to a sort of wine pressed hard from the husks.

STIMPLES, in Mining, crofs bars of wood in the shafts, which are fink to mines.

In many places, the way is to sink a perpendicular hole, or shaft, the fides of which they strengthen from top to bottom with wood-work, to prevent the earth from falling in: the tranfverfe pieces of wood, used for this purpofe, they call flemes, and by means of thefe the miners in some places defend, without using any rope, catching hold of thefe with their hands and feet.

STEMSON, in Ship-Building, a piece of capproat timber, wrought on the affide of the apron, the lower end of which fears into the keel. Its upper end is continued high enough to tenon into the under fide of the middle or upper deck hook: its ufe is to fuccour the fears of the apron, as that does thofe of the item.

Gen. Ch. Cal. Perianth inferior, permanent, double; the inner of five broad, oval, equal, convolute leaves; outer of numerous ovate, concave, imbri cate, blinfih, pointless fcalas, not fo long as the former. Cor. of one petal, tubular, deciduous; tube twice the length of the calyx, swelling, smooth, and naked within; limb in five short, spreading, lanceolate, blinfih fegments, bearded underneath at the extremity, as well as half way along the dife from the base. Nectary a cup-shaped undivided gland surrounding the bafe of the germin. Stam. Filaments five, inserted into the tube, and enclosed within it, thick and fleshy, broader than the anthers, which are linear, in the mouth of the tube. Pjlk. German superior, roundifh, of five fefs; style capillary, the length of the tube; stigma fimple, obfute. Peric. Drupa nearly dry, globofe. Sec. Nut of three or more fells, with a thick, not very hard, fhell, not burfting, with a pendulous kennel in each cell.

Eff. Ch. Outer calyx of many imbri cate leaves. Corolla tubular; its tube swelling, twice as long as the calyx, naked within; limb much fhorter, spreading, bearded half way. Filaments included in the tube, fleshy, broader than their anthers. Drupa almost dry, of from three to five fells.

1. S. pinifolius. Pine-leafed Stenanthera. Br. n. 1. — Native of the neighbourhood of Port Jackson, New South Wales, from whence we have a fpecimen gathered by Dr. White, but this shrub has not yet found its way into the gardens of England. It is the only known fpecies of its genus. The stem is woody, erect, spreading, branched, feared; the younger branches hairy, clothed with innumerable, crowded, awl-shaped, pungent, revolute, roughift, feffile leaves, about an inch long. Flowers axillary, erect, feffile, about the bafe of each branch, very beautiful, with a rich fearlet tube an inch long, and a yellow-green limb, making a fingular, but molt agreeable, contrail. Drupa the size of a small pea, invcled with the brown chaffy calyx.

STENAY, in Geography, a town of France, in the department of the Menf, and chief place of a canton, in the ditref of Montmedy; 21 miles N.N.W. of Verdun. The place contains 3599, and the canton 14,434 inhabitants, Vol. XXXIV.

on a territory of 170 kilometres, in 18 communes. N. lat. 49° 30'. E. long. 5° 36'.

STENBOCK, Magnus, in Biography, a distinguished Swedish general, fon of Guiflauus Otto Stenbock, a general under Charles X. and XI., was born at Stockholm in 1664. He was educated at Upfal, and in 1683 he went to his travels, and having entered into the Dutch army, he served several campaigns with the allied forces in the Netherlands, and on the Rhine, under the princes of Wal- dec and Baden. He distinguished himself to much by his bravery and good conduct, that he was, in 1697, appointed to be colonel of a German regiment, then in the garrison at Wifmar, where he employed his leisure time in com- posing a work on the art of war, entitled "The Swedish Military School," which, however, he did not find kifure or inclination to publish. He accompanied Charles XI. in almost all his expeditions, and contributed by his skill and exertions to the victory obtained at Narva. In the Polish campaign, till 1706, he sometimes accompanied the king and the main army, and sometimes was entrusted with the command of detached bodies employed chiefly in levy- ing contributions; a service for which he was exceedingly well qualified: he was also employed in constructing bridges over luch rivers as the Swedish army had to pass, on its in- cursions into Poland, and on its return from that country. In the year 1706 he attended the king to Saxony, where he was appointed governor of Scania. When he arrived there, he found every thing in the utmost confusion; the most shameful abuses had been committed; and in order to put an end to them, and deter others from similar practices, he put the laws into mott severe execution; but a war breaking out put a floop to his plans of reform. When in- telligence of the Swedes being defeated at Pulawa reached Frederic IV. of Denmark, he made preparations for the invasion of Scania. Stenbock was appointed to oppose him; he put himfelf at the head of 8000 old troops and 12,000 new levies, and went in pursuit of the Danes, who were committing incredible ravages in the country. There was no time to clothe the newly raised troops in military array; of whom the greater part was drefled in frocks, and had pitfols tied to their girdles with cords. They at- tacked the enemy; and what was wanting in order and discipline, was amply compensated in zeal; and these raw troops completely defeated the regular army of the king of Denmark. The Danes quitted Sweden with great precipitation, having firit killed their horses, and destroyed by fire their baggage and magazines. They left behind them about 4000 wounded foldiers, of whom the greater part died, as well by the infection from the dead horses, as by the want of food, of which they had been deprived by their own countrymen. After Scania had been freed from the ravages of the enemy, Stenbock's first care was to ftrengthen the fortifications of Christianfled, being a place of great importance, for the defence of that part of Sweden. The activity which he displayed on this occasion, induced Charles, the year following, to enthrall him with the direction of another enterprise, to the successful and speedy execution of which great im- portance was attached. This was to repair, as speedily as possible, with several regiments to join the troops in that province and to proceed afterwards, under the command of Stenbock, to meet his Swedish majesty, on his propofed return from Turkey. In this meafure he was thwarted by the Senate, and he experienced many difficulties which he did not anticipate; of these, one was the want of money. He, however, went to Stockholm, and exerted himfelf to succefsfully, that he collected, in the courefe of a month, T
more than 300,000 rix-dollars, and fitted out some vessels for his intended expedition. In the course of his voyage he fell in with the Danish fleet, by which he was attacked, and more than thirty of the Swedish ships were lost. In consequence of this unfortunate event, Stenbock drew up a paper in vindication of his own conduct. After this he took Rodlof; and having received a considerable reinforcement of troops, gained a memorable victory, in 1712, over the Danish and Saxon forces: he then proceeded to the army in Holstein, and having burnt Altona, was, in the month of May, 1713, hemmed in at Tommningen, by the combined Danish, Saxon, and Russian army, in such a manner, that he was obliged to sign a capitulation. Being now a prisoner, he was conveyed by order of his Danish majesty to Copenhagen, and so closely confined, that he was separated from all his attendants, except two domestics, who obtained leave to wait upon him, and was in other respects subject to great restraint and severity. At length, exhausted by misery, chagrin, and disease, he drew up, in the beginning of the year 1716, an account of his sufferings, to serve, to use his own words, as a consolation to his distressed relatives, and, at the same time, to preserve his name and reputation to posterity. This work was printed in 1773, in Lönomb's "Anecdotes of celebrated and distinguished Swedes," He died in 1719, and was interred, with military honours, in the garrison church of Copenhagen. After the conclusion of peace, his body was conveyed to Sweden, and deposited in the cathedral of Uppsala. Stenbock was a man of talents, and always held in high estimation by Charles XII. In his political sentiments he adopted the system of his father-in-law, the celebrated Oxenhierna. He spoke his sentiments with freedom, and gave such advice as he thought most conducive to the good of his country. In speaking of the Polish war, in one of his letters, dated June 20th, 1702, he says, "according to every appearance, unless Providence interfere in a very remarkable way, war will be declared against the republic. How we shall get out of it God only knows. For my part, I would run no risks, but in a war really undertaken on just principles." He had no share in the deposition of Augustus, for whom he had a sincere esteem. He incurred considerable blame for the severity which he exercised at Altona, and the minillers and generals of Poland and Denmark wrote to him complaining of his cruelty on that occasion; but Stenbock, who considered this measure, however harsh, as a just retaliation for the conduct of the Saxons and Danes at Stade, which they had bombarded and burnt to ashes, replied, "that he proceeded to such an extremity, in order to teach the enemies of his sovereign, in future, not to wage war like barbarians, and to cause the law of nations to be respected." Gen. Biog.

STENBRUGGE, in Geography, a town of Norway, in the province of Vingenhus; 8 miles N. of Tonborg. STENBY, a town of Sweden, in Earl Gotland; 11 miles E. of Nordenkoping. STENCH. See STINK.

STENCILLING. See PAPER-HANGINGS.

STENCKBACH, in Geography, a river of Saxony, which rises 4 miles S. of Landsberg, and runs into the Fuhe, 2 miles N. of Zorbig.

STENDAL, a town of Westphalia, and late capital of the Old Mark, containing four churches, with considerable manufactures, introduced by the French refugees; 18 miles W.N.W. of Brandenburg, N. lat. 52° 50'. E. long. 12°.

STENDALICHEN, a town of Brandenburg, in the Ucker Mark; 10 miles N.E. of New Angermunde.

STENDORP, a town of the duchy of Holstein; 6 miles E.N.E. of Eutin.

STENE, a town of Norway, in the province of Drontheim; 48 miles E. of Drontheim.

STENFORT, a town of Hinder Pomerania; 8 miles S. of New Stettin.

STENHEL, a town of Sweden, in Velt Botnia; 32 miles N.W. of Lulea.

STENO, Nicholas, in Biography, a distinguished physician, and subequently bishop of Titiopolis, and vicar-apostolic of the northern countries, was born at Copenhagen in 1638. His father was a Lutheran, and goldsmith to Christian IV., king of Denmark. Having had the advantage of studying medicine and anatomy under the celebrated Bartholin, whose friendship he obtained by his ingenuity and industry, he was well prepared to profit by his travels through various parts of Holland, Germany, France, and Italy, in visiting the best schools, of which he palled several years. He was at Amsterdam in 1669, and resided during the three succeeding years at Leyden, where he purified his studies with the utmost diligence. He arrived at Paris in 1664, and at the end of two years more went to Vienna, travelled part of Hungary, and entered Italy by the Tyrol. He visited the principal cities of this fine country, and passed some time especially at Rome and Florence, in the latter of which cities his reputation reached the court of Ferdinand II., grand duke of Tuscany, who appointed him physician about the year 1667, with a liberal salary. He was afterwards honoured with the efeete and confidence of Cosmo III., who selected him as preceptor to his son. His attachment to the Protestant religion had been shaken by the eloquence of Boffuet while he was at Paris, and in 1669 he abjured that faith, and adopted the Roman Catholic persuasion. Frederick III., king of Denmark, invited him, near the close of his reign, to return to Copenhagen; but he refused the invitation, because he could not obtain permission to exercise the religion which he had adopted; but Christian V., repeating the invitation without any such restraint, about the year 1672, Stenso returned to his native city, and was appointed professor of anatomy. He found his change of sentiments and circumstances, however, productive of less agreeable results than he had anticipated, and he again quitted Denmark, and resumed the education of the young prince of the house of Colmo, at Florence. Some time after his return, he entertained a wish to enter the ecclesiastical state, and he embraced that profession in 1677. He was speedily nominated, by pope Innocent XI., to the bishopric in Iauria, which we have already mentioned; and was afterwards appointed vicar-apostolic to all the states of the north, in which capacity he became a zealous preacher in Hanover, Munster, Hamburgh, and various parts of Germany, and died in the course of his missionary labours, at Schwerin, in the duchy of Mecklenburgh, in 1686, in the 49th year of his age.

The works of Steno which are extant, relate principally to medical subjects. He was a zealous cultivator of anatomy, and the author of some discoveries relative to the minute circulation of the eye, the sense, and organs of voice, and to the lymphatic vessels; as the papers which he communicated to the Academy of Copenhagen, and his other works, will testify. The titles of the latter are, "Observationes de Oris, Oculorum, et Narium Vasa," 1662; this was enlarged and reprinted in 1664, with the new title "De Musculis et Glandulis Observationum Specimen." "Elementorum Myologie Specimen, seu Muculi Deferptio Geometrica," 1667. "De solido intra solidum naturaliter

1. S. Forsteri. Oval-leaved Stenocarps. Br. Tr. of Linn. Soc. n. 1. (Embothrium umbellatum; Linn. Suppl. Linn. Soc. 128.) Lamarck Dict. v. 2. 355. Illutr. n. 1285. t. 55. f. 1. Willd. Sp. Pl. v. 1. 358. E. umbelliferum; Forit. Gen. t. 8. f. a-f.). — Leaves elliptic-oblong, obtuse, with prominent ribs. — Gathered by Forster in New Caledonia. The flom is shrubby, with alternate, round, smooth, leafy, dotted branches. Leaves alternate on short thick flanks, coraceous, smooth, entire, an inch or inch and half long; tapering at the base; obscurely triple-ribbed in a dry state. Flowers about half an inch long, red, about six or seven together, in axillary, flatked, smooth umbels, subtended by three or four small, membranous, ovate bracts. Follicle near two inches long, like a small legume, with hollows for the seeds.

A genus of New Holland shrubs, either nearly smooth, or clothed with very fine greyish down. Leaves alternate, without veins; mostly undivided. Flowers single-lobed, foliary, single-lobed, without bractees. Flowers either purple or yellowish. Nut of the drupa often with only two cells, the others proving abortive.

"Bonitas", though very nearly related to Stenochilus, differs in having the upper lip of its corolla emarginate, the lower three-ribbed; a two-lobed stigma; and the nut of two divided cells, each with four seeds, according to the younger Gartner, in his v. 3. 168. t. 142.

1. S. glaber. Smooth Stenochilus. Br. n. 1. — "Leaves lanceolate or elliptical, undivided, smooth, scarcely longer than the flower; sometimes toothed at the extremity. Young branches downy. Stem diffuse." — Gathered by Mr. Brown, on the south coast of New Holland. This gentleman mentions another species, nearly akin to the present, except being hoary with down, which was gathered on the western coast of New Holland; but he leaves the description of it to his friend Lechenault.

2. S. longifolius. Long-leaved Stenochilus. Br. n. 2. — "Leaves linear, somewhat lanceolate, elongated, undivided; hooked at the point; smooth, when full-grown. Young branches downy. Stem erick." — Found also on the south coast of New Holland, by Mr. Brown. The flowers were pale, but the habit, as well as fruite, answered to the preceding. The flowers are from three to five inches long.

STENOGRAPHY, Short-hand, from ρωμοι and κατα. Palling over the Egyptian mode of writing by hieroglyphics, we may observe, that "The History of Hebrew Abbreviations, as a Key to understand the Rabbinical Authors," by the learned Buxtord, appears to have unfolded one of the earliest notions mankind had of a method of short-writing. Some of these abbreviations are merely the incipient letters of several words jointed together as one, and marked at the top with points; others are the final or terministical letters of words; and others, again, are contracted words, wherein two or three letters are made to denote an entire word.

The Jews, we are told, were particularly partial to these methods of abbreviation; to which they added a few arbitrary characters, to express certain proper names, such as God, Jehovah, and the like awful and sacred terms.

By degrees the Greeks acquired this mode of writing, and it was very successfully practised among them. Indeed, the Greek abbreviations and contractions have very much the character of genuine lenography. It was at Nicolai that this method of writing was first introduced to the Greeks by Xenophon himself, who wrote by certain arbitrary notes, in the nature of characters. This opinion is confirmed by Laertius, who particularly notices two distinct methods of lenographic writing: namely, one by simple contractions; and the other by arbitrary marks or symbols.

The Romans practised this art at a very early period. Some writers have even ascribed to the poet Ennius the merit of having first invented a method of writing, by which he gave to the notarii the power of following the most rapid of their orators. This, however, is extremely hypothetical. It is added, that Ennius's method was much improved upon by Tyro, Cicero's freed-man; and still more by the learned Seneca.

Ennius, it appears, began at first to write with one thousand one hundred marks of his own contrivance, to which he might add, as circumstances and necessity de-
STENOGRAPHY.

mended. In what the subsequent improvements confided
we have no account; probably only in the invention of new
symbols or characters, and not in any attempt to write in a
short manner, by the combination of new and more simple
terms.

It is evident the Romans held this art in great estima-
tion; for Suetonius, speaking of Caligula, expresses his
surprise, that an emperor, who, notwithstanding his nu-
merous vices, was not deficient in capacity and parts, should
remain ignorant of the art of stenographic writing. Titus
Vespasian, however, in almost every respect a very different
character from Caligula, is mentioned as being remarkably
attached to short-hand, and himself practised it with great
facility, and often made it not only his business but his
amusement. He seemed to have great pleasure in calling
his amanuenses together, and witnessin g which of them
wrote the fastest. He not only amused himself with steno-
graphic, but with imitating the hand-writing of others;
and, by constant practice, acquired such a command of
hand, and such a facility in imitation, that he was wont
humorously to oblige concerning himself, that he should
have made an excellent mimic or counterfeit.

Various were the schemes, as at present, which were for-
erly used to write after public speakers; but they were
probably all of them exceedingly arbitrary, and, for the
most part, unintelligible to any but those who practised
them; and, on that account, were soon forgotten and de-
stroyed. The art was consequently much neglected, as is
evident from two books of short-hand, mentioned by Tri-
themius. The first was a Short-Hand Dictionary, which he
bought of an abbot, a doctor of law, for a few pence, to
the great satisfaction of the community to which he be-
longed, who had defied the short-hand marks to be erased,
for the sake of the parchment on which they were written.
The other was a short-hand copy of the Book of Psalms,
which he met with in another monastery, where the monks
had inscribed upon it, by way of title, "A Pfalter in the
Armenian Language."

Several copies, however, of a Dictionar y and Pfalter, in
Roman short-hand, are mentioned as extant in different
libraries; but they are in general the same method, as may
be conjectured from those who mention them, and also from
the appearance of an old short-hand Pfalter in the library of
St. Germans, at Paris, carefully preserved as a steno-
graphical curiosity. The late Mr. Byrom had a few pages
of this transcript for his inspection and use.

Plutarch, in his Life of Cato, informs us, that the cele-
brated speech of that patriot, relating to the Carthaginian
conspiracy, was taken and preserved in short-hand; and
there are numerous epigrams of Aufonius, Martial, and
Manlius, descriptive and commendatory of this art. But
we must pass over all other ancient allusions and conjectures,
observing, that, probably, the oldest method of short-
writing at present extant or known is a Latini MS., entitled
"Ars Scribendi Characteris," or "The Art of writing in
Characters." The author of this is not known, but it was
printed about the year 1412.

We may jult, however, remark on this head, that the
ancient Irish alphabets, called Bobcob, a specimen of which
may be seen in Lediwick's Antiquities, and also in Dr.
Fry's Pantographia, have much the appearance of some of
our modern short-hands. Two of their alphabets were
called Irish Logums: Celtic words implying letters written
in cypher, and, indirectly, an occult science. They were
first stenographic, then Pegarographie, then magical, and,
lastly, alphabetic.

The Japanele alphabets (for they have three, two of
which are in general use among the natives, the other only
at court, and among the great) appear to have a steno-
graphical character; most of them combining two, and
others three, letters.

The two alphabets attributed to king Solomon, but upon
what authority is not stated, by Theelcus Ambrofrus, in his
"Appendice des differentes Lettres et des diferentes
Langues," and cited by Druet, p. 132, have much the
same cast in their formation; but the one, of which a
beautifully engraved specimen may be seen in the Encyc.
Franc. pl. xxv., partakes rather of the nature of short-hand
of any other yet mentioned. The Japanese has, in fact,
but 328 sounds, which are all monosyllables, applicable to
80,000 characters, of which the whole language is com-
posed.

Lambinet, in his "Recherches upon Printing," observes,
that modern stenography, which, like the telegraph, dates
in France from the foundation of the republic, has neither
the inconvenience, nor the obscurity, nor the danger of the
ancient. The old characters varied under the hand of the
copiers, and the sense changed according to the genius of
the interpreters; so that their contractions are become so
many enigmas, because we can refer to no other copies to
ascertain the true reading, and because the authors are no
longer in existence. "But," continues this writer, "by the
present system of stenography, the writers follow the
words of the public orators, take down their speeches,
the motion, the debates of the tribune, or the lectures of the
professors of the Lyceum, and produce a literal translation
at last, in the usual characters and in print." It is to be
feared that this description of Gallic stenography is a little
too highly coloured; no system of French writing, that has
hitherto come under our notice, having any such perfect
facility of copying as is here stated; but, certainly, our
neighbours across the Channel can both speak and write
with wonderful rapidity.

The attempt of the late learned and ingenious bishop
Wilkins to form a real character and philosophical language
should not be overlooked. This partakes, perhaps, more
than all others, of short-hand, properly so called; but was
not intended so much for expedition and brevity in writing,
as for an universal communication or correspondence of
ideas. Of its fitness for such a purpose, it is not the object
of this article to discuss. We know a gentleman at this
time, of great opulence and well-known character in the
metropolis, who is of opinion, that he can express all ideas
common to mankind in general by only three letters, which
may be known all over the civilized world; and we be-

lieve it is his intention to make an experiment of the prac-
ticality of his scheme.

The art of short-hand was first attempted in this country
by Dr. Timothy Bright, who published his "Characteris"
in the year 1688. The "Writing School-Master" of Mr.
Peter Bale, appeared two years after Dr. Bright's work.
Bale's book is divided into three parts, the first of which is
entitled "Brachygraphy," and contains rules to write as
fast as a man can speak with propriety and distinctness.
In 1618 appeared Willius's "Stenography, or Short-Hand
Writing by speaking Characters."

This method consists of ten alphabets, denominated words of fort; seven of which are composed of the initial letters of words; the rest principally by the omission of unnecessary letters, and by
symbolical figures.

Henry Dix's "Brachygraphy" was an attempt to im-
prove upon Willius's; but all improvements of the art, till the
invention of Byrom, were little better than the original:
--

arbitrary and mysterious.
STENOGRAPHY.

It is not requisite to detail the history of this art more minutely; nor to mention the numerous systems or methods, all tending to perfection, though each professing to excel its predecessors. We will, therefore, proceed to lay before the reader such a system of stenography, which, if generally known and practiced, would infallibly supersede the necessity of any other; and yet, it must be confessed, that the art of short-hand is far from having attained that perfection of which it may be capable.

The next system, as to beauty and practical utility, to the one about to be here developed, is doubtless that of Dr. Ma-

von's invention, who, however, candidly admits that, in the construction of his own work, he has proceeded upon Mr. Byrom's "general principles," which, he owns, "must for ever form the basis of every future rational system."

Mr. Byrom's method of short-hand, as improved by Mr. Molinex, being now generally esteemed the best and most practical system extant, we shall give a brief yet comprehensive analysis of the whole, premising, that the rules which the inventor had prescribed to himself, in the execution of his plan, were,

1st. That all the simple sounds of the language should be denoted by the shortest and simplest marks in nature

2dly. That those marks which were the shortest, and most easily formed, should be assigned to the letters which are of most frequent occurrence.

3dly. That those letters which are most frequently combined in pronunciation, should be denoted by such marks as are most easily joined by the pen.

4thly. That all the marks of which any word may be composed, should generally be written without taking off the pen; and that the writing should not rise above or sink below the parallel lines, between which it should be uniformly comprised.

5thly. That all the rules of abbreviation should be founded upon the properties of the language, and expressed by the characters of the short-hand alphabet only, without the introduction of any arbitrary marks, either for abbreviation or any other purpose.

To unite so many different perfections in one scheme, and to make a regular and scientific system of the whole, was an undertaking of no common labour and difficulty. Mr. Byrom, the inventor, was well qualified for such an arduous undertaking, by a very extensive knowledge of the nature of language in general, and a thorough acquaintance with the properties and peculiarities of his own in particular; and it was by an indefatigable perseverance in making, through the course of many years, continual trials, alterations, and amendments, that he at last succeeded, to the satisfaction of himself and a few learned and judicious friends, to whom he first communicated the particulars of his invention. To remove any doubt which the public might entertain of its merit, these gentlemen, his scholars, drew up and signed a recommendatory description of his method of short-hand, which testimonial was prefixed, by way of preface, to the original publication.

Mr. Byrom's method of short-hand is there flated to be the art of expressing all the words and phrases of the English language by a character which is perfectly regular and beau-
tiful, and at the same time the shortest possible. Perfect beauty and regularity indeed, so far from being inconsistent with the greatest possible brevity, are in fact the only means of obtaining it; and by a strict adherence to these principles, Mr. Byrom has completely succeeded in the invention and establishment of his system. In fine, his method of short-hand writing is no fanciful theory; but, on the contrary, is founded upon rational and philosophical principles: it pro-

poses nothing impracticable; it is not a mere jumble of awkward marks thrown together without order, and con-

sequently unintelligible to the writer himself after the lapse of a few months or years.

For beauty, legibility, and the greatest possible uniformity in the writing, it stands unrivalled. It was a principal ob-

ject with the inventor to expunge every thing arbitrary, both from the short-hand characters and the rules of abbrevi-

ation; and in this truly effential point he has succeeded to

happily, that his system seems to claim pre-eminence over every other.

It may be useful to refer such of our readers as may wish to attain a complete knowledge of Mr. Byrom's system, to "An Introduction to Byrom's Universal English Short-Hand," by Mr. Molinex, of Macclesfield, explaining the theory of the art in a very clear and perspicuous manner; and to a supplemental work, entitled "The Short-Hand Instructor, or Stenographical Copy-Book," which exhibits the practice, adorned with its peculiar characteristics of ease and beauty. These two elegant little works form together a complete system of stenography, and have the merit of familiarizing Mr. Byrom's excellent method for the general use of schools, and for the particular guidance of those who, without the aid of a living instructor, may be devoid of a literary attainment, which is at once useful and ornamental.

The letter C, having always the found either of k or s, is here represented by those letters respectively; s and z, and also f and v, having a near affinity to each other in found, are denoted by one and the same mark. The short-hand alphabet consists of the following consonants: w, b, d, f, or v, (the latter being easily distinguished when necessary, by a thicker stroke,) g, j, k, l, m, n, p, q, r, s, (differing in the latter, when necessary, by a thicker stroke,) t, w, x, y, z, ch, th, and sh.

The vowels, w, a, e, o, and u, though often omitted in short-hand, are easily repre-
sented by a dot or dots in five different positions, either preceding or following a single consonant, or when any of them are to be interposed between two consonants. When a dot stands alone, the vowel which is meant to be represented by it is easily ascertained, by observing what part of the space it occupies between the short-hand parallels; thus, a is meant if it be found at the top, u, if it be at the bottom, i, in the middle, &c.

1st. When any consonant stands by itself, it expresses some common word or particle, as denoted in the third column of the engraved table or alphabet.

2dly. When a single consonant mark is prefixed, or placed close before any other characters, it denotes some common preposition, or leading part of a word. These prepositions are respectively given in the fourth column of the alphabet.

3dly. When a consonant mark is subjoined, or placed close at the end of other marks, it signifies an appropriate termination or ending. These terminations are given in the fifth or last column of the short-hand alphabet.

From the easy and regular arrangement of a threefold power or signification to each consonant, a threefold advantage naturally follows. First, by allotting to each mark, standing by itself, a word or particle of which it is the head or some constituent part, we obtain a number of common words, some or other of them perpetually occurring, expressed by a single character, which otherwise would stand for nothing.

Secondly, The prepositional part of a word being de-

signified by its leading consonants, placed near, but not joined to the following part of it, secures alike the beauty and...
and brevity of the characters, which in many cases could not otherwise be maintained.

Thirdly, A similar advantage is gained by representing the terminational part of a word by an appropriate conso-
nant subjoined, but not connected with the end of the other
characters, when, by the mutual help of each other, they
describe long and complex words in a neat and concise man-
er, and are easily distinguished from all others.

Two marks, it will be seen, are allotted to the consonant
B, and they are each used, when standing alone, to denote
two different words, the first be, and the second but. The
principal reason, however, for assigning two marks to the
fame consonant, is to secure a more easy combination of the
marks in writing, the first being used, for instance, before a
defending character, as be, or be, and the latter before one
which ascends, as or or . The first character is generally
written upwards, but the second is always made downwards.

Ufed as a preposition, the first denotes be; and the second,
used as a termination, represents , or -ible.

One of the most common terminations in our language is
denoted by the letter D, which the learner will observe stands
for the word and when written separately, for de as a pre-
position, and for ed as a termination. This letter is never
written upwards, and the same rule will invariably apply to
all those characters, whether curved or straight, that are
strictly perpendicular; the oblique letters may be written
either upwards or downwards.

Neither prepositions nor terminations are invariably de-
tached from the roots of their respective words. It is diffi-
cult to lay down any precise rule for this; certainly in cases
wherein the preposition or termination can conveniently be
joined, it would be a needless waste of time to lift the pen.

Misch, however, depends upon the degree of force or im-
portance which the termination may poifea in the correct
pronunciation of the word, in writing the phrase, a learned
man, he is learned in the law, &c.; it is not chaff to say
a learned man, learn'd in the law. On this account it will
admit of a question, whether it would not be more correctly
to detach the termination ed in short-hand, notwithstanding it
will so very conveniently join in this word. And here let
the learner observe, once for all, that he should acquire
such a method of writing short-hand as will create the least
possible ambiguity, or difficulty in reading it; and this can
only be done by adhering as much as possible to the rules
of a correct orthography and pronunciation.

The letters F and are always written downwards. In
cases where dispatch is not required, the letter w may be
denoted by writing the character a little thicker. And this
distinction is not only convenient, but perfectly rational:
there is a kind of affinity betwixt the sound of the letter w,
and the thickness of the line by which it is expressed; the
letter j has, to use such a term, a thinner sound, and may
only be denoted by a thinner character; the sound of f and
w, however, is so nearly the same, that the same shaped
character is very properly used for both characters. These
remarks will apply to the letters s and z; in which is the fame
sound of sound, denoted by the same respective strength
in the pronunciation.

This character, as a word, stands for g or j; prefixed to
other characters, it represents the preposition for; and, as
a termination, -ify.

The letter G is represented on the Short-hand plate by a
character which is to denote both the hard and the
soft sound of that letter. In the latter capacity, it is
eventually used instead of j. Standing by itself, it de-
notes, when written at the top of the line, the word
again, and at the bottom, again. It has no prepositional
or terminational character.

H is denoted by two characters; but the first only is to be
considered as the proper representative of that letter.
It is written downwards from the twirl. The other char-
acter might very well have been dispensed with; but
being retained in the alphabet, may still be used simply
to denote the word but; and notwithstanding the twirl is
at the bottom, it is better to write it downwards. The
first character stands for the word have.

When it is requisite to write the words hat, hit, hat, but,
or any others beginning with h, and ending with t, with
one or more vowels in the middle, the vowels may be indi-
cated by placing the vowel in its appropriate position with
reference to the line, but out of its usual order in other
repetitions, viz., immediately before the consonant, and not
lengthening the last letter, or t, below the line. By writing
the letter r, in the words hitter and bitter, only half its
usual size, the t in the former part of the word denotes th.

The letter J having been accidentally omitted in the
plate, it is supplied here by the following characters
j, standing, when written separately, for the words judge, and just; but the first only is the proper mark
for the words which the other character standing in a similar
situation to the last character for b; being in a manner
unnecessary: when used, however, it must be written down-
wards. There are some instances in which the letter g may be
used for j.

The next letter, K, is a very important one; for it re-
pre sents the c hard, and of course is the initial letter of all
those words beginning with that letter, and in all other
places where it is required; it is also the first letter in words
beginning with k. The soft sound of the letter c is expre-
sed by the letter s; and sometimes the k and q are
used promiscuously for each other, whenever greater facili-
ity, convenience, and beauty of joining, may be brought
by such means be obtained. This character being, moreover, an
horizontal one, may be placed at the top, middle, or bottom
of the short-hand space or line. When written at the top
of the space, it stands for can; and at the bottom, for could
or could. As a preposition, it represents, at the top,
middle, or bottom, con-, con- and contra:- in the middle
of the space, it denotes the terminations -ical or -ical.

Cm and cn occurring very frequently at the beginning of
words, the corresponding characters may be shortened,
by cutting off the horizontal part of the letter k or c, and
beginning the next letter, m or n, immediately after the
formation of the twirl. This will, however, apply only to
the commencement of words.

L is represented by three characters, of which it may be
observed generally, that in all of them the twirl is formed
to the right hand. When written singly, the first character
denotes the word all, the second always, and the third
al-together.

M, and indeed the horizontal characters generally, are
of frequent and important use in short-hand. This letter,
when written at the top of the space, represents the word
am, and at the bottom, among, or among. As a preposi-
tion, at top it is magni-, in the middle mix-, and at the bottom
omn-. Used as a termination, it is ment; and it is cus-
tomary, in this case, to write it at the top of the line.

N, the letter m reversed, is also of frequent use. As a dif-
ficult word, it stands for an at the top, in the middle,
and under at the bottom. Prepositionally, it is
ante- or anti-, inter- or in-; and at the bottom, under- or un-
. As a termination, it stands for ent at the top, and -m at
the bottom; but when used in the latter case, it is cus-
tomary
STENOGRAPHY.

Stomary to add a short s, or horizontal straight line, to it. Both this and the letter m, when used as a preposition or termination, should be made somewhat less than the usual alphabetical size. The same observation will apply to the letters b, d, r, t, w, &c.

P is the same letter in a perpendicular position, and is, in fact, the d revered. As a word, it stands for open; and as a preposition, for per-, pre-, or pre-. It may also occasionally be used for "ge.

Q is the k revered. In the middle, and at the end of words, it is frequently used instead of that letter. Ufed fingly, it is the word question.

R is the oblique character used for s, with its inclination to the right, and may be written either upwards or downwards, according to the nature of the marks which may happen to precede or follow. When not joined to other characters, it is always supposed to be written downwards; and in that case the vowels are, of course, reckoned from the top downwards. As a word, it stands for or; as a preposition, for re-; and as a termination, for ropy and sing; the plural of which may be denoted by a small 3 added to it. It is seldom necessary to use the detached preposition re- in short-hand, except when the consonant which follows that preposition does not admit of being conveniently joined to the letter r.

S, or Z, expressed by a straight horizontal line, the z being made a little thicker if necessary, is a letter of infinite service in our language, and in short-hand particularly. It is, as before observed, the c soft. At the top, when used independently, it stands for as, in the middle for is, and at the bottom for us. By the same rule of position, it stands for the prepositions fat-is, circums-, super- and jub-. And, again, as a termination, according to the order of the vowels, for atom, a-otion; atom, a-ition; atom, a-reon; atom, a-cion; et cetera. Indeed, for the common terminations -aion, -aion; but whenever this termination is preceded by a single consonant only, the word must be written at length; as motion (mofin), nation (natin). When placed close after any of the pronouns, it no longer represents a-ition, or any other termination of that kind; but stands for self and selves, or sever, or severer; the first in the c's, and the last in the s's place.

T is a perpendicular line or stroke. As a word, it stands for the; as a preposition, for tran-; and as a termination, for -ty. It should uniformly be written downwards.

When two t's form a word, or part of a word, a little break must be made, to signify that such is the case. This may be done without lifting the pen; but only very lightly moving it on the paper to the right, before the last letter is commenced. This letter, in short-hand, is often used to denote th, which is done by making the adjoining consonant, either preceding or following the t, only half its usual size: thr, nth, &c. are very conveniently so signified. In all other cases, a letter of half the size denotes that the adjoining character is to be resolved into two letters or parts; as, when in the words terror, prayer, &c. the first letter is made small, and the other, the r, is its usual length; this, however, should be referred to as seldom as possible.

V is the oblique letter f, made a little thicker when needful.

W has two characters, of which the first is the proper one for the letter, as in the case of j and l. This character stands for will, the other for would and wouldst, and is written downwards: as a preposition, it is with-; and as a termination, -ward and -wards. With respect to the use of the letter y, in union with w, see the observations on k respecting that point.

X has also two characters, but the first only is used as the letter. The one stands for except, and the other for extra. As a preposition, it is ex- and extra-. The letters k r and g will often express the sound of this letter.

T is used only at the beginning of words, and for the word yet. At the end and in the middle of words, the vowel i is always used.

Z is the same as i, made thicker, when needful.

Ch are denoted by a character resembling the short-hand g revered, and stands for the word which. When founded hard, like k, as in words from the Greek, it is not used, but this latter letter used instead of it.

Sh have two characters, but the first is the only proper representative of these combined letters. This character stands for the word shall, and the other for should and shouldst.

As a termination, it is used for ship.

Th, a very frequent combination of consonants, are denoted by two characters, either of which may be considered as the legitimate representative of these united letters; but Mr. Molineux prefers the latter, which is used for the word that; the first in the formation of words only.

Et cetera. This common abbreviation is denoted by a i, and a small t or c left, drawn from the e's place.

Thus have we gone through the alphabet, as exhibited on the plate; and the reader, by comparing the one with the other, may readily acquire a pretty competent knowledge of the leading principles of this system of short-hand writing. So far appears to be every thing that is absolutely necessary to lay down by way of instruction to learners withing only to acquire so much knowledge of stenography as will enable them to use it for the convenience of epistolary correspondence, for the purposes of literature and study, in the writing of common-places, making extracts, private memoranda, &c.

But as there is a higher and more definable object to be attained by the practice of this art, eis. that of taking down the speeches of public orators, trials, &c. it is essential, to effect this object, that a still more concise method of writing should be acquired; and this may be accomplished by attention to the simple rules given in the following short extracts, abridged from Mr. Molineux's excellent treatise.

Of Abbreviations.—An alphabet, formed upon the most just and natural plan, by which, with the help of a few general rules, all the words of the language to which it is adapted, may be easily, neatly, and speedily written, will not alone be sufficient to satisfy the expectations of an inquisitive reader; who must be sensible, that however complete the alphabet may be, yet many copious applications of it may be obtained by an inquiry into the nature of our language, and the abbreviations of which it admits. He will not be satisfied with being only taught how to express all the letters of a word by the shortest and easiest strokes, but will also require further instruction how to describe intelligibly words and sentences, by as few of those strokes as possible. To investigate from a few things given, many which are omitted, will be found no unpleasant exercise of the learner's capacity; and if the few be properly given, the sense of the passage, and a due attention to the ideam of our language, will render the discovery of the omissions more certain, and also less difficult, than the unexperienced would be apt to imagine. Without some rules of abbreviation, one end of short-hand, that of following a speaker, would fearfully be attainable.

It may be proper, however, to advise the learner not to embarras himself with short-hand abbreviations, till, by a competent
STENOGRAPHY.

Competent practice of writing according to the rules already laid down, he becomes so well acquainted with the characters, as to be able to write and read them with nearly as much ease as common long-hand. He will then meet with little more difficulty in reading words contracted, than he formerly did in those written more at length, provided that the rules of abbreviation be duly attended to. A summary of the principal rules and most practical methods of abbreviation is here given, and it is left to the skill and discretion of the writer, by observing their nature, and proceeding upon the same principles, to make such farther advances and improvements as his occasions may require.

A brief Summary of the principal Rules of Abbreviation.

Rule 1.—To join the auxiliary verbs, the particle not, and the pronouns together; as can be, have been, must be, cannot be, he must be, ought not to be, &c.

Rule 2.—To join the marks in an unusual manner, in order to shew that each particular mark denotes a word, and not a single letter; as in this, it is, as it is, since it is, it was, it was not to be, &c.

Rule 3.—Derivative substantives may be very conveniently represented, by placing a point at the end of the words from which they are derived. Derivative adjectives and adverbs may be represented also by points, distinguishable by their situation, both from the substantive and the vowel points; which may be done by placing them in a line, which, if produced, would pass through the substantive point, and would also be perpendicular to the last consonant mark; one placed before the substantive point, signifying the adjective, one after it, the adverb; as, forgetful, forgetfulness, forgetfully; reasonably, reasonableness, reasonably; sufficient, sufficiently, sufficiently.

No great accuracy is necessary with respect to the adjective and adverb points, provided they be placed so as to be clearly distinguished from the vowel and substantive points.

Rule 4.—Such words as, either by their particular relation to the subject, or frequent occurrence, are easily discoverable, however conceivably written, may be denoted by the first letter, if they begin with a consonant, if not, by the first vowel and consonant, with the adjective, substantive, or adverb point annexed; as, “life and immortality are brought to light by the gospel;” “the resurrection of the dead, and a future state of rewards and punishments, are plainly and positively taught in the gospel.” The adjectives which usually accompany such substantives may also be denoted by their first consonant, joined to the substantive; as, “with humble submission to your lordship.”

Most writers of short-hand accustom themselves to mark such words as most frequently occur in their own particular prolixities, by the initial letters only, with the substantive, adjective, or adverb points, which, through custom, easily suggest the words to them at first sight. But it must not be understood, that those marks imply those words exclusively, and no other. They may fland for any other beginning with the same letters, which the sense of the passages necessarily requires.

Rule 5.—A dot placed at the point of concurrence of two consonant marks, denotes two substantives, of which those marks are the first consonants; and also that the latter is governed of, or connected to, the former by some proposition, which is omitted; as, “the love of money is the root of all evil;” “seek ye first the kingdom of God, and his righteousness, &c.” “the effects of gravity are visible in every part of that system to which we belong, but the cause of gravity still remains undiscovered.”

And if an adjective precedes either of the substantives, they may all three be represented by their first consonants joined together, with the dot always placed at the end of the first substantive; as, “the great goodness of God is manifest in all his dealings with his creatures;” “his majesty the king of Great Britain.”

Rule 6.—The substantive point, placed before a single consonant mark, denotes that the substantive is to be repeated, with some intervening proposition; as, “day after day,” “from time to time.”

Rule 7.—The substantive, adjective, or adverb point, placed before two or more consonant marks joined together, denotes two or more substantives, adjectives, or adverbs, of which those marks are the first consonants, and also that they are connected by a conjunction; as, the “precepts both of natural and revealed religion, forming us to do our neighbors any injury;” “what doth the Lord thy God require of thee, but to live soberly, righteously, and godly in this present world.”

Rule 8.—Many long words, especially those in which the marks for the consonants will not join neatly, may be denoted by their first syllable, with as many points annexed as there are syllables wanting; as, multitude, correspondence.

And when great dispatch is required, the points may be omitted, especially if the words do not begin with prepositions; as, signification, difficulty, negligence.

Rule 9.—Words beginning with prepositions may be denoted by their respective prepositions, together with the next consonant and vowel, and sometimes with the next consonant only, adding, when necessary, the substantive, adjective, or adverb point; as, deliberate, transmutation, recommendation, confidentiality, &c.

The participles may be abbreviated after the same manner, by adding, instead of the points, the terminations -ing or -ed to the latter consonant mark; as, confounding, confedered.

Words beginning with double or treble prepositions, may be written after the same manner, joining the prepositions together; as, representation, misrepresentation, incomprehensibility. If two consonants begin the next syllable, the writing of them both will help to discover the remainder of the word; as, misunderstanding, transconfabulation.

Rule 10.—Words ending in any of the terminations which in the alphabet are denoted by consonant marks, may be expressed by their first consonant and vowel, together with the proper mark for its termination; as, arbitrary, opportunity, curiosity, lowfulness.

Rule 11.—Such words as are easily discoverable by the particular prepositions which they require, may be denoted by their first consonant only; as, “this belongs to me;” “he made some good observations upon it;” “we must guard against such passions as we are most liable to.”

As few English words end with the syllable -to, the preposition to may be joined to the preceding word, which is signified by its first consonant only; as, this belongs to me, liable to, satisfactory to.

Other prepositions which are denoted in the alphabet by a single consonant, may, in like manner, be joined to the preceding word; as, “he made some good observations upon it.”

Rule 12.—Prepositions generally require after them either a noun or pronoun. The pronouns being few in number, and used as substitutes for nouns, must occur very frequently, and by that means soon become familiar to the learner; pronouns, therefore, may be joined to the prepositions, without danger of creating any difficulty to the reader; as, to me, to you.

Rule 13.—The preceding word, the preposition, and pronoun, may be joined all together; as, belongs to me, extends to us, agreed with me, depend upon me, observations upon this.

The words some, any, none, which, each, both, &c. followed
S TE

lowed by a preposition and pronoun, may be denoted by their first connotants, and may be joined to the preposition and pronoun; as, some of them, any of us.

Rule 19.-The adverbs preceding the verbs, and the sub-

stantives following the pronominal adjectives, may be joined to the verbs and adjectives respectively, denoting both the adverbs and substantives by their first connotants, or at most by their first connotants and vowels; as, "you may safely de-

pend upon my word."

Rule 15.-Many common phrases, formed by a sub-

stantive preceded by the prepositions with, without, in, &c., and followed by to, of, &c., may be very conveniently abbrevi-

ated; as, with regard, reefs, or reference to, in order to, in con-

sequence, comparison, or consideration of.

Rule 16.—Common adverbial phrases are, in like manner, often denoted by their initial connotants joined together; as, at the same time, at present, in this manner, in like manner, in a great measure, in the same manner, in the mean time, in general, in particular.

And when the proportion of equality is expressed, with some one word intervening, they may be all joined together; as, so much as, as well as, as soon as.

Rule 17.—The contractions which may be made, when it is or it was, are followed by an adjectival, and to or that, are very numerous; as, it is impossible to, it was unnecessary to, it is contrary to, it is according to.

STENOMARGA, in Natural History, a name used by some authors for a light marly earth, more usually called agerinum, and has been given by the later writers, and terra, or ereta Selenenata, by Dionysius and Galen.

STENOSA, in Geography, an island in the Grecian Archipelago, about 10 miles in circumference, inhabited only by a few goats and their keepers. N. lat. 37° 5'. E. long. 25° 55'.

STENSKAR, two or three small islands on the W. side of the gulf of Bothnia. N. lat. 65° 12'. E. long. 21° 30'.

STENSSITZA, a town of Poland, in the patinate of Sandomirz; 28 miles E. of Radom.

STENTATO, in Geography, an island of the Grecian Archipelago, about 10 miles in circumference, inhabited only by a few goats and their keepers. N. lat. 37° 5'. E. long. 25° 55'.

STENSKAR, two or three small islands on the W. side of the gulf of Bothnia. N. lat. 65° 12'. E. long. 21° 30'.

STENSSITZA, a town of Poland, in the patinate of Sandomirz; 28 miles E. of Radom.

STENTATO, an Italian musical term, given by Brof-

ard, which no longer occurs in musical works at present. It seems to have been superceded by Sforzando.

STENTEROPHONIC TUBE, a speaking-trumpet, so called from Stenter, the vociferous Stenter, celebrated by Homer (Iliad, lib. v.) as the most illustrious throat-per-

former, or herald of antiquity: "Stenter the strong, endowed with brazen lungs, whole throat surpafs'd the noise of fifty tongues."

Pope observes on this passage, that "there was a necessity for cryers whose voices were stronger than ordinary, in those ancient times, before the use of trumpets was known in their armies. And that they were in esteem afterwards, may be seen from Herodotus, where he takes notice that Darius had in his train an Egyptian, whose voice was louder and stronger than that of any other man of his age."

The speaking-trumpet, under the title of the Stentero-

phonie tube, was long ascribed in England to Sir Samuel Moreland; but Kircher has formally laid claim to it in his "Musurgia;" however, the Stenterophon horn or tube of Alexander the Great claims primogeniture, as well as im-

mortal magnificence; for it is said that he could give orders to his army at the distance of 100 stadia, which is above twelve English miles. See Trumpet.

STENVICK, in Geography, a town of Norway, in the province of Drammen; 24 miles S.W. of Drammen.

STENYCLARUS, in Ancient Geography, a town of La-

Vol. XXXIV.

conia, upon the river Parnius, N. of the gulf of Melas; where Cretphonte, one of the chiefs of the Heracles, established his residence, and which he made his capital, so that it was called a royal city, or βασιλικά. —Also, a plain of Melosia, W. of the river of Paunosias, known on account of a battle very disastrous to the Lacedemonians, in the year 684 B.C. Paunosias places this plain on the road from Megalopolis of Arcadia to Ithome.

STENZYLY, in Geography, a town of Poland, in Vol-

ymia; 15 miles N.E. of Luckow.

STEPS. See Place, Throne, &c.

STEPS. In Ship-Building. Steps for masts, into which their heels are fixed, are large pieces of timber. The main and fore-step are fixed across the keelson, and that for the mizen-mast upon the lower-deck beams. The holes or mor-
tises into which the heel of the mast steps, should have suffi-
cient wood on each side, to accord in strength with the tenon left at the head of the mast, and the whole cut rather less than the tenon, as an allowance for shrinking. The step for the capitan is a solid lump of oak, let down between the beams, in which the spindle at the head of the capitan trav-
eres in an iron cup. Steps for the ship's side are pieces of oak quartering, with mouldings, nailed on the sides at the gangway, about nine inches asunder from the wales upwards, for the convenience of getting up the sides.

STEP, or Tongue, in Rope-Making, for the tar-kettle, is made of three-inch oak-pank, five feet long and thirteen inches broad, which tapers to nine inches at the bottom, and is put into the kettle through a mortise in the bridge. Within four inches of the lower end of the step is a round hole five inches diameter, for the yarn to pass through. The step is suspended and regulated by a tackle.

STEP and LEAP, in the Mange, one of the seven airs or artificial motions of a horse, consisting, as it were, of three airs: 1st, the pace or step, which is terra-a-terra; the rising before, which is a curve; and the whole finished with a fault or leap, which is a capriole.

This manage is infinitely less painful to a horse than the capriole; for when you dree a horse to the capriole, he will of himself take to this air for his ease and relief; and in time those horses which have been dree to the caprioles, will execute only baloteades and croupades, unless particular care is taken to make them jump our.

It is this, likewise, which, next to running a brisk course, enlivens and animates a horse most; to reduce a horse to the juftness of this air, you must begin by embolming and making him lose all fear of correction, teaching him to keep his head steady, and in a proper place, lightening his fore-paws by putting him to make pefades, and teaching him to know the aid of the switch, the same as in the lefion of the capriole, and by giving him a firm and good appui, and full in the hand; though it is certain that the step contributes to give him this appui, inasmuch as it puts him in the hand; besides, that it gives him strength and agility to leap, just as we ourselves leap with a quick step while running, than if we were to stand quite still and leap; therefore, most old horses generally fall into this air.

When your horse is sufficiently knowing in these several particulars, teach him to rise, and hold him in the air; then let him make three or four pafades, and afterwards let him walk four or five steps slow and equal. If he forces the hand, or retains himself too much, he should be made to trot these four or five steps rather than walk; after this, make him rise again, and continue this lefion for some days.

When he is so far advanced as to comprehend and un-
derstand this sufficiently, begin by putting him to make a
pèfades; demand then a leap, and finish by letting him make two pèfades together.

There are two things to be observed, which are very essential in this lefson: one, that when he is to make the leap, he should not rise f0 high before as when he makes pèfades only, fo that he may yerk out with greater cafe and liberty; the other caution is always to make your latt pèfades longer and higher than the other, in order to prevent your horse from making any irregular motions, by fluffing about his legs, if he should be angry and impatient, as well as to keep him in a more exact obedience, and to make him light in the hand, if he is naturally heavy and loaded in his fore-parts, or apt to lean too much upon the hand.

Again, reduce the third or fourth pèfade into a leap, as you did the first, then make two pèfades following; and after this, let him walk quietly four or five flps, that he may make again the fame number of pèfades, and in the fame order. In proportion as the horfe begins to under-

fand, and is able to execute these lefsons, you fhould aug-

ment likewise the leaps one by one, without hurrying or

changing their order, making always between two leaps a

fingle pèfade, but lower than thofe in the firft lefson, and

then two more again after the laft leap, and fufficiently

high.

By degrees the horfe will grow active and light in his hinder parts: you muft raife him then higher before, and

support him longer in the air, in order to make him form

the leaps perfect, by means of prudent andjudicious rules,

often practiced and repeated.

If a horfe forces the hand, or prefles forward more than

you would have him, either from heavines of make, or from

too much fire in his temper; in this cafe, you fhould oblige him to make the pèfades in the fame place, without

flurring from it; and instead of letting him advance four or

five flps, you fhould make him go backward as many.

This correction will cure him of the habit of prefing for-

ward, and forcing the hand. Upon this occafion, likewise,
you fhould use a hand-flpur to prick his croupe, instead of a

flwitch.

To make this air juft and perfect, it is neceffary that the

action of the leap be finifhed as in the caprifes, except that

it ought to be more extended; and that the pèfade, which

is the two leaps, fhould be changed into a

time of a quick and fhort gallop; that is, the two hinder

feet ought to follow together in a quick time, and briefly;

the fore-feet, as in curvets in the mezzair; but in this the

horfe fhould advance more, not be fo much together, nor

rife fo high.

The perfection of this time of the gallop depends upon

the juftnefs of the horfeman's motions. They ought to be

infinitely more exact in this lefson than in the caprifes, or

any other airs which are performed in a ftraight forward.

In reality, if the horfeman is too low, and does not catch

the exact time which parte the two leaps, the leap which

follows will be without any fpring or vigour, becaufe the

animal fo refrained and held back can never extend himfelf;
or put forth all his force. If he does not support and

raife his flhoulders fufficiently high, the croupe will then be

lower than it ought to be, and this difproportion will force

the horfe to tofs up his nofe, or make fome other bad mo-

tion with his head, as he is coming to the ground in his

leap; or elfe it will happen from this, that the fucceding

time will be fo precipitate, that the next leap will be falle

and imperfect, as the horfe will not be fufficiently united,

but will be too heavy, and lean upon the hand. If he is not

together, the leaps will be too much extended, and con-

fquently weak and loofe; becaufe the horfe will not be able
to collect his strength, in order to make it equal to the

first.

Learn then, in a few words, what fhould be the horfes-

man's feat, and what actions he fhould ufe in this lefson.

He fhould never force, alter, or loose the true appui,

either in raifing, supporting, holding in, or driving forward

his horfe.

His hand fhould be not only firm and feady, but it is

indispensably neceffary that his feat be exactly ftraight and

juft; for since the arm is an appendix of the body, it is cer-

tain that the motions of the horfe make or diforder the body

of the rider: the bridge-hand muft inevitably be fhook, and

confequently the true appui deftroyed.

In this attitude then approach the calves of your legs,
support and hold your horfe up with your hand; and when

the fore-pate is at its due height, aid with the fwitch upon

the croupe.

If your horfe rifes before, keep your body ftraight and

firm; if he lifts or tofles up his croupe, or yers out, fling

your flhoilders back, without turning your head to one fide

or the other, continuing the action of the hand that holds

the fwitch.

Remember that all the motions of your body be fo neat

and fine, as to be imperceptible: as to what action is the

most graceful for the fwitch-hand, that over the fhoulder is

thought the belt; but then this fhoulder muft not be more

back than the other; and care muft be taken that the motion

be quick and neat, and that the horfe do not fee it fo plainly

as to be alarmed at it.

It is faid, that when the horfe makes his leaps too long

and extended, you fhould then aid with the hand-flpurs,

and for this reafon, because the hand-flpurs will make the

horfe raife his croupe without advancing, as the effect of

the fwitch will be to raife the croupe, and drive the horfe for-

ward at the fame time; it fhould, therefore, be ufed to fuch

horfes as retain fhemselves.

Remember that you fhould never be extreme with your

horfe, and work him beyond his strength and ability: indeed

one fhould never alak of a horfe above half of what he can

do; for if you work him till he grows languid and tired,

and his strength and wind fail him, you will be compelled
to give your aids rough and openly; and when that happens,

whether the rider nor the horfe can appear with brilliancy

and grace.

STEPAN, in Geography, a town of Poland, in Vol-

hynia; 15 miles N.E. of Luckow.

STEPENITZ, a river of Mecklenburg, which joins the

Trave, at its entrance into the Baltic.—Alfo, a river of

Saxony, which runs into the Ellie, near Wittenberg.—

Alfo, a town of Hinder Pomerania; 6 miles N.W. of

Golnow.

STEPHANE, in Ancient Geography, a town of Asia,

in Paphlagonia, upon the coast of the Euxin sea, with a

port, where vessels were secure, between Cimilis and Po-

tani, according to Arrian.

STEPHANIOUSKO, in Geography, a town of Bo-

hemia, in the circle of Chrudim; 16 miles N.E. of

Chrudim.

STEPHANIA, in Botany, fo named by Lorencio,

from sèphos, any thing encircling the summit of some-

thing else; whence comes sèphos, a crown; and hence the above

appellation alludes to the anther, "which surrounds the head of

the filament, like a crown of gold."—Loureir. Cochin.

608.—Clafs and order, Dioccia Monandria. Nat. Ord.

Sarmentae, Linn. Alpargi, Jull.

Gen. Ch. Male, Cal. Perianth of five rather acute,

spreading leaves; the three alternate ones smaller. Cor.

Petale
Petals three, small, obtuse. Stem. Filament one, as long as the calyx, thick and abrupt at the summit; anther circular, crowning the filament.

1. S. rotunda. Round-rooted Stephania.—Leaves petate, roundish. Umbels compound.—Native of the woods of Cochinchina. Stem shrubby, twining, scarcely branched, very long, round, smooth, without thorns. Leaves alternate, falcate, petolate, roundish, obliquely triangular, acute, wavy, smooth. Flowers in lateral compound umbels. Petals of the male blossoms, which Lourier terms a three-leaved petalary, yellow. The root is a large, roundish, rough, brown knob, rifting above the ground, of a very bitter flavour, and agreeing with the Aristolochia rotunda in shape as well as qualities. It tends down into the earth a very long, central, perpendicular, thread-shaped radicle.

Stephania is also the name of a genus in Wildenow, Sp. Pl. v. 2. 193, dedicated by that author to the honour of professor F. Stephan, of Moscow; but this cannot aftide the long-published Stephania of Lourier, if the latter should prove, as appears by the above description, a good genus. There seems indeed more doubt respecting Wildenow's Stephania, which is thus defined.—Clas and order, Hessandria Monografia. Nat. Ord. Capparidaceae. Jaffé.

1. S. colominosa. Willd. n. 1. (Capparis paradoxus; Jacq. Hort. Schen cob. v. 1. 58. t. 111.)—Native of the Caraceas, from whence it was brought to Vienna by Dr. Joseph Marter, to whom we are obliged for a native specimen. The stem is fleshy, crept, with round leafy branches, clothed when young with rusty down. Leaves alternate, deflexed, lanceolate, pointed, entire, slightly wavy, from four to six inches long, with one rib and many transverse veins, marked with scattered glandular dots, each of which, in an early state, is furnished, on both sides of the leaf, with a hairy tuft of deciduous hairs. Footstalks half as long as the leaves, or more, straight, clothed with rusty down. Stipulae none. Clavicles terminal, solitary, simple, slightly leafy; their partial stalks clothed, like the calyx, with orange or tawny hairy down. Petals yellow, acute, downy, a little longer than the calyx. Stamens, and fork of the genus, four times as long. The genus of Capparis is so ill defined, that we know not how far this plant accords or not with some of the species, nor whether they require separation from the rest. If this should be the case, a new name must be sought for.

Stephanitae, in Antiquity, an epithet given to games and exercises, where the prize was only a garland.

Stephanium, in Botany, Schreb. Gen. 124, a name given by this author to Aublet's Palicourae. (See that article.) The genus itself is, however, abolished, Dr. Swartz having reduced it to Physutria. Fl. Ind. Occ. v. 1. 433, in which he is followed by Willdenow, Sp. Pl. v. 1. 971. These authors call Aublet's plant Physutria Paltuera. It is a native of Guinea and the West Indies. Stephania would be too near Stephania, if the genus of Schreber and Aublet were a good one.

Stephanakowice, in Geography, a town of Poland, in the patrinate of Belz; 34 miles N. of Belz.

Stephanophorus, i.e. Crown-Bearer, in Mythology, one of the priests in the festival of Ceres, called Thafmophoria; which see. Priests of the same denomination, called also Flamines, from a kind of bonnet and fire-coloured veil with which they covered their heads, officiated at the sacrifices appointed by Numi, and offered in the temple consecrated to Romulus.

Stephanowze, or Stephanestein, in Geography, a town of European Turkey, in Moldavia, at the confluence of the Pruth and the Bafzen; 40 miles N. of Jaffa. N. lat. 47° 58'. E. long. 27° 30'.

Stephanusberg, a town of Germany, in the principality of Anspach; 4 miles N. of Maybernheim.

Stephanus Dord, a town of Silefia, in the principality of Neill; 4 miles N.W. of Neill.

Stephanus, a town of Asiac Turkey, in Natolia, on the coast of the BlackIce; 18 miles N. of Sinob.

Stephanus, Byzantium, in Biography, a grammarian who flourished, as it is conjectured, about the close of the fifth century, was professor in the imperial college of Constantinople, and composed a dictionary containing nouns-adjective derived from the names of places; and designating the inhabitants of those places. Of this work there exists only an abridgment, made by Hermodaus, and dedicated to the emperor Justinian. This work is known by the title Praep. nabus, de Urbibus; but that of the original was Ladox; hence it has been inferred, that the author's intention was to write a geographical work. Much of the value of the original is unquestionably lost in the abridgment; yet learned men have derived considerable light from it; and it has been an object of critical illustration to Cahnorn, Scliger, and Salmasius. It was first printed in Greek at Venice, in 1522, under the superintendence of Aldus Manutius. An edition of it, with a Latin version, was published at Amsterdam, in 1678, by Pineda, a Portuguese Jew; and ten years after this, an edition was printed at Leyden, with a translation by Abraham Berkheius, who added a very copious commentary. This edition was not completed when the learned editor died, and it was finished by James Grunovius. A fragment of the original, relative to Do- donna, is extant; and an edition of it was given by Gro- novius.

Stephen I., Pope, succeeded Lucius about the year 244. His pontificate was rendered memorable by his dispute with Cyprian, bishop of Carthage, concerning the baptism of heretics. Stephen had already displayed a degree of temerity, by pronouncing the restoration of Balsides and Martialis, two Spanish bishops, who had been deposed by the other prelates of that country, and who went to Rome to appeal to the pope. Cyprian, in this discussion, maintained that baptism by heretics could not be valid;
STEPHEN.

an opinion which was confirmed by a council of seventy-one bishops, held at Carthage. Their determination was lent to the pope, who not only rejected their decrees, but enjoined them, under the penalty of excommunication, to renounce their decrees; and he concluded with some severe re-
flections against Cyprian. The latter instantly summoned another and still more numerous council, which unani-
mously confirmed the determination of the former af-
semble. The pope, in his turn, proceeded to anathema-
tize all the bishops who had affixed at the council, and all who adopted the same opinion, which comprised the pre-
lates of Africa, Egypt, and Leiffer Afa. Stephen's au-
thority was not much regarded, and his death, in 257, put an end to the dispute. The church of Rome, which has
pronounced in favour of his opinion, enrolled him in the
list of its saints, as it has done his antagonist.

Stephen II., pope, a presbyter, was chosen in 752 to
succeed Zachary, but who died within a few days of his
election, and before he could be consecrated. He is omitted
by all the ancient authors in the papal catalogue, but by
later writers he has been admitted, upon the principle that
election alone confers the papal authority, and that he is
therefore to be regarded as a real pope. He was suc-
ceded by

Stephen III., who was elected in the same year. He
was a native of Rome, the son of a perfom named Con-
flantine, and had acquired the dignity of deacon of the Roman
church, when he was chosen to fill the pontifical chair. At
this time Afothphus, king of Lombardy, who had made
himself master of all the exarchate of Ravenna, threatened
Rome, requiring its submission, and the payment of a
tribute. The pope attempted to divert him from his de-
signs, but without effect; the haughty monarch invested
the city, nor could he be deterred from his purpose by the soli-
citation and threats of the emperor Constantin. The pon-
tiff applied now for the aid of Pepin, king of France, who
received him into his court with every mark of respect.
Here he was taken ill, but having recovered, he solemnly
anointed Pepin, with his queen and two sons, in the church
of St. Denis. The king then marched with an army into
Italy, taking the pope with him, and besieged Afothphus in Pavia,
who was obliged to submit to the terms of restoring
to the church all the territories which he had feigned from it,
and also of relinquishing the exarchate of Ravenna. No
former, however, had Pepin repaired the mountains, than
Afothphus refused his arms, and marched to Rome, to which
he laid siege. Stephen had again recourse to his protector,
imploiring him, in the most urgent and pathetic manner, to
come to the relief of the holy see in its imminent danger.
He also employed all artifice for rendering effectual his
entreaties, which was to write a letter to Pepin in the name
of St. Peter, calling upon him in his own person, and that
of the Blefséd Virgin, to halten and rescue his favourite
people. Pepin did not wait for the second invitation, but
immediately on hearing of the danger of the pontiff, marched
without delay, and laid siege to Pavia. Afothphus was now
obliged to raise the siege of Rome, and enter into a treaty,
by which he confirmed the former terms, with some farther
sacrifices. Pepin then caused an instrument to be drawn up,
signed by himself and his sons, by which he ceded for ever to
the holy see all the places thus yielded up by the Lombard
king, including the exarchate, which he had taken from the
emperor of Conflantinople. He afterwards caused the in-
frrument of donation, with the keys of all the cities, to be
laid on the tomb of St. Peter in ROME. Stephen had thus
the honour of being the founder, or fist polleffor, of the
temporal grandeur of the pontificate. He died in April
757, after having fat in the papal chair somewhat more
than five years. Seven letters, and a collection of canonical
constitutions, are extant under the name of this pope.

Stephen IV. (III.), born in Sicily, came to Rome in the
pontificate of Gregory III., and was in great esteem
with several preceding popes. He was titular priff of St.
Cecilia at the time of the death of Paul II. in the year
767. On that event, Toto, duke of Nepi, coming to
Rome with an armed band of friends and vassals, caufed
his own brother, Conflantine, then a layman, to be proclaimed
pope; and taking him to the Lateran palace, oblid the
bishop of Paleftrina to ordain him, and afterwards to confe-
crate him bishop. This ufurpation produced great discon-
tent at Rome, and various parties were formed, who elected
two popes, of whom one was instantly thrown into prifon,
and the other as quickly depofed; after which there was a
regular election, and the unanimous choice fell upon Ste-
phen, who was consecrated in August 768.

The firft act of the new pope was to fend a letter to
Pepin, and his sons Charles and Carломan, requesting
their protection, and also desiring that some learned bishops
might be fent from their dominions, to affift at a council
which he proposed to assemble at Rome, for the purpose of
reforming the ecclesiastical discipline, which had gone to
decay during the ufurpation. Pepin was dead before the
arrival of Sergius; nevertheless, he was received with great
repeft by Charles and Carломan, who complied with the re-
quell of sending bishops to the council. This was assem-
bled in the Lateran; and Conflantine, who had usurped
the popedom, and who had been deprived of his eyes, was
brought before it, and condemned to confinement for life in
a monastery; and all those who had received the eucharift at
his hands, among whom was Stephen himself, were obliged
to perform penance. The pope was now in peaceful pe-
feflion of his fee, but some differences arose between him and
Defiderius, king of the Lombards, who had not delivered
up all the places to which the church was entitled by the
treaty of Pavia, and had nominated a fucceffer to the vacant
archbishopric of Ravenna. Defiderius, having a party in
Rome, marched towards that city at the head of a body of
troops, and he obliged the pope to dismiss his minifters Chri-
topher and Sergius, whom he treated with great cruelty,
under the pretence that they were the partifans of Caralom.
He also urged Stephen to enter into an alliance with the
Lombards, till a solemn embassy from Charles and Car-
ломan, offering to maintain him in the possession of all
that their father had bestowed on the holy fee, relieved him
from his difficulties. A marriage being afterwards proposed be-
tween the daughter of Defiderius, and Charles, the pope
opposed it, in a letter which he wrote to the two French
princes, filled with declaration, not only against the Lom-
bards, but against the female sex. The match was, how-
ever, determined upon; and Bertrade, the mother of the
princes, visiting Rome, was received by the pope with great
honour, and was probably instrumental in procuring the de-
ivery, by Defiderius, of some places which he had still
withheld from the Roman fee. Stephen died in the beginning
of 772, after having governed the church nearly three years
and a half. Three of his letters are extant.

Stephen V. (IV.), pope, succeede Leo III. in 816. He
was of an illuftrious Roman family, and had been made
deacon by Leo, who, as well as the clergy in general,
etertained a high opinion of his learning and virtue.
Imme-
diately after the consecration, he obliged all the Roman
people to take an oath of allegiance to the emperor Lewis,
fan of Charlemagne, and he sent legates into France, to pro-
pose an interview with that sovereign. Rheims was the
place fixed upon for that purpose, and Stephen repaired
thither, accompanied by Bernard, king of Italy. The em-
peror went to meet him upon his approach, and honoured
him by protestations and other tokens of profound reverence.
Stephen repaid his attentions, by solemnly crowning him
and his queen with rich crowns, which he had brought from
Italy. After passing two months in France, he returned to
Rome, where he died about seven months after his election.

STEPHEN VI. (V.), pope, whose original name was Basili,
was of a noble Roman family, a prebendary of the church of
Rome, and highly venerated by all ranks, as well for the
purity of his morals as the sanctity of his life. He suc-
cceeded to the popedom in May, 885, upon the death of
Adrian III., and was forcibly carried for installation to the
Lateran, which ceremony was followed the next day by his
consecration. His election gave great offence to the em-
peror Charles the Gros, who immediately sent a delegate to
depose the pope, as having been appointed without his con-
sent, or even knowledge; he was, however, pacified by a
solemn embassoy bringing the decree of election, signed by
thirty bishops, and all the leading laity; and Stephen was
confirmed in his seat. The eastern emperor, Basili the Ma-
cedonian, having formerly written a letter to the pope's pre-
decessor Adrian, severely reflecting upon him and the former
pope, Marinus, for refusing to communicate with the pa-
triarch of Constantinople, Photius; Stephen now wrote a
reply to the letter, defending the conduct of his predeces-
sors, and strongly expressing his own disapproval of Photius.
This patriarch being afterwards deposed by the emperor Leo the Philosopher, who placed his own brother
Stephen in the see, the pope was applied to by the eastern
bishops and clergy, requesting that he would grant a di-
penation for the new patriarch, who had been ordained
deacon by Photius, and would forgive those who had com-
unicated with Photius. The pope expressed much sati-
faction in the expulsion of Photius, but refused the dispas-
ification till he could be more fully informed of the case, for
which purpose he defined that bishops might be sent to him
from both parties. On the death of Charles the Gros
without male heirs, in 888, there was a competition for the
succession to the crown of Italy, between Berenger, duke
of Friuli, and Wido, duke of Spoleto; the pope and the
emperor declared for the latter, who was eventually chosen by
Stephen at Rome, in 891. This pope died in
the same year, after a pontificate of somewhat more than
six years.

STEPHEN VII. (VI.), pope, a native of Rome, placed
on the pontifical throne on the expulsion of Boniface, in
896, disgraced himself by the treatment which he beheld on
the dead body of pope Formosus, who had preceded
Boniface. Having assembled a council for the purpose, he
caused it to be disinterred, and placed in its episcopal robes
in the papal chair. It was then asked, "Why didst thou
dare usurp the universal see of Rome?" No defence being
set up, Formosus was pronounced guilty of the charge of
intruding by unlawful means into the apostolic see; the
body was stripped of the pontifical ornaments, three of its
fingers were cut off, and it was thrown into the Tiber. At
the same time the council declared, that Formosus having
been incapable of conferring orders, all persons who had
received them at his hands must be re-ordained. Stephen
re-
verted the decree of Adrian III., which determined, that on
a vacancy, the pope elect should be consecrated without
waiting for the presence of the imperial envoys. He en-
joyed his dignity only a very short time; for in 897 he was
dethroned, hurried into a dungeon, and there strangled.
Two letters to the archbishop of Narbonne are attributed to
him, but probably without sufficient authority.

STEPHEN VIII. (VII.), pope, was also a native of
Rome, and elected successor to Leo VI. in the year 929;
he held the pontificate rather more than two years, and then
died, without having done any thing which has been deemed
worthy of record.

STEPHEN IX. (VIII.), pope, elected in 939, at the
vacancy made by the death of Leo VII., is said to have
been a German, and to have owed his election to the in-
fluence of the emperor Otto the Great. It is related of
this pontiff, that he sent the pallium to Hugh, archbishop
of Rheims, son of count Herbert, who had been expelled
from his see, and reformed and consecrated by a council of
bishops, although at that time he was only eighteen years
of age; that he warmly espoused the cause of Lewis d'Ou-
tremer against his rebellious subjects, sending a bishop into
France, with letters addressed to the nobles of that country
and Burgundy, in which he exhorted them to submit to their
lawful sovereign, and then threatened them with excommu-
nication in case of disobedience. He also attempted to me-
diate between Hugh, king of Italy, and Alberic; and for
that purpose sent for Odo, abbot of Cluny, to Rome;
but both the abbot and he died very soon after, in the
year 942. He held the see of Rome three years and four
months.

STEPHEN X. (IX.), pope, whose former name was
Frederic, was brother to the duke of Lorraine. In the
time of Leo IX. being archdeacon of the church of Liege,
he was one of the delegates sent by that pontiff to the em-
peror Constatine X., in order to conclude a union between
the churches of Rome and Constantinople. On his return he
was created chancellor of the Roman church, and was made
abbot of the monastery at Monte Cassino. By pope Vi-
tor II. he was raised to the dignity of cardinal, whom he
succeeded in the popedom. The election occurring on
the festival of St. Stephen, he assumed the name of that
faint. He immediately undertook the reform of the
clergy, and held councils, in which several canons were made
against marriage, and the concubinage of priests. He
effected the submision of the church of Milan to that of
Rome, after it had for some years withdrawn itself from
that jurisdiction; and he sent an embassy into the East, for
the object of uniting once more the two churches. His brother
Godfrey, who had married Beatriz, widow of Boniface,
duke of Tuscany, projecting to be chosen emperor, the
pope was very anxious to bring the design to effect, and for
that purpose he sent a perfon to secure all the t財re in the
monastery of Monte Cassino, which however he restored in
consequence of the tears and intreaties of the monks. His
regia was short: he took a journey into France, in order to
conferr with Godfrey, in which city he died, in the year
958, having fat in the pontifical chair only a few months.
Two letters of this pope are preserved, one to the archbishop
of Rheims, the other to the bishop of Marli.

STEPHEN, king of England, the son of Stephen, count
of Blois, by Adele, fourth daughter of William the Con-
queroor, was born about 1104. He and his younger brother
Henry were invited over to England by the late king
Henry I., and were loaded with riches, honours, and high
preferences. Henry entered into the ecclesiastical profe-
sion, and was created abbot of Glafonbury, and bishop of
Winchelter. But Stephen received higher marks of favour,
and more substantial endowments. He cau-
him to be married to Matilda, the daughter and heiress of
Eulace, count of Bolognus, gave him the earldom of Mor-
tagnie
Normandy, and the forfeited estates of Robert Mallet and others in England. Stephen, by his marriage, acquired a new connection with the royal family of England, as his wife's mother was sister to David, king of Scotland, and also to Matilda, the first wife of Henry, and mother of the subsequent Stephen, who, on his return, professed the most tender affection for his uncle; and displayed a marked eagerness in taking the oath for securing the succession of the empress Matilda, daughter of Henry I., and lawful heir to the crown. In the mean time, however, he continued to cultivate, by every art of popularity, the friendship of the English nation; and the display of some virtues which he seemed to possess, favoured the success of his intentions. By his bravery, activity, and address, he acquired the esteem of the barons. By his generosity, and by his affable and amiable manner, not at all usual in that age among men of his high quality, he obtained the affections of the Londoners, and he now entertained the most languid hopes, that by accumulating riches and power, and by acquiring popularity, he might in time make his way to the throne.

As soon as Henry was dead, in 1135, he hastened from France to England, and was received in London with the loudest acclamations. But in order to obtain a formal coronation, it was necessary for him to gain the concurrence of the clergy; and for this purpose, his brother, the bishop of Winchester, was of material service. Roger, bishop of Salisbury, chief judiciary and regent of the kingdom, was readily brought over to his party; but the archbishop of Canterbury refused, till Hugh Bigod, steward of the household, made oath that the late king, upon his death-bed, had declared an intention of disinheriting his daughter Matilda, and leaving the crown to Stephen, although several of the nobility had declared, and Stephen, in return, professed his most grateful declaration. Such was the reminiscence of the age, or the lax ideas of hereditary succession, that Stephen was solemnly crowned, and allowed to enter upon the exercise of the regal functions, though very few of the barons attended at his coronation. He made many concessions, promised to abolish certain exactions and arbitrary measures of the reigns since the Conquest, and engaged to restore the popular laws of Edward the Confessor. The first opponent of his government was David, king of Scotland, who, either to support the cause of his niece the empress, or to take advantage of the discontent incident to an usurpation, entered the north of England with an army, and took possession of Carlisle and Newcastle. Stephen outnumbered him, and made wide exactions as the price of peace. Robert, earl of Gloucester, natural son of Henry II., who was in Normandy when Stephen feized the crown, fearing lest he should be deprived of his English estates, came over, and took an oath of fealty to the usurper, but under the condition that he should be obliged to keep it no longer than all the engagements made to himself should be complied with. Most of the other nobles, in submitting, stipulated for the right of fortifying their castles, which at length filled England with strong holds for rapine and every kind of disorder.

The sucesses of Stephen were, at first, equally flattering in Normandy. He was invited over to allume the sovereignty of that duchy, and in 1137 he accepted the invitation, and formed an alliance with the king of France. The kingdom of Scotland made a second incursion into England, on the pretext of occupying Northumberland, upon which province his son Henry had a claim; and his demands being rejected, he cruelly laid the country waste with fire and sword. Stephen marched to oppose him, but was recalled by disturbances in the south. The northern barons, provoked at the successes of the Scottih arms, raised an army, with which they encountered David at Northallerton, and gave him an entire defeat in the battle of the Standard. Stephen, in the mean time, had involved himself in a dangerous contest with the ecclesiastical power. The bishop of Salisbury, his two nephews, the bishops of Lincoln and Ely, and his natural son, the chancellor of England, had combined in a conspiracy, which they held in defiance of the royal authority. Stephen having called, in 1139, a council of the nobility at Oxford, feized the bishops of Salisbury and Lincoln, and the chancellor, and in a short time made himself master of the other castles. These violent proceedings caused the assembling of a synod at Westminster, by the bishop of Winchester, Stephen's brother, and legate of the holy see, who felt more for the privileges of his order than the ties of blood. The synod sent a summons to Stephen, who delegated a nobleman to appear for him, and an open breach was prevented only by the firmness of some barons, who regarded the conduct of the bishops as seditions and undermining their character. Difcontents were, however, aggravaled, and Matilda, who had fled from England, was received into Arundel castle by Adelais, the queen-dowager. Stephen instantly marched thither, and invested the place, but Matilda escaped to Gloucester, where she remained under the protection of the earl. A number of barons declared for her cause; and in the following year, 1140, the flames of civil war spread throughout the kingdom; and from the cruelty, bloodshed, devastation, and famine which every where prevailed, this year proved one of the most calamitous in the English annals. Stephen performed his part with vigour and courage, but being taken prisoner in a battle which was fought under the walls of Lincoln in 1141, his party was broken, and Matilda, generally acknowledged as his heir. Before, however, she was well seated on her throne, her haughty and impolitic conduct excited an insurrection against her government. The legate, bishop of Winchester, joined the party of his brother Stephen, who was always popular with the Londoners. Matilda was invested in Winchester castle, whence, with the utmost difficulty, she made her escape; but her protector and friend, the earl of Gloucester, was taken prisoner in the flight. Stephen was exchanged for the earl, and the civil wars renewed. The events of the following years were disastrous to the country, which was plunged into a state of continual wretchedness. The emperors, after various changes of fortune, retired to Normandy, and Stephen, who was with them, was invested with the most extensive powers, and finally declared his will as the will of God. He married the earl of Gloucester's sister, and having thus gained a foot, was at length invested with the earl's estates, and obtained the earl's hand. He was received with the utmost honours, and the mark of respect paid to him was increased by a public declaration of the rights of the crown, laid all his party under an interdict.

The young prince Henry, son of Matilda and the count of Aipur, now advanced to majority, and displayed those qualities which afterwards rendered his reign in England glorious. By various fortunate circumstances, he became a powerful sovereign on the continent, and in 1153 he resolved upon an attempt to enforce his claims upon the English crown. He landed in England with a small army, which was soon augmented by the barons in his interest, and the contestants met at Wallingford. A decisive action was every day expected, for nearly a week, when the principal nobles, deñrous of putting an end to the miseries of a civil war, proposed an accommodation, and a treaty was set on foot, the difficulties of which were much alleviated by the death of Eustace, Stephen's eldest son. It was at length agreed that Stephen should pollese the crown during his life, that justice should be administered in his name, even in the provinces which had submitted to Henry, and that this latter
fter prince should, on the demise of Stephen, succeed to the kingdom, and William, Stephen's son, to Boulogne, and his patrimonial estate. After all the barons had sworn to the observance of this treaty, and done homage to Henry, as to the heir of the crown, that prince evacuated the kingdom; and the death of Stephen, which happened in the next year, after a short illness, prevented all these quarrels and jealousies which were likely to have ensued in to dedicate a situation.

"England," says Mr. Hume, "suffered great miseries during the reign of this prince; but his personal character, allowing for the temerity and injustice of his usurpation, appears not liable to any great exception; and he seems to have been well qualified, had he succeeded by a just title, to have promoted the happiness and prosperity of his subjects. He was possessed of industry, activity, and courage, to a great degree: though not endowed with a sound judgment, he was not deficient in abilities; he had the talent of gaining men's affections; and notwithstanding his precarious situation, he never indulged himself in the exercise of any cruelty and revenge. His advancement to the throne procured him neither tranquility nor happiness; and though the situation of England prevented the neighbouring states from taking any durable advantage of her confusion, her intestine disorders were to the last degree ruinous and destructive. The court of Rome was also permitted, during those civil wars, to make farther advances in her usurpations; and appeals to the pope, which had always been strictly prohibited by the English laws, became now common in every ecclesiastical controversy." Hume. Henry.

Stephen I., King of Hungary, called Saint Stephen, succeeded to the throne in 997, on the death of his father Géza. He was then very young, but had been declared king by the States in the preceding year, which title he is said to have been the first who bore in Hungary. He is celebrated for his piety, which he displayed by his great zeal in the conversion of his heathen subjects. The nobles, adhering strongly to their ancient religion, raised a rebellion against him, headed by the duke of Csep : their leader was slain, and themselves completely routed. The body of Csep was divided into four parts, and exposed in four of the principal cities of Hungary. After this great victory, he established tea bibliography, richly endowed, and built many churches; and was so devout, as to erect a church at Constantinople, another at Rome, and a monastery at Jerusalem. In the year 1002, Gúla, prince of Transylvania, Stephen's uncle, making an irruption into the adjacent provinces, Stephen marched against him, and in a few months made himself master of Transylvania, which he annexed to the crown. He afterwards repelled an invasion of the Bulgarians, pursued them to their own country, and obtaining a signal victory, returned laden with booty. Beside the glory derived from his successes in war, he had that of being the legislator of his country. He published a code composed of fifty-five chapters, in which, though marked with the barbarism and ignorance of the times, was very long popular among the Hungarians. Towards the end of his reign, it was his intention to reign his crown to his son, in order that he might pass the remainder of his days in a religious retreat, but the premature death of the prince disconcerted this design. He died at Buda in 1034, and was canonized by the church of Rome. His memory is held in profound reverence by the Hungarians, who have preferred the crown sent to him by the pope as the palladium of their kingdom.

Stephen, John, in the Latin tongue Stephanus, a learned Dane, was born at Copenhagen in 1599. He studied at the school of Herleufsholm, and after having twice travelled into foreign countries, was made professor of eloquence at Soroe, in 1630. In 1639 he became professor of history in the same seminary, and was afterwards appointed to be historiographer by Christian IV. He died in 1650. Among his works are enumerated the following: "Breves Emendationes et Notae in Saxonem Grammaticum," 1627. "Florestium Sententiarum ex Saxone," 1627. "De regno Danie et Norvegia, Infulis adjacentibus Tractatus variis," 1629. "Suenonis Agononis Filii Opuscula, Notis illustrata, accedunt Leges Calabrense Canuti magi, et incerti Autoris Genealogia Regum Danie," 1642. "Historia Daniae Libri duo, qui componitur res memoratuis dignas, in Dania gellas, Regnante Christiano III. ab Anno 1550, ad Annum 1559." STEPHENS, in Geography, a river of Vermont, which runs into the Connecticut.

Stephens, Cape, a point of the American continent, opposite to Stuart's island, situated in N. lat. 65° 33', and E. long. 197° 41'.

Stephens's Passage, a strait between Admiralty Island, and the continent of America; the fourth entrance is between Point Hugh and Point Windham, from whence it extends about 70 miles north, a little inclining to the west. N. lat. 57° 20'. E. long. 226° 35'.

Stephens's Island, an island in the North Pacific ocean, about 14 miles in circumference, situated to the north of Pitt's Archipelago. N. lat. 54° 11'. E. long. 229° 32'.

Stephens's Island, a small island in the N.W. part of Cook's Straits, in New Zealand. N. lat. 40° 30'. W. long. 185° 6'.

Stephens's Islands, two small islands in the Eastern Indian sea, discovered by captain Carteret in 1767. They had a green pleanant appearance, and were well covered with trees; but whether they were inhabited he did not know. They run about N.W. by W., and S.E. by E.; one is about three miles long, and the other about fix. The passage between them appeared to be about two miles broad. S. lat. 0° 22'. E. long. 138° 39'. Hawkeworth's Voyages, vol. ii. p. 387.

Stephens's Point, a low rocky point on the coast of New Holland, New South Wales, on the N. side of which is an inlet, called "Port Stephens," sheltered from all winds, lying in S. lat. 32° 40'. W. long. 207° 51'. At the entrance are three small islands, two of which are high; and on the main, near the shore, are some high round hills, which at a distance appear like islands.

Stephens's Medicine for the Stone. Mrs. Stephens having folded medicines for the stone in the bladder, or kidneys, Dr. Hartley published several cafes of their success; and so much was said of them, that the parliament appointed trustees to examine into the truth of what was alleged in their favour. The report of these trustees being favourable, she had 500£ contoured pledge her, in 1739, for publishing the receipt.

Her medicines are a powder, a decoction, and pills. The powder is fix parts of fine powder of hen-egg shells, calcined till they become of a greyish-white colour, and of an acid salt taste, then left two months in an open vessel, till what is sufficiently calcined falls into a fine powder, to be separated from the grocer parts by passing it through a hair-sieve. To this egg-shell lime add one-fifth part of the powder of nails, with their shells burnt in a crucible, till they have done smokings. A dracon of this powder is to be taken thrice a day, in a large tea-cupful of white wine, cider, or small punch, and half a pint of the decoction is to be drank after each dose. If the patient feels pain, it
is to be made milder by opiates; if he is colicive, gentle laxatives are to be taken, and purging is to be restrained: if the powder is too strong in the above proportion of six parts of the powder of egg-shells to one of snail-powder, it is to be weakened by increasing the proportion of the snail-powder.

To make the decoction, the prepared balls composed of four ounces and a half of the belt Alnicant foap, a large spoonful of the powder of swine's-creffies, burnt to blackness, and as much honey as was necessary. She boiled one of these balls fried with cut green chamomile, or chamomile-flowers, sweet fennel, parsley, and burdock-leaves, of each one ounce, in two quarts of water, half an hour, then strained it off, and sweetened it with honey. When these herbs are not to be had green, the takes the tame quantity of their roots, cut and fried. Those whose stomachs cannot bear this decoction, may take one-sixth part of the ball formed into pills, with every dose of the powder.

The pills are made by taking equal quantities, by measure, of snails calcined as before, of wild carrot-feeds, burdock-feeds, ashken-keys, hips and haws, all burnt to blackness, and reduced to a fine powder: with a large spoonful of this powder, four ounces of foap, and as much honey as is necessary, bring them to the constancy of pills of about sixty, which are to be formed out of every ounce of the composition. In fits of the gravel, five of these pills are taken every hour awake, till the complaints are removed.

During the ufe of these medicines, the patient ought to abstain from salt meats, red wines, and milk, drink few liquors, and use little exercise.

Dr. Hartley, leaving out the superfluous part of Mrs. Stephens's prescription, reduces her receipt to a more simple form; for an account of which, see LITHONTRIPPTICS.

Dr. Halles, after several trials on the different ingredients, found that the disolving power of them lay in the lime, which Dr. Rutty confirmed; and Dr. Jurin having taken foap-lees, the ingredients of which are pot-athes and lime, beginning with a few drops, and increasing the quantity till he took an ounce, or an ounce and a half every day, in a proper vehicle, was cured of bloody urine, pain, &c. and pallied several small stones; after which he had no uneasines.

For other forms of administering foap and lime, and remarks on Mrs. Stephens's medicine, see LITHONTRIPPTICS. See also LIME-WATER.

STEPHEN, in Geography, a large and populous parish in the hundred of Oldkton, and county of Middlesex, England, may be regarded as a suburb of London, as it is connected with the eastern side of that metropolis. This parish now comprises the hamlets of Mile-End, Ratcliffe, and Poplar and Blackwall; the whole of which contained in 1811, 6146 houses and 35,199 inhabitants.

The origin of the name of Stepany is very doubtful, but is supposed to have been derived from the Saxon steb-hyche, a timber-hall or from Stiben, a corruption of Stephen. It is bounded by the parishes of Bromley, Stratford-Bow, Hackney, Bethnal-Green, Spitalfields, St. George in the East, and Shadwell; all of which, about a century since, were parts of the parish of Stepany. In the year 1794 it contained, as Mr. Lysons remarks, "about 1530 acres of land, (exclusive of the site of buildings,) of which about 80 were then arable, about 50 occupied by market gardeners, and the remainder meadow, pasture, and marshy land." But since that year, the increase of buildings has produced a considerable diminution in the ground appropriated to agricultural and horticultural purposes.

In 1599, Edward I. held a parliament here, in the house of Henry Walleis, lord mayor of London, and gave his confirmation to the great charter. The manor of this place was formerly poached by the bishops of London; and Roger Niger is thought to have died at the manorial residence in 1241. It palled, however, from that fee to king Edward VI. by gift from the ill-fated Ridley; and after being granted to lord Wentworth, defended through him to Thomas, earl of Cleveland; by whose influence with the king it was endowed with a court of record, a weekly market at Ratcliffe-Crofts, and an annual fair on Michaelmas day. Stepney manor is now vested in the family of Colebrook. Exclusive of this the principal manor, the Dome-
day Survey states that the parish of Stepney contained several smaller ones; all these were held, with the exception of two, of the bishop of London, and were entitled Stepney. Huikarls, Pomfret, Lord Wake's, Helles, Popham, Coebam, Mile-End, Ewell, and Runbadls. In 1567, a water-course, which had formerly belonged to the convent of Friars-Minors, was granted to William, marquis of Winchester, with...
with liberty to conduct its streams to his mansion-house in London.

Almost opposite the present rectory-house, Henry, first marquis of Worcester, possessed a large manorion in 1665, of which the gateway only remains. It afterwards devolved to the family of Mead; and in this dwelling Dr. Richard Mead was born, and first commenced the practice of his profession. The church, dedicated to St. Dunstan and All-Saints, is large, and consists of a chancel, nave, and two aisles, separated by columns and pointed arches. At the west end is a square tower. Tombs of several illustrious characters are to be found in this place, especially those of Sir Henry Colet, lord mayor in 1486 and 1497, the father of Dr. John Colet, who founded St. Paul's school; and Sir John Berry, a distinguished officer in the reign of Charles II., by whom he was knighted; Jane Nevill, lady Dethick; and Sir Thomas Spert, comptroller of the navy to Henry VIII., and founder of the Trinity-house. The font stands on a circular pillar, surrounded by four others of a smaller size. On the south side of the church are sculptures of the crucifixion, and of a figure in the posture of adoreation before the Virgin and the infant Saviour. The wall of a porch towards the north-east contains a house, on which some veres, dated 1665, Rate to have been brought from Carthage. The church-yard contains, with many other celebrated names, those of Dr. Richard Mead, and his father. A short distance to the west of this edifice is an ancient wooden mansion, built, it is supposfed, in 1524, by Sir Henry Colet, and leased to Thomas, earl of Effex. It is now considerably altered, divided into several small tenements, and its name changed from the Great Place to Spring Garden coffee-house. Another of these relics of antiquity stands on Mile-End Green, and is now let in separate apartments. This latter, with some other contiguous habitations, are held under Clare-hall, Cambridge. The brick wall, which enclosed the site of the ancient rectory, still remains. John Colet, before mentioned, who was vicar of Stepney, lived at the north end of White-Horse-street, Ratcliffe. Some time after his resignation, it was received by Dr. Pace, who died here in 1532, and was buried in Stepney church. This parish likewise contains several dissenting and Methodistical meeting-houses: these are Sion-chapel, a chapel belonging to the society of Friends in Brook-street, Ratcliffe, one of Mr. Whitefield's at Mile-End, which formerly occupied by Mr. Brewer, and some others of recent erection.

Popular hamlet, including Blackwall, is on the south-east side of Stepney, and is about seven miles in circumference. The revision of this manor was granted by William of Wykeham, bishop of Winchester, to the abbey of St. Mary de-Graces, near the Tower of London. At the dissolution of religious houses, it remained for some time vellied in the crown, and afterwards was given to Charles I., when prince of Wales; and, since that period, has been possesséd by different persons. The manor-house was formerly occupied by the family of Dethick. The chapel is a brick building, with a wooden turret at the west end; commenced in 1650, and finished in 1654, by a subscription, to which the East India company mortally contributed; and by them, in 1776, it was nearly rebuilt. The right of presentation, after several disputes, remains vested in them, on the condition of their keeping it in future repair. Its interior is divided into a nave, chancel, and two aisles: the windows contain escutcheons of some of the contributors, among which are those of Dethick. Within it are monuments to the memory of Robert Ainworth, the lexicographer; and the Shakspearean commentator, George Steevens, to whom one is erected after a design by Flaxman. Attached to this building are several alm-houses, for the support of decayed officers belonging to the East India company; and in various parts of the hamlet are other institutions of a like nature. In 1769, an ancient town-hall belonging to Poplar was taken down, and the present built in the following year.

Sir Richard Steele made his residence here for some time, and, in a vain pursuit after alchemicall treasures, considerably decreased his fortune. Adjoining to Poplar is Stepney Marsh, a tract of land lying between the former place and Blackwall. It appears, from an inquisition in the time of Edward II., that a considerable portion of land had been recovered from the river by a former lord of the manor, and had been by him granted to his vassals and retainers. This marish is peculiarly celebrated for the richness of its purltere, and once contained an ancient building, called the chapel of St. Mary.

The hamlet of Ratclifl lies in the western division of the parish. It is about two miles and a half in circumference; and in 1794 contained nearly 1150 houses, of which 456, with 36 warehouses, in the month of July in the same year, were destroyed by an alarming conflagration. The charity-school of Ratcliffe was instituted in 1716, and the schoolhouse in White-Horse-street built by subscription in 1719, to which great additional benefactions have since been made.

There are situated in this hamlet the church, the Friends' meeting, the mercers' alm-houses, a cemetery belonging to the Protestant dissenters, with dwellings for seven poor persons, and a school instituted by them in 1783, and the school-house built in 1785. The fire already mentioned left in ruins some buildings belonging to a dock, several manufacturies, and a free-school, founded by Nicholas Gibbon, sheriff of London.

Mile-End, Old-town, occupies the greater part of the northern division of the parish; its extent is about five miles, and in 1794 it contained about 1300 houses. In the time of Henry VI. the mutinous people of Effex, under the direction of Jack Cade, encamped at Mile-End.

In this hamlet is Brewer's meeting-house, (now Ford's,) and a Methodistical chapel. On the north side of the road are two Judicai cemeteries, entitled "The house of the living," where the dead are interred in rows, divided into certain spaces; and no grave is ever opened a second time. There is also an hospital built in 1793, and an adjoining almshouse near the same spot.

Several other charitable erections, belonging to public bodies, are also situated on this road, viz., the Trinity almshouses, founded by that corporation in 1697; Bankcroft's hospital, founded in 1757; the skinners' almshouses, built in 1698; the vintners'; and three others, for the benefit of the whole parish collectively. A lazar-house existed here in the 16th century.

Lands in the manors of Stepney, Poplar, and Bromley, deeded by the custom of gavel-kind. Lyons' Environ of London, vol. iii. 470. 1794.

STEPPE, a name given in Russia to its plains and flats, which are very extensive, and interposed among its mountainous tracts. Some of the chief of these are the following; viz., the steppe of Pethora, bounded on the north by the Frozen ocean and the White sea, to the west by the Dwina, to the east by the Pethora, and to the south by the Floetz mountains, which extend from the Uralian chain westward across the government of Vologda. It therefore properly lies between and on both sides of these rivers. The ground is for the most part sandy, very marshy, thick grown with forets, and almost entirely uninhabited; the districts about Archangel, Meffen, &c. excepted. The trees, in the western
southern part, consist chiefly of the pinus sylvestris, firs, and birch; and on the elevation beautiful larches. On this level are several lakes and rivers.

The flesse of the Don river comprehends a large plain, which lies in the government of Ekaterinoslaw, between the Don and the Donetz, as far as the Terek and the sea of Azof and the Euxine. This extensive plain, comprehending the greater part of the governments of Ekaterinoslaw, Taurida, and a part of Voronech, Korkhof, and Kief, is, in general, a very dry and sandy quality, and contains many salt-lakes and salt-plots, but is little inhabited.

The flesse of the Don and Volga comprises the whole space between the Don, the Volga, and the Kuban; and is a large, very arid flesse, altogether destitute of wood and water; it has few inhabitants, and contains several salt-lakes and salt-plots. It spreads through the greater part of the government of Caucasus, and into those of Ekaterinoslaw and Saratof, where, in its sandy and calcareous flesse mountains, it contains coals, sulphur, pyrites, and warm baths. Within the confines of this flesse lies what is called the Kuman flesse, comprehending the whole space from this flesse to the spot where the Kuma flows out of the mountains, and reaches southward to the banks of the Terek and the Caufian sea, northward to the other side of the Sarpa, and eastward as far as the Volga. In this flesse lie the salt-lakes of Altrakhan, some bitter lakes, warm springs, &c. This flesse, it is said, has all the appearance of a dried-up sea: it is a sandy, part clayey and salt plain, without trees. Many circunmstances render it probable that it might really have been sea-bottom, as the flat shores of the Caufian and Azof seas, and the salt-lakes of their coasts, the low situation of the flesse, the saline lakes, and the sea-plants, &c.

The flesse of the Volga and Ural is extensive, and comprehends, between the rivers Volga and Ural, that whole flat country which formerly bore the name of the Kalmik flesse, and between the Ural and the Yenika, a part of the Kirghizs flesse lying within the Russian borders. The above-mentioned flesse is called the Kalmik flesse, because it was left in possession of a horde of that nation, by whom it was inhabited till the time of their flight in 1771. It consists of a far-stretching ridge of sand-mountains, called Narym, and is said to be between 50 and 150 ells in breadth, extending from the Ural mountains, through the middle of the flesse, quite to the Caufian sea. The soil consists of sand, marl, and clay, often mixed with sea-plants, which indicate this to have been, like the Kuman flesse already mentioned, the bottom of the sea. To return to the flesse of the Volga and Ural. This to the south makes the margin of the Caufian sea, and to the north it skirts the flesse of amphibious animals that run out from the Ural chain. This plain, for the most part sandy, is very deficient in fresh water and wood; but is so much the richer in rock-fall, and salt-lakes that are very productive. It contains many districts well adapted to the purposes of agriculture and the breeding of cattle; but is very poorly inhabited. One part of it lies in the Caucasian, and the other in the Ufimskian government.

The flesse of the Irtysh denotes that large plain which extends between the Tobol and the Irtysh, and between the latter and the Alby and Oby, as far as the confines of the Irtysh into the Oby, including an enormous territory. This plain, with lakes of several kinds of flesse, among numerous wood firs, firs, and birch, and is in most places well suited to pasturage and agriculture; but, in proportion to its extent, very thinly peopled. Between the Irtysh and the Oby, this plain includes all that fine well-watered level called the Barabian flesse, on which is found many considerable lakes; extending in length from north to south above 600 ells, and in breadth 400 from west to east. Its plain has generally a good black soil, enlivened on its surface by many pleasant flesse of birch; hence it has been concluded, that the Baraba must have been one general bed of waters, and far more moray and abounding with lakes than it is at present. Another part of the large plain consisting the flesse of the Irtysh, between the Ichieh and the Irtysh, is called the Ichieh flesse, and is found to abound in bitter lakes, but in other respects resembling the Barabian flesse, in both which many ancient tombs occur. The greatest part of the whole flesse of the Irtysh lies in the government of Tobols, but the other part in that of Koliyvan.

The flesse of the Oby and Yenilfie includes the whole of that large tract beyond the Tihulim, (which falls into the Oby,) between the Oby and the Yenilfie, and extends to the shores of the Frozen ocean. The belt forests are found towards the south; on the northernmost margin of the Frozen ocean the wood is low and stunted. The whole of this flesse lies in the government of Tobols.

The flesse of the Yenilfie and Lena is a large tract of defert, bounded by the Yenilfie, the Tungulka, and the Lena; reaching northward, like the former, to the Frozen ocean, and resembling in its nature and quality. One part lies in the government of Tobols, and the rest in that of Irkutsk.

The flesse of the Lena and Indighirka is a vall extended plain along the shores of the Frozen ocean, between the Lena and the Kovyma, to the two sides of the Indighirka, and is wholly in the government of Irkutsk. Tooke's Ruff. Emp. vol. i.

STERA, in Anatomy, a word used by some of the barbarous writers to express the uterus. It seems to have been only a corruption of the word hydros.

STERANG, in Geography, a town of Norway, in the province of Aggrebun; 16 miles N.N.W. of Christiansia.

Gen. Ch. Cal. Peranth inferior, of three or five, roundish, concave, acute leaves. Cor. Petals three or five, roundish, notched, unicellular, longer than the calyx. Stam. Filaments numerous, capillary, inserted into the receptacle; anthers roundish. Fil. German superior, ovate; style long, incurved at the tip; stigma capitate, concave. Peric. Legume cylindrical, long, corticose, fleshy, one-celled, not barbating. Seeds numerous, large, angulated, incumbent on each other, imbedded in the pulp.

Eif. Ch. Calyx of three or five leaves. Petals three or five. Legume corticose, not barbating. Seeds numerous, imbricated, imbedded in pulp.

I. S. Interifera. Wild. n. 1. (Singana guianensis; Aubl. Guian. t. 257.) A mass of woods in Guiana, where it flowers, and bears fruit in September.—This shrub is remarkable for throwing out numerous, knotted, creeping roots or stems, which run in a scattered manner over other trees, and are much branched. Leaves nearly opposite, falked, ovate, acute, smooth, entire. Flowers corymbose, scattered,
scattered, axillary, white, on short stalks. Legume a few-coloured.

STERCORARIANS, or STERCORANISTE, formed from stercus, dung, a name which thofe of the Roman church anciently gave to such as held that the hoft was liable to digestion, and all its consequences, like the food. STERCORARIUS Fiscer, the dung-fish, in Ichtyology, the name of an Ealt Indian fish; so called from its frequenting necessary-houses which are over the water, and other places where the like natfines is to be found. It is, for this reafon, supposed unwelcome by some, but is really a very well-tafted fish, and eaten by most people where it is to be had. It is a broad and thin fish, of about fix or seven inches long, and nearly as much in bread. Its back is variegated with spots of deep brown; its belly is bluefin.

STERCORARY, in Agriculture, a place properly fecured from the weather for containing dung. In collecting manures from time to time, as they come to hand, farmers generally keep them together in what they call dung-hills, where they remain exposed to the heat of the fun, the washing of rain, and the drying winds; by which means a great deal of their virtue is diffipated and loft. The making of fer- coraries has, therefore, been advised, which may be done by digging a square or oblong pit, of the fize fufficient to the quantity of the compofit wanted, or proportioned to the extent of the ground intended to be manured; the fide next the field or place where taken away being made floping, fo as to receive a cart to load or unload eafily. The bottom fhould be well paved, and both the fides lined with pure clay, (unless it be made in a bed of clay or chalk,) that it may be capable of retaining water like a cafern; and as it is of great importance for the dung to have a proper degree of moisture. And where channels or gutters can be directed to the pit, from the flables and other offices about the house, they will be of great service. Some think that they should be covered, fo as at leat to hinder rains from falling upon them: but if care be taken to make the pit in a place where no running water or fprings can come to it, and if the farmer covers the dung, as it is collected, with a coat of mould, to prevent the fun's exhaling, or the rains washing away its richness, the quantity of water which falls in rain may not be more than requisite to moiften the mixture, and bring on that putrid fermentation which is neceffary for the due incorporating and perfecting of the compofit. It will, however, be right to have a shed to put it over occasionally, in cafe the feafon fhould prove extremely wet. It has been observed by Columella, that the Romans covered their ferocaries with hurdles; but he does not fpeak of covering them with mould, in the manner mentioned above. See Compoft, Fart-Tard, and Manure.

Gen. Ch. Calr. Perianth inferior, of one large, coloured, rather coriaceus leaf, deciduous; somewhat turbinate at the bafe; its lima in five deep, segment-like, in the dried state, none. Organs of impregnation elevated on a cylindrical curved column, various in length, but always much shorter than the calyx. Stem. Filaments scarcely any; anthers from ten to fifteen, cluftered, inserted into the notched margin of the top of the column, roundish, of two definite lobes. Pfl. German foliage above the anthers, roundish, of five lobes; fyle vertical, deflexed, cylindrical, not half the length of the column; fligma cleft, notched. Peric. Follicles five, spreading, ovate, oblong, large, coriaceus, or woody, furdling along the upper fide. Seeds feveral, oval, attached to each margin of the follicle.

Eif. Ch. Calyx in five deep segments. Corolla none. German and anthers elevated on a column. Follicles five, with many seeds.

Obf. Many of the flowers, on the fame or a different plant, have no pitif. In thofe with a pitif, the anthers are sometimes, but not always, imperfect. Several of the follicles in each flower, as well as many seeds in each follicle, are liable to prove abortive, at leaft in gardens. The margin of the column is scarcely defcribible in fome fpecies, nor is it, in any, confpicious enough to be taken for the filament of the flamen. We would therefore rather concur with Schreber and Wilfdenow in the defcription of this genus. The fyle is fometimes divided down to the bafe into five parts.

1. S. lanceolata. Lanceolate Chinefe Sterculia. Cavan. Diff. n. 416. f. 142. Willd. n. 1. Lamarrac n. 2. — No leaves lanceolate. Follicles oblong. — Native of China. A very certain fpecies, adopted by Cavannilles from a Chinefe drawing, in which the leaves were reprefented about one inch and a half long, and half an inch broad; the follicles about the fame length, narrow, crimfon, with three or four black feed in each. If fuch be the natural fize of the parts, the plant is different from any other known Sterculia. A fimilar reprefentation, however, of various dimensions, is common on Chinefe papers, and we fuppref it may, in every instance, be meant for a fpecies hereafter defcribed by the name of nobilis.

2. S. Balangas. Balangas Sterculia. Linn. Sp. Pl. 1340. Willd. n. 2. (S. folius ovalibus integerimis alterni petiolatis, florebus paniculatis; Linn. Zeyl. 166. Cydonia arbor, Balangas dicta; Burn. Zeyl. 84. Nux juglanis zeylanica minor bifida, flore puncceo; Rh. 170. Nawaghzas; Hern. Zeyl. 27, Colaba Syen in Rhedos. Hort. Malab. v. 1. 93, note ?) — Leaves exactly elliptical, with a fmall point; very flightly downy beneath. Panicles much fhorter than the leaves. Calyx hairy on both fides; denfely fringed at the margin. — Native of Ceylon. The flem is arborea, with round, fMOOTH, pale branches, leafy at the end. Leaves alternate, flalked, fiv or fix inches long, and two or half three broad, very excially oval, rather coriaceus, entire, in the whole genus, tipped with a fmall blunt point, scarcely half an inch in length; fur- nihed with one longitudinal, and many tranfverfe, ribs, all pale and fMOOTH, connected by innumerable minute reticulations; their upper surface bright green, shining, and smooth; under very little paler, foftcil to the touch, from scarcely discernible itary down. Footstalks fMOOTH, an inch or more in length, with a fhort of joint at the fummit. Panicles axillary, about the ends of the branches, manyflowered, twice as long as the footstalks; their branches alternate, thread-shaped, green, hairy. Flowers foltary at the end of each partial flalk, fmal, foid to be very fett. Bafe of the calyx cup-shaped, smooth within; fegmentS of its limb converging, and connected by their points, hairy on both fides, and particularly lipfided at the edges, relenitly divided, purple, yellow, or velvet or plufh. A fpecimen of this, communicated by Thunberg to Lin- neus, and marked Sterculia Balanghas, seems to be the
the real plant described with "ovate leaves" in the Flora Zeylaniae, from Hermann's herbarium. But in writing the Species Plantarum, Linnaeus uses the term "ovate," from a view probably of the figures, which he considered as belonging to this species, not having then a specimem before him. What those figures represent, we shall endeavour to ascertain hereafter. We have been the more precise in describing what we take for the genuine Balanghas, because no recent author seems acquainted with this plant; though its name, in every body's mouth, is misapplied to several very distinct from it and from each other.

3. S. rubiginosa. Rusty Sterculia. Venten. Malmaif. sub fol. 91. Lamarck n. 4. (S. Balanghas; Wild. n. 2?) Cavan. Dill. n. 415. t. 144. bad. Cavalam; Rheed Hort. Malab. v. 1. 89. t. 49. Nux malabarica fulca mutulaginofa fabacea; Pluk. Almag. 256. —Leaves elliptic-oblong, taper-pointed, plant; downy and rusty beneath. Panicles much longer than the leaves. Calyx hairy on both sides, fringed at the margin.—Native of Malabar, Chittagong, Java, and Ceylon. A tall tree, with copious spreading branches. Rheed. The young branches, clothed with rusty down, are leafy and copiously flowery at their extremities. Leaves from three to six inches long, (on downy rusty flalks about an inch in length,) plant, not rigid or coriaceous; rounded at the base, though gradually contracted towards that part; dilated upwards to the breadth of one and a half or two inches; then tapering into a point; entire, though somewhat wavy, at the margin; furnished with one longitudinal rib and many transverse ones, connected by reticulations; the upper side green, shining, nearly or quite smooth; under, paler, opaque, soft with rusty furry down, which is very copious on the ribs and veins. Panicles numerous, axillary, nearly twice as long as the leaves, alternately and repeatedly branched, spreading, with flender, downy rusty flalks, and scattered, lanceolate, downy, deciduous bracteas. Tube of the calyx short, shallow, nearly hemispherical, very hairy externally, roughish within; limb three to five long, converging as in the leaf, most hairy at the edges, well compared by Rheed to red velvet, which holds good even of the dried flowers, though the colour is brown, or more faded, than in our S. Balanghas. Follicles resembling those of a Penny, two inches half long, containing brown seeds, hairy, downy at the outside; smooth, reddish, and wrinkled, internally. Such is the plant sent by Mr. Buchanan from Chittagong, exactly agreeing with Commeron's Java specimem, in fruit, and not less accurately with the plant of Rheed; whose figure, we must observe, is copied, or rather perverted, by Cavanilles. What was raised from Sierra Leone feeds, in lady Amelia Hume's Jive, appears by the leaves to be our rubiginosa, though their pubicence is less copious and less rusty than in dried specimem. Their texture is plant, not coriaceous. This may however be a distinct species. The seeds of the present, as well as the foregoing, are much eaten, like our chefunas, in India. They seem, by Plukenet's synonym, to be the real Malabar Nut; a name which, by some accident, has been vulgarly applied to Abylicia Adhatoda. Perhaps a similarity between the leaves of the two plants, raised from feed, may have led gardeners into this error.

5. S. urceolata. Pitcher-flowered Sterculia, or Wild Chocolate. (Complanus minor; Rumph. Amboin. v. 3. 169. t. 107.) —Leaves elliptic-oblong, acute, plant; pale and finely down beneath. Panicles close, hardly longer than the foot-flalks. Calyx pitched-shaped, hairy all-over. — Sent in 1797, by Mr. Christopher Smith, from the island of Honima, near Amboyna, where it is called Wild Chocolate; but whether from the resemblance of its seeds to those of real chocolate in shape, or from being roasted and used as such, we know not. We conceive Rumphius's synonym, hitherto misapplied to the Balanghas, must belong to this species. Our specimena are distinguished by the longer proportion of their foot-flalks, which sometimes measure more than two inches. The leaves, though shaped like the leaf, are pale at the back, being very minutely down with whitish, not rusty, furry hairs. The flowers are much fewer in each panicle, and more crowded, the hairs of the flalks, calyx, and especially the margin of the latter, being hoary or white, not red or rusty. Bracteas ovato-lanceolate, with long points. Tube of the calyx pitched-shaped, contracted at the mouth, and nearly as long as the limb. We have seen no fruit. Rumphius describes his plant with whitish flowers, whose fect is opprobrious, but not lathing; the fruit of a fine crimson.

4. S. nobilis. Great Chinese Sterculia. (S. Balanghas; Art. n. 1. S. monosperma; Venten. Malmaif. t. 91.) Lamarck n. 3. Southwellia nobilis; Salif. Parad. t. 69, excluding all the synonyms, except Ventenata. —Leaves elliptical, obtuse, with a small point, coriaceous, very smooth and shining on both sides. Panicles spreading, longer than the leaves. Calyx somewhat hairy.—Supposed to be a native of China, from whence it was imported in 1787, by lady Amelia Hume, and flowered in her Jove for the first time in England, in the spring of 1789. By her ladyship's liberality it was quickly dispersed among the collections of this country, and found its way into France, being easily raised from feeds, which are ripened in the Jove or conservatory. The Jem is arborescent, of quick growth, round, with many smooth branches. Leaves from four or five inches to a foot, or more, in length, three or four inches in breadth, when fully grown very smooth, and copiously reticulated, of a rigid or coriaceous texture. Foottalks smooth, flout, above an inch long. Panicles drooping, very large, and copious, repeatedly subdivided; their Jalks pale, flender, downy and rather vilcet, very tender. Flowers drooping, of the fame pale buff hue as their Jalks. Tube of the calyx bell-shaped, nearly smooth; its limb downy, and sparingly hairy, with converging combined points. Anthers yellow. Gynaeceum of two Jalks two inches long, though shorter, and two united; fill Jes inwards. Seeds bluish black. When ripe, the calyx and Jollid, it having been merely from partial abortion that Ventenata's plant bore foliary feed. This fruit is sometimes seen delineated on Chinese papers, along with others in common use. Nothing can afford a more striking appearance than this tree in a hot-houfe, whether in April, when covered with flowers, or in the latter part of summer, when laden with its large black feeds, standing on the edges of the red and brown feed-veffels. It is cultivated in the botanical garden at Calcutta, by the name of S. Balanghas.

STERCULIA.

lumn very short. Styles five, reflexed."—Native of the Mauritius. Commen. A. Cr. 21. 6. The leaves are fleshy, leathery, at the summit. Leaves six or eight inches, or more, in length, four at least in breadth, coriaceous, with a long point, smooth and shining, finely veined. Footstalk thick, two inches long. Panicle large and spreading, somewhat cymose, with thick, compressed, very smooth branches. Calyx large, with five, widely spreading, smooth, lanceolate, coloured segments. German near the cell, surmounted with five reflexed styles or stigmas, which cause a doubt concerning the genus of this species. —Poir.

Lamarck n. 15. (Cola; Bauh. Pfl. 507, Bauh. Hist. v. t. 210.)—Leaves elliptic-oblong, pointed, coriaceous, smooth on both sides. Panicles lateral, forked, hardly longer than the footstalks. Segments of the calyx ovate, spreading. Column very short. Native of the coast of Africa, from whence we have a specimen in flower, gathered by Dr. Asfels. The branches of this tree are round and smooth, leafy at the ends. Leaves imperfectly opposite, three or four inches long, one and a half or two inches broad, strongly veined, firm; rufly, though quite smooth, beneath. Footstalks an inch or inch and half long, smooth. Panicles lateral, below the leaves, solitary, forked, dense, of about ten to twelve large flowers, their stalks, as well as the outside of the calyx, rough with dense hairy hairs, or rather a fort of deciduous m. quilts. Calyx spreading, an inch broad, in five, sometimes six, broad, ovate, obtuse segments; smooth and colored within. Column scarcely any. German rough, five-lobed. Stigmas five, reflexed. We do not find the calyx has more than five divisions; Poiret describes six. The follicles are said to be five, with solitary reddish seeds. The five stigmas, or styles, agree with the last. Probably this character, and the nearly feline germen, to say nothing of the spreading calyx, may indicate a generic difference. The seeds of this species, known by the name of Cola, have long been celebrated by voyagers, as possessing a high degree of value among the natives of the Guiana coast, who are reported to take a portion of them to enhance the flavour of any thing they may subsequently eat or drink. Dr. Asfels found these seeds in high estimation at Sierra Leone, and was not a little pleased to procure specimens of the plant, though he had no idea of its genus. If we mistake not, he brought it alive to this country, but it has not lately been heard of.

8. S. nitida. Shining Sterculia. Venten. Milm. fl. fol. 91. Lamarck n. 17. —"Leaves lanceolate-oblong, pointed. Segments of the calyx spreading. Column scarcely any."—Native of Africa; cultivated in the island of Mauritius. Venten inspected the flowers to be dubious. This may possibly not be distinct from the last species, but we have not sufficient information to form an opinion on the subject.

9. S. crinita. Hairy-fruited Sterculia. Cavan. Diff. n. 413. t. 142. Willd. n. 3. Lamarck n. 5. Ait. n. 2. (S. IViri; Swartz Ind. Occ. 1160. IVira pruriens; Aubl. Guan. 655. t. 279.)—Leaves ovate, acute, entire. Panicles as long as the leaves. Segments of the calyx lanceolate, pointed, spreading. Follicles hairy at the base; whitish within. —Native of the woods of Guiana, flowering in October and bearing fruit in May. Trees of this country, or the larger trees of that country, its trunk being fifty or sixty feet high, and four or five in diameter. The bark is red, thick. Wood white, not compact. Leaves from six to twelve inches long, firm, flaked; green and smooth above; opaque, somewhat glaucous and roughish at the back. Panicles about the ends of the branches repeatedly compound, downy, spreading. Calyx yellow and downy on the outside, red and smooth within. Column nearly as long as the calyx. Anthers ten. Follicles three, four, or five, large, almost woody, clothed at the base with a tuft of long reddish hairs; their cavities filled with fine, rigid, pungent, red bristles, enveloping the black seeds, and causing an intolerable itching, when incautiously handled.

10. S. frondosa. Wavy-leaved Sterculia. Richard Aft. Soc. Hist. Nat. Paris. v. 111. Lamarck n. 6. —"Leaves crowded, oblong-obovate, very blunt, somewhat wavy, smooth and shining, Panicles axillary, on long stalks."—Native of Cayenne. Richard: We inspect this plant may have been confounded with the last, even by Dr. Swartz. A specimen gathered by M. De Ponthieu, in the West Indies, and given us by f'r J. Banks, having very large and wavy leaves, answers in far to Richard's description. Some of its leaves seem moreover to be slightly three-lobed; and as Dr. Swartz cites De Ponthieu, it should seem that corresponding specimens to ours has been his only authority. Thus Willdenow has been led to alter the specific character of S. crinita for the worse.

11. S. cordifolia. Heart-leaved Sterculia. Cavan. Diff. n. 414. t. 143. 1. 2. Willd. n. 4. Lamarck n. 7. —"Leaves roundish heart-shaped, obliquely three-lobed, five-ribbed, smooth. Follicles downy at the outside, bristly within."—Brought from Senna by Adanson, and preserved in Jussieu's herbarium. The above characters sufficiently mark this species. Its leaves are two or three inches long, and almost equally broad. Footstalks not an inch in length. Flowers not observed.

Lamarck n. 16. —"Leaves undivided or three-lobed, irregularly toothed, on long stalks. Panicles terminal."—Native of the inland parts of the kingdom of Oware, Africa. A taller tree than S. acuminata, with large, broad, handsome leaves, either entire, fringed, or finely toothed. Calyx five-cleft. Column scarcely any. —Poir.

13. S. macrophylla. Large-leaved Sterculia. Venten. Milm. fl. fol. 91. Lamarck n. 10. —"Leaves roundish heart-shaped, somewhat wavy, rather coriaceous; downy beneath. Follicles very smooth within, with two seeds."—Native of Java. Là Hayes. The leaves are about eight inches broad, rounded, or slightly oval; heart-shaped at the base; thickest and rather coriaceous; smooth and dark-green above; downy, and reddish or whitish beneath, with strong branching lateral ribs; their margin entire, slightly wavy. Footstalks thick. Panicles terminal, moderately branching. Follicles strong, reddish, wrinkled, obtuse. Flowers not observed. —Poir.

14. S. colorata. Coral-flowered Sterculia. Roxb. Coromand. v. 1 t. 26. t. 25. Willd. n. 5. Lamarck n. 12. —Leaves palmate, five-lobed, pointed; somewhat downy beneath. Calyx downy, club-shaped, with shallow upward lobes. Follicles italked, membranous, oblong, reticulated, expanded, smooth.—Native of mountains in the East Indies, calling its leaves during the cold season, and flowering in April, soon after which fresh leaves appear. The Gentoo, or Telinga, name is Karaka. This is a very large tree, with smooth greyish branches, leafy at the end. Leaves long stalks, more or less; leaves five-lobed, heart-shaped at the base, five-ribbed, minutely reticulated; smooth above; very finely downy, especially at the bases of the ribs, beneath. Panicles appearing before the leaves, about the ends of the branches, from four to six inches long, compound,
STERCULIA—Stinging Sterculia. Stinging Sterculia. Roxb. Coromandel. v. 1. 25. t. 24. Wild. n. 6. Lamarck n. 11. Ait. n. 3. — Leaves five-lobed, pointed, very downy; deeply heart-shaped at the base. Calyx bell-shaped. Column conical. Follicles fleshy, coriaceous, rough with pungent bristles. — Native of mountainous parts of the coast of Coromandel, flowering during the cold feason, and putting forth leaves, as the fruit advances, in the beginning of the hot weather. This is a very large tree, whose soft spongy wood fearcely serves but to make Hindoo gutters. The branches are leafy at the ends. Leaves measuring from nine to twelve inches each way, much left deeply lobed than the leaf, on long stalks. Panicles repeatedly compound, shorter than the leaves, with a linear brown bracteæ under each subdivision. Such bractæas however are not, as Willdenow supposes, peculiar to this species, though they are usually so deciduous, in many instances, as to escape notice. The flowers are small, greenish-yellow. Column short and thick. Anthers ten, supported by a more dilated membrane than in many others of the genus. Style simple, short and thick, with a five-lobed stigma. Follicles five, greenish-brown, an inch and a half long, oval, coriaceous, concave, clothed with copious flingling bristles, so as not to be touched with impunity. Seeds four or five, oval, the size of a pea, roasted and eaten by the Hindoos.

16. S. villosa. Villous Sterculia. Roxb. M.S.S. — Leaves five-lobed, pointed, toothed, very downy, feeven-ribbed; heart-shaped at the base. Calyx deeply five-crested, spreading. Column cylindrical. Follicles coriaceous, rough with flary hairs. — Native of the coast of Coromandel. Our specimen was given by Dr. Roxburgh to lord vifcount Valentia, with the above name. The leaves are the size of the leaf, but with coarsely toothed lobes; the under side hoary, soft and downy. Flowers much taller than those of S. uren, with a longer and more slender column, as well as style; the latter, like the uren, very hairy. Calyx widely spreading, downy, with deep ovate segments. Follicles covered with rigid flarly pubescence, but no flingling hairs.

17. S. plataniifolia. Plane-leafed Sterculia. Linn. Suppl. 423. Wild. n. 7. Lamarck n. 9. Ait. n. 4. Cavan. Diff. n. 417. t. 145. Vahl. Symb. v. 1. 80. (Sterculia; Jacq. fil. in Ait. Nov. Helvet. v. 1. 40. t. 34. S. tomentosa; Thumb. Jc. Pl. Jap. dec. 4. " Firmiana; Maril. in Ait. Acad. Patav. v. 1. 106. t. 1, 2." Culhamia; Forl. Ægypt.-Arab. 96. Hibiscus simplicifolius; Linn. Sp. Pl. 977.) — Leaves palmate, smooth, five-lobed; heart-shaped at the base. Segments of the calyx linear, very deep. Follicles flaking, membranous, ovate, reticulated, concave, roughish. — Native of China and Japan, whence it has been differeered over many parts of the East Indies, and introduced into the gardens of Europe. At Padua it feeds in the open air. In England it is a hardly greenhouse plant, flowering in July. The tree in its native soil is said to attain a vast size. The leaves are broader than long, measuring from ten to eighteen inches across, and in length two feet, with acute entire lobes, and rounded finules; smooth above; rather paler, and sometimes sparingly downy, beneath; their ribs and veins strong, with axillary, tubular, hairy pores. Panicles terminal, a foot long, much branched, spreading, downy. Calyx pale yellow, hairy externally; its segments reflexed and twisted, above half an inch long. Column smooth, slender, a quarter of an inch in length. Germin pyramidal, hairy, as well as the simple cylindrical style. Follicles more like those of S. colorata, n. 14, but green, much broader, and more concave. Seeds two or three, globose. Jacquin says the flowers are fragrant, molt of them perfect, a few males only being intercifted.

18. S. fistula. Petal Sterculia. Linn. Sp. Pl. 141. Wild. n. 8. Lamarck n. 8. Ait. n. 5. Cavan. Diff. n. 412. t. 141. Sonnerat Ind. Occ. v. 2. 234. t. 132. (Clompanus major; Rumph. Amboin. v. 3. 168. t. 107.)— Leaves digitate. Segments of the calyx oblong, very deep, hairy. Follicles woody. — Native of the East Indies. Sonnerat says it is planted before houles, on the coast of Malabar, for the sake of its thick shade. The roasted seeds taste like chestnuts, and are eaten by the Indians. The tree is straight and tall. Leghias from feven to nine, lanceolate, a finger's length, entire, smooth, on a long common footstalk. Clusters terminal, compound, drooping with smoothe italaks. Flowers smelling like human excrement, larger than the leaf, widened expanded; molt hairy, and of a brownish-red, on the upper side; brighter red underneath. Column cylindrical, near half an inch long, much dilated, or cup-shaped, at the top, where the anthers are inserted. Germin roundish, five-lobed, very hairy, as well as the simple⌠fly. Follicles oval, obtuse, woody, nearly as big as the fil. Seeds numerous along each margin. Cardi, Rheede Malab. v. 4. t. 36, cited by Linnaeus, seems rather of the order of Fitts. A superficial confusion of this very curious and remarkable genus might lead us to think nothing more easy than to divide it into several; but however strikingly different certain parts of the fructification may be in some species, such differences do not support each other. Thus the follicles of S. colorata and plataniifolia are so unlike all the rest, and agree together so remarkably in their partial flanks, and membranous veiny texture, that they at once indicate a distinct genus. But when we consider their ca-lyxes and stylæ, all particular relationship seems dissolved; for they accord better, in those parts, with many other Sterculia than with each other. Whether the simple or mani-fold stylæ, when properly understood, may lead to generic distinctions, we have not, as yet, materials to decide. The length of the column, very different in different species, does not appear of any generic importance.

The filipulas of this genus have hardly been noticed, being very fugacious, but we believe they are always originally present, in pairs, at the base of the footstalks, and uniall of a lanceolate or awl-shaped figure. The bractæas frequent under the branches of the panicles, are larger, but nearly as quickly deciduous as the filipulas, at leaf in most of the species.

STERCULIUS, in Mythology, one of the firmans given to Saturn, because he was the first that laid dung upon lands to make them fertile.

STERCUTIUS, the god of ordure.

STERE, in Commerce, the unit for solid measures in the new French systém. See Measure and Standard.
STEREOBATA, or Stereobates, formed from εἰκοσιοσκελός, solid prop, in the Ancient Architecture, the bafis, or foundation, wherein a column, wall, or other piece of building is raised.

This answers pretty well to the continued fole or base-meat of the moderns. See Socle.

Some confound it with the ancient στρεφεῖον, or pedestal, (which see); but, in effect, the Stereobata is that to the stylobate, which the stylobate is to the spire or base of the column.

As it stands at present, in the newly-published Synopis of Acharius, where nine species are enumerated, this has every character of a natural genus. Its firm, branching froid, attached by a slender but very tenacious root, is formed to occupy the interstices of crumbling granite, and especially the cells of volcanic sferic. Hence it is the first of its tribe that clothes the loyly decaying lava of Veluvus and other burning mountains.

Of the nine species of Stereocalon above-mentioned, we feel least confident. The original one may serve to exemplify the genus.

Such is our only certain British species. What occurs on the lava of Veluvus, and which we did not, in gathering it, disfigure to be at all different, is called by Perfoon S. vesuvianum, and made a variety by Acharius of his own S. brotysum, n. 3, a Swijs species, unknown to us, whose characters indeed do not found very distinct.

STEREORAPHIC Projection of the Sphere, is that in which the eye is supposed to be placed in the surface of the sphere. For the fundamental principles and chief properties of this kind of projection, see Projection, Stereographic.

The method and practice of this projection in all the principal cases, viz. on the planes of the meridian, equinocial, and horizon, are as follow.

STEREORAPHIC Projection on the Plane of the Meridian. Let Z Q N E (Plate XIV. Geometry, fig. 10.) be the meridian, Z and N the poles, as also the zenith and nadir; E Q the equinocial and horizon; Z N the equinocial colure, and prime vertical circle: Z 15 N, Z 30 N, Z 4$5$, N, N 15 $9^2$, N 30 $9^2$, N 45 $9^2$, &c. are hour-circles, or meridians, and also azimuths, because the pole is in the zenith. To describe these circles, find the points 15, 30, 45, 60, &c. in the equinocial, by setting the half-tangent of their distance from $\gamma$; and then their centres are found by setting their co-feccants both ways, from their points of intersection with the equator: $\varphi$, $\varphi$, and $\psi$, $\psi$, are the northern and southern tropics, which are described by setting the half-tangent of 23° 30' from $\gamma$; then the tangent of its complement, viz. 66° 30', each way from thence on the colure produced, gives their centres. By this method all parallels of declination may be drawn. Or you might have set the co-feccant of the parallel from the centre of the primitive, which would also have found the fame point for the centre of the parallel, whose radius is equal to the tangent of its distance from its pole.

The parallels in this projection are also alimacants, or parallels of altitude; $\varphi$, $\psi$, is the ecliptic, which must be divided from the division on the scale of half-tangents; but denominated according to the signs in the zodiac, reckoning 30° to each sign.

STEREORAPHIC Projection on the Plane of the Equinocial. Let S C (fig. 11.) be the meridian, and folliollial colure; E N the equinocial colure, and hour-circle of 6; P the north pole; $\varphi$, $\varphi$, the northern tropic; E $\equiv$ N the northern half of the ecliptic (whole centre is found by letting off the feccant of 23° 30' from $\varphi$), and its pole is at a, the interfection of the polar circle and meridian, being the place through which all circles of longitude must pass; and E z N the horizon of London, which is described thus: set the half-tangent of the co-litude from P to Z; then the tangent of the fame, from P to O, or its feccant from Z to O, gives its centre; and its pole will be at $\beta$, 38° 30' (in the half-tangents) diiland from P, where $\beta$ is at the zenith.

To draw any other circles in this projection. 1. For cir-}

icles of longitude, which must all pass through $\alpha$, and the several degrees of the ecliptic; set the tangent of 66° 30', from a downwards, on the meridian produced; which will find a point, through which a perpendicular, drawn to the meridian, shall contain in it the centres of all the circles of longitude, whose distances from the pole P $\alpha$, shall be the tangents of the degrees of their distances from the meridian S P C (which is that belonging to 180°.) 2. All parallels of declination are drawn off by setting the half-tangents of their distances from P. 3. All azimuths, or vertical circles, must pass through $\beta$ at the zenith: hence, therefore, the zenith is 38° 30' distant from P, set the co-feccant of that (or the feccant of 51° 30') from $\beta$ on the meridian extended below, and that will find the point $\kappa$, the centre of the azimuth of east and west; viz. E $\equiv$ N; and the centres of all the rest are in a line that is perpendicular to the meridian, and drawn through $\kappa$. 4. Circles of altitude, or alimacants, are feller circles, whose poles are not in the plane of the projection, thus the circle O P is a parallel of altitude 50° above the horizon. 5. All hour-circles are ftraight lines from the centre to the limb.

STEREORAPHIC Projection on the Plane of the Horizon. First draw a circle representing the horizon, and quarter it with two diameters; then will $\varepsilon$ be the zenith of the place; 12 z 12 the meridian; $\varepsilon$ z 6 the prime vertical, or azimuth of east and west (fig. 12.) Make $\varepsilon P =$ half-tangent of 38° 30' (or tangent of 19° 15'); and $P \equiv$ shall be the pole of the world. Make $\varepsilon = \varepsilon =$ half-tangent of 51° 30' (or tangent of 25° 45'); and $\varepsilon$ $\varepsilon$ = $\varepsilon$ = tangent of 51° 30'.

In this projection all alimacants are all parallel to the primitive circle; and azimuths are all right lines passing through $\varepsilon$, the centre of the primitive, to the equal divisions in the limb. Parallels of declination are all feller circles, and parallel
tereoigrapat, and their intersections with the meridian are found, by letting the half-tangent of their distance from the zenith, southward or northward, or both ways from it. Their centres are found by biseecting the distance between those two points; for the middle will be the centre of the parallel. Thus, \[ \pi = \text{half-tangent of } 28^\circ \text{ to } \text{from the zenith,} \]
and \[ \pi = \text{half-tangent of } 75^\circ \text{ to the southward, or} \]
= distance of the tropic of \( \pi \) from the zenith;
from the zenith.

And the intersection again with the north of the meridian, is at \( \{105^\circ 30'\} \) for \( \{\pi \} \) to the northward, or upward from \( \pi \).

For the hour-circles, make \( \pi = \text{tangent of } 51^\circ 30' \), or
\( P \cdot \pi = \text{tangent of } 51^\circ 30' \); draw \( G \cdot T \) perpendicular to the produced meridian; then, if from \( \pi \), with the radius \( \pi \), you let off the tangents of \( 15^\circ 30', 45^\circ 45' \), &c., both ways, you will have the centres of the several hour-circles, 7 and 5, 8 and 4; &c.

Note, in all stereographic projections, all diameters are measured on the scale of half-tangents; and this is the ground of all dialling, or the true projection of the hour-circles of the sphere on any given plane. See Perspective, Projection, and Spheres.

STEREOGRAPHY, is that branch of solid geometry which demonstrates the properties, and shews the construction, of all solids which are regularly defined.

It explains the methods for constructing the surfaces in planes, so as to form the entire body, or to cover the surface of a given solid; or, when a solid is bounded by plane surfaces, the inclination of the planes is determined by the rules of stereography. The sections of solids are also a branch of stereography; but this we shall refer to the article Stereotomy, with which it is more intimately connected.

Mr. Hamilton has denominated the principles of perspective by the name of stereography; but in this sense the term is too limited, as perspective is only a branch of the doctrine of solids, and extends only to the sections of pyramids and cones, and the representations of solids. See Perspective.

The eleventh and twelfth books of Euclid, which treat of the properties of solids, may be looked upon as the elements of this branch of geometry; and to them we shall refer our readers for the first elements to be acquired.

It is somewhat singular, that though the first principles of solids have long been demonstrated, no practical application to mechanical constructions has been made of them. The knowledge of solids is of the greatest importance in the constructive parts of architecture, as in masonry, bricklaying, carpentry, &c.

To be proficient in the art of construction, this branch of geometry is indispensable, and contains the very essence and foundation of the whole in abstract.

Definitions.

1. A solid is that which has length, breadth, and thickness.

2. The exterior surface of a solid is called its surface.

3. A straight line is perpendicular or at right angles to a plane, when it makes right angles with every straight line meeting it in that plane.

4. A plane is perpendicular to a plane, when the straight lines drawn in one of the planes, perpendicularly to the common section of the two planes, are perpendicular to the other plane.

5. The inclination of a straight line to a plane is the acute angle contained by that straight line, and another drawn from the point in which the first line meets the plane, to the point in which a perpendicular to the plane drawn from any point of the first line above the plane meets the plane.

6. The inclination of a plane to a plane is the acute angle contained by two straight lines, drawn from any of the points of their common section at right angles to it, one upon one plane, and the other upon the other plane.

7. Two planes are said to have the like inclination to one another, which two other planes have, when the fide angles of inclination are equal to one another.

8. Parallel planes are such as do not meet one another, though produced.

9. A solid angle is that which is made by the meeting of more than two plane angles, which are not in the same plane, in one point.

10. Similar solid figures are such as have all their solid angles equal each to each, and which are contained by the same number of similar planes.

11. A prism is a solid of which the ends are similar and equal plane figures, and the sides paralleleograms.

12. When the ends of the prism are perpendicular to the sides, it is called a right prism; but if otherwise, it is termed oblique.

13. When the sides and ends of the prism are equal squares, it is called a cube.

14. When the ends are parallelograms, the prism is called a parallelepiped; and when the planes of the parallelepiped are at right angles to each other, then the prism is called a rectangular prism.

15. When the ends of the prism are circles, it is called a cylinder; but if the ends are ellipses, and alike situated, the prism is then called a spheroid.

16. The straight line extended between the centres of the two bales is called the axis.

17. A solid having any plane figure for its base, and its sides plane triangles terminating in the same point, is called a pyramid.

18. A solid having a circle for its base, and terminating in a point, such that a straight line extended from any part of the circumference of the base to the terminating point may be in the surface of the solid, is called a cone; and the surface which lies between the circumference of the base and the terminating point is called the conic surface.

If the plane of a circle be supposed perpendicular to a given plane, with its circumference or edge upon that plane; and if there be a straight line standing on any other point perpendicular to the said plane; and if another straight line be made to move parallel to the plane on which the circle stands, so as always to touch the circumference and the straight line, beginning at any given point, and proceeding entirely round until it arrives at the same point; then the solid bounded by the circle, and the surface passed over by the straight line contained between the circumference of the circle and the straight line, is called a cone; and the surface generated by the straight line is called a conoidal surface.

A sphere is a solid formed by the revolution of a semicircle upon its diameter.

The centre of a sphere is the same with that of the semicircle.

The diameter of a sphere is any straight line which passes through the centre, and is terminated both ways by the superficies of the sphere.

A cube is a solid figure contained by six equal squares. A tetra-
STEREOGRAPHY.

A tetrahedron is a solid figure contained by four equal and equilateral triangles.

An octahedron is a solid contained by eight equal and equilateral triangles.

A dodecahedron is a solid contained by twelve equal pentagons, which are equilateral and equiangular.

An icosahedron is a solid contained by twenty equal and equilateral triangles.

The solids defined in the last five definitions are called the five regular solids.

Propositions.

I. One part of a straight line cannot be in a plane, and another part above it.

II. Two straight lines which cut one another are in one plane, and three straight lines which meet one another are in one plane.

III. If two planes cut one another, their common section is a straight line.

IV. If a straight line stand at right angles to each of two straight lines in the point of their intersection, it shall also be at right angles to the plane which passes through them.

V. If three straight lines meet all in one point, and a straight line stand at right angles to each of them in that point, these three straight lines are in one and the same plane.

VI. If two straight lines be at right angles to the same plane, they shall be parallel to one another.

VII. If two straight lines be parallel, the straight line drawn from any point in one to any point in the other is in the same plane with the parallels.

VIII. If two straight lines be parallel, and one of them at right angles to a plane, the other shall also be at right angles to the same plane.

IX. Two straight lines which are each of them parallel to the same straight line, and not in the same plane with it, are parallel to one another.

X. If two straight lines meeting one another be parallel to two other that meet one another, and are not in the same plane with the first two, the first and the other two shall contain equal angles.

XI. Problem.—To draw a straight line perpendicular to a plane from a given point in space above the plane.

Draw any straight line in the plane and from the given point above the plane; draw a second straight line at right angles to the first straight line; from the point where the perpendicular meets the first straight line draw a third straight line in the plane, at right angles to the said first straight line; and, lastly, from the given point in space draw a fourth straight line at right angles to the third straight line; and the fourth straight line, thus drawn, is perpendicular to the plane.

XII. Problem.—To erect a straight line at right angles to a given plane from a given point in the plane.

From any given point above the plane draw a straight line perpendicular to the plane, and through the given point in the plane draw a straight line parallel to the other straight line; and the second line, thus drawn, is the perpendicular required.

XIII. From the same point in a given plane there cannot be two straight lines at right angles to the plane, upon the same side of it; and there can be but one perpendicular to a plane from a point above the plane.

Vol. XXXIV.

XIV. Planes to which the same straight line is perpendicular are parallel to one another.

XV. If two straight lines meeting one another be parallel to two straight lines which meet one another, but are not in the same plane with the first two; the plane which passes through the first parallel to the plane which passes through the others.

XVI. If two parallel planes be cut by another plane, their common sections with it are parallels.

XVII. If two straight lines be cut by parallel planes, they shall be cut in the same ratio.

XVIII. If a straight line be at right angles to a plane, every plane which passes through it shall be at right angles to that plane.

XIX. If two planes cutting one another be each of them perpendicular to a third plane, their common section shall be perpendicular to the same plane.

XX. If a solid angle be contained by three plane angles, any two of them are greater than the third.

XXI. Every solid angle is contained by plane angles, which together are less than four right angles.

XXII. If every two of three plane angles be greater than the third, and if the straight lines which contain them be all equal, a triangle may be made of the straight lines that join the extremities of those equal straight lines.

Properties of Solids arising from the Definitions.

In a prism, all parallel sections which cut the sides are similar and equal figures; or, all parallel sections which would cut the plane of the base, if produced, are similar and equal figures.

In a pyramid, all the parallel sections which are not parallel to the plane of the base are unequal similar figures.

The properties of a cone are numerous and interesting. If the cone is cut parallel to the plane of the base, the section is a circle; if it be cut in any direction through the apex, the section is a plane right-lined triangle; if the cone be cut by a plane inclined to the plane of the base at any given angle, the section is an ellipse; if the cone be cut by a plane parallel to any straight line within the solid passing through the apex, the section is demarcated an hyperbola; if a cone be cut by a plane parallel to another plane which touches the curved surface, the section formed by this portion of the cutting plane is called a parabola.

For the purposes of stereography, we shall suppose the cone a right cone, and consequently the abscissa of the curves or sections will bisect all the double ordinates at right angles.

If any semi-conic section be supposed to rotate upon its abscissa, so as to perform an entire revolution, the surface generated by the curve line is called a conoid, and the abscissa the axis.

If the semi-conic section be a semi-ellipse, the solid generated is called an ellipsoid.

If the generating figure be a semi-parabola, the solid is called a paraboloid.

If the generating figure be a semi-hyperbola, the solid is called an hyperboloid.

All solids whatever, generated by revolving plane figures upon an axis, are called solids of revolution.

All parallel sections of conoids are similar figures.

General Principles of Stereographic Constructions.

Definition.—Solid angles which consist of three plane angles are called trihedrals.

In the construction of trihedrals, besides the three plane angles which form the boundaries of the solid, are the three inclinations.
STEREOGRAPHY.

Inclinations. These inclinations are, by way of distinction, called the angles, and the three boundaries are called the sides, and the sides and angles are indifferently called parts, any three of which, excepting the three angles, may be found by the following constructions. We shall first show the construction of right-angled trihedrals, not only as being the most useful, but as being necessary to the construction of oblique trihedrals.

PROBLEM I.

In a right-angled trihedral are given the two sides containing the right angle, to find the acute angles, and the side or hypotenuse which subtends the right angle.

Make the angle $E B H$ (Plate I. Stereography, fig. 1.) equal to one of the given sides, and the angle $E F$ equal to the other; draw $E H$ perpendicular to $E B$, and $E I$ perpendicular to $B F$, cutting $B F$ at $F$; from $B$, with the radius $B H$, describe an arc, cutting $E I$ at $I$, and join $B I$; then $B I$ is the hypotenuse, from $E$, with the radius $E F$, describe an arc, cutting $E B$ in $G$, and join $G H$; then $E G H$ is the angle contained by the hypotenuse and the side $E F$, or the angle opposite the side $E B H$; or make $F I$ equal to $G H$, and join $B I$.

In the same manner the angle opposite the side $E F B$ may be found.

The reason will appear thus: raise the plane of the triangle $B E F$ upon $B E$, so as to be perpendicular to the plane $B E H$; raise the triangle $E G H$ upon $E H$, until $E G$ fall upon $E F$; then the plane $E G H$ will become perpendicular to $B F$; revolve the plane $B I F$ upon $B F$, and $F I$ will describe a circle, whose plane is also perpendicular to $B F$, from the point $F$; therefore, the plane of the circle and the plane $E G H$ will be both in the same plane; therefore, since the plane $F I$ coincides with $G H$, the straight line $F I$ may be made to coincide with $G H$: let this coincidence take place; and because $F I$ is equal to $G H$, and the point $G$ falls upon $F$, the point $I$ will fall upon $H$; therefore, the straight line $B I$ will fall upon $B H$; and the angle $F B I$, joining $F B$ and $B H$, is the hypotenuse.

Again, it is evident from the planes thus raised, that the angle $E G H$, contained by the planes $E B F$ and $B F I$, and perpendicular to $B F$, their common intersection, is the measure of the angle contained by the planes $F B E$ and $F B I$.

PROBLEM II.

Given one of the sides containing the right angle and the angle opposite, to find the remaining side which contains the right angle.

Let the given side be $H B E$ (fig. 2.); in $B E$ take any point $F$, and make $E F H$ equal to the angle required; draw $H E$ perpendicular to $E B$; from $E$, with the radius $E F$, describe an arc $E G$; draw $E G$ perpendicular to $B D$, cutting it in $G$, and $E H$ perpendicular to $A B$; make $E F$ equal to $E G$, and $E F H$ equal to the given angle; draw $B H C$, and $A B C$ will be the measure of the plane angle opposite.

The following propositions show the construction of all the cases of trihedrals or spherical triangles, which are all represented by right-lined triangles. In each of the cases it will be found, that two of the sides of the spherical triangle are represented by the tangents of the arcs drawn from the same angle; and the angle included by these tangents is the measure of the spherical angle. The representation of the third side is a line joining the extremities of the tangents; the other two angles are measured by this proposition. If each of the three plane angles be denominated a side, and each of the three inclinations an angle, the geometrical construction will be the same as that of a spherical triangle, and the manner of expressing the data of the one is the same as expressing that of the other. The sides are always measured by the three plane angles of the folio angle.

PROBLEM IV.

Given two sides and the contained angle, to find the other parts.

Make the angle $A B C$ (fig. 3.) equal to the contained angle; draw $B D$ perpendicular to $A B$, and $B E$ to $B C$; make $B D$ and $B E$ equal to each other, the angle $B D A$ equal to one of the containing sides, and $B E C$ equal to the other. Upon $C$ as a centre, with the distance $C E$, describe an arc $F I$; and upon $A$ as a centre, with the distance $A D$, describe another arc, cutting the former at $F$. Join $F A$ and $F C$, and then the angle $A F C$ will be the measure of the third side.

Now if the triangle $A B D$ be turned round the line $A B$, the triangle $C B E$ round $C B$, and the triangle $A C F$ round $A C$, until the points $D, E, F$, coincide, each of the two planes, $A B D$ and $C B E$, will be perpendicular to the plane $A B C$; therefore, there will be given two of the sides of a fold angle, one perpendicular to the other, to find the inclination of the vertical plane with that of the hypotenutal. Proceed, therefore, as in the last problem, and find the angle $G H K$, which will be the inclination of the two planes $C B E$ and $C A F$. In the same manner may the inclination of the planes $A B D$ and $A C F$ be found.

Note. The triangle $A B C$ represents the spherical triangle, of which $A B$ and $B C$ are the tangents of two arcs; and the angle $A B C$ is the spherical angle contained by the arcs, of which $A B$ and $B C$ are tangents.

PROBLEM V.

The three sides of a spherical triangle being given, to find the angles.

Make the three angles, $A B C$, $C B E$, and $E B F$ (fig. 4. N° 1 and 2.) equal to the three sides of the spherical triangle, that is, to contain the same number of degrees. On $B$ as a centre, with any radius $A B$, describe an arc $A F$; draw $A C$ and $F E$ tangent at $A$ and $F$; join $C E$; draw the straight line $G H$ equal to $C E$. On the centre $G$, with the tangent $A C$, describe an arc at $I$; and on the centre $H$, with the tangent $F E$, describe another arc, cutting the former at $I$. Join $G I$ and $H I$; draw $I K$ and $I L$ perpendicular to $I G$ and $I H$, making them equal to $A B$ or $B F$; join $K G$ and $L H$. Now if the triangles $G K I$ and $H I L$ be raised on the lines $G I$ and $H I$, until the points $K$ and $L$ coincide; then each of the triangles $G K I$ and $H I L$ will be perpendicular to the triangule $G I H$. Proceed, therefore, as in the fifth proposition, to find the angles, which in the representation of the spherical triangle $G I H$ are represented by $G$ and $H$.

Scholium.—Since each of the extreme angles may be made the middle angle in N° 1, the triangle $G H I$, N° 2, may be
Three angles, made in each separate triangle, are the measures of the three spheric triangles; but this mode requires more lines than that described in the above proposition.

There is another method of finding the angles of a spheric triangle, when the three sides are given, pointed out by bishop H.Olry, at page 215 of his Elementary Treatises. The substanke of it is as follows: Draw a right angle; make one of the legs equal to the difference of the coines of the fides containing the required angle, the hypotenuse equal to the chord of the third side. Upon the remaining perpendicular fide, as a base, confruct a triangle, whose two other sides are equal to the lines of the fides containing the required angle; then the angle contained by the lines will be the measure of the spheric angle. This may be very easily accomplished by means of a scale of lines and chords from Gunter's scale.

**PROB. VI.**

Two angles and a fide opposite to one of them being given, to find the other two fides and the remaining angle. Make the angle $ABC$ ($\text{fig. 5.}$) equal to the spheric angle next to the given fide; draw $BD$ and $BE$ perpendicular to $BA$ and $BC$; make $BD$ of any length, and $BE$ equal to it; and make the angle $BDA$ equal to the measure of the given fide. Draw $AF$ perpendicular to $BC$, cutting it in $F$; make the angle $FAG$ equal to the complement of the other given angle. On the centre $F$, with the distance $FG$, describe an arc $GH$; draw $CHE$ a tangent to the arc at $H$, the fame as in the second proposition. Join $AC$, and the angle $CEB$ will be the measure of the included fide. On the centre $C$, with the distance $CE$, describe an arc at $K$; and on the centre $A$, with the distance $AD$, describe another arc, cutting the former at $K$. Join $AK$ and $KC$; then will $AKC$ be the measure of the third fide of the spheric triangle.

**PROB. VII.**

Given two angles, and the contained fide, to find the other three parts. Make $ABC$ ($\text{fig. 5.}$) one of the given angles. Draw $BE$ perpendicular to $BC$. Make $BEC$ equal to the number of degrees contained in the given fide. In $BC$ take any point $G$. Draw $GI$ perpendicular to $CE$, cutting it at $I$, and $GK$ perpendicular on the other side of it. Make $GH$ equal to $GI$, and the angle $GKH$ equal to the other given angle. Draw $CBA$ (as in Prop. III.), then $ABC$ is a plane triangle representing the spheric one.

Now, because $ABC$ is the angle included by the tangents, draw $BD$ perpendicular to $BA$, and equal to $BE$, and join $DA$; then $BDA$ is the measure of the fide, of which $AB$ is the tangent. On the centre $A$, with the distance $AD$, describe an arc at $F$; and on the centre $C$, with the distance $CE$, describe another arc, cutting the former at $F$. Join $FA$ and $FC$; then $AFC$ is the measure of the third fide.

**PROB. VIII.**

Two fides, and an angle oppofite to one of them, being given, to find the three remaining parts. Draw $AC$ ($\text{fig. 6.}$), representing the fide adjoining the given angle, and $AB$ perpendicular to it. Make the angle $ABC$ equal to the given angle. In $AC$ take any point $E$. Draw $ED$ perpendicular to $BC$, cutting it in $D$, and $EC$ perpendicular to $AC$. Make $EF$ equal to $ED$; and the angle $EFG$ equal to the given angle. Draw the line $CGH$. On $A$ as a centre, with the tangent of the other given fide, describe an arc $KH$; which, if it cut the straight line $CH$ in two points, $H$ and $K$, join $AK$ and $AH$. Draw $AI$ perpendicular to $AH$, and equal to $AB$. Join $IH$. On the centre $H$, with the distance $HI$, describe an arc at $M$; and on the centre $C$, with the distance $CI$, describe another arc, cutting the former at $M$. Join $HM$, $K$, $CM$; then the angle $CAK$, or $CAH$, is the measure of the spheric angle included by the tangents. The measure of the angle $AHC$, or $AKC$, representing the spheric angle oppofite the given fide, fhewn by the tangent $AC$, is found by Prop. 1. The angle $CMH$, or $CMK$, is the measure of the remaining fide; viz. that oppofite the angle included by the tangents.

N.B. This cafe is not always ambiguous; for if $AH$ be equal or greater than $AC$, the arc $KH$ will only cut $HC$ in one point; and, therefore, there can only be one triangle: or, if the angle $AHC$ be a right angle, $AH$ will only touch $HC$; in this cafe also there is only one triangle.

**PROB. IX.**

The three angles of a spheric triangle being given, to find the three fides. Take the supplements of each of the angles, and describe a triangle by Prop. V., whose fides are equal to thefe supplements; then the measure of the angles of this triangle will be: the supplements of the fides of the fides of the triangle sought. This is demonstrated by writers on spheric trigonometry.

Though the writer of this article has not given formal demonstrations of the preceding propositions relating to the geometrical construction of spheric triangles, as it would have swelled the article too far, he hopes that enough has been laid to enable any one, who has a clear conception of the parts of a spheric triangle, to derive the representation of it, and to find the measure of its parts in the most easy manner, without having recourse to the projection of the sphere, which frequently runs into conic fecttons, and, from their difficulty of description, renders the projection very inaccurate. The representation of the spheric triangle belonging to the preceding propositions, is nothing else than a plane triangle, which is a tangent to the sphere at one of the spheric angles, and whose fides are bounded by the interferences of the planes of the three great circles of the fides of the spheric triangle; consequently two of the fides of the representative triangle are always two tangents from the same spheric angle. The included angle by thefe tangents in the representative triangle is the measure of the spheric angle contained by the fides which the tangents represent.

And the third fide in the representative triangle is a line joining the extremities of the tangents, as has been already mentioned. In another point of view, the whole may be conceived to be a pyramid, whose fides are planes from the centre of the sphere, falling through the three arcs of the spheric triangle; and the base a triangle, a tangent of the sphere at one of the angles, which meets the fides. The vertical angles of the fides of this pyramid are the measures of the fides of the spheric triangle; the angles of the pyramid are the measures of the spheric angles; and the base of the pyramid is the representative triangle. Consequently one of the angles of the pyramid is always perpendicular to the base. The angle intercepted by the two planes upon the base is equal to the inclination of the plane.

The triangle belonging to the preceding propositions is such, that when all the parts are completed, the fides may be turned.
turned up upon the base, which is the representative triangle, until the edges of all the triangles forming the sides are united in one common vertex. A pyramid will then be formed, equal, familiar, and similarly situated to that above. The Rev. George Walker, in his ingenious doctrine of the sphere, Prop. I. p. 258, states, that "if there be a spherical triangle, and a plane quadrilateral figure be formed, two of the whole sides are the facets, the other two the tangents of two of the sides of the spherical triangle, and the angle comprehended by the facets be measured by the spherical base, the angle comprehended by the tangents shall be the measure of the spherical angle opposite the base; the diagonals of the quadrilateral shall intersect each other at right angles; the segments of the diagonal joining the angle of the facets, and the angle of the tangents, shall be the tangent and tangent of the spherical perpendicular, drawn from the vertical angle to the base; the angle which this diagonal makes with the facets, shall be measured by the spherical segments of the base; and the angles which this diagonal makes with the tangents, shall be the measures of the spherical angles which the perpendicular makes with the sides." This theorem is very analogous to Prob. V.; but the properties shown by it do not apply to the construction from any given data, nor can all the parts be found from any one datum; they may be very well applied when two sides and the contained angle are given, or when the three sides are given, by varying the triangles, as has been here shown, in order to find the other two angles; but this is both troublesome and inelegant.

From what has been said, it will be easy to construct any solid similar to any other solid given, whose sides are planes, by constructing each solid angle, that is, by dividing it into as many solid angles, each consisting of three plane angles, wanting two, as the number of plane angles bounding the whole solid angle; then completing the figure of any side, of which a plane angle of the described solid angle is one similar to the side of the solid given. From the several angles of this figure construct other solid angles in the same manner.

**Prob. X.**

In a solid, such that all sections parallel to the base are similar and regular polygons, there are given the base of the solid, a vertical section perpendicular to the base through its centre, and to the sides of the polygon, to find the angular or common section at the meeting of every two equal and similar prismatic parts.

From the centre of the base draw a line at right angles to the sides of the polygon; apply the base of the perpendicular section to this straight line, which now calls the base of the perpendicular section. Draw a line from one of the next angles to the centre of the base; call this the diagonal line. Take any number of points in the base of the perpendicular section, and draw lines parallel to that side of the polygon to which it is perpendicular, till they cut the diagonal line. From these intersections draw perpendiculars to the diagonal line. Draw perpendiculars also to the base of the perpendicular section, till they cut the curve of this section. From all the intersections of the diagonal apply all the perpendiculars of the section; through the points now found draw a curve, and it will be the section of the diagonal plane required. This will be evident, if the perpendicular and diagonal sections are raised perpendicular to the plane of their bases.

**Example.—** Plate II, fig. 2, No. 1, is the hexagonal base of a solid, whose perpendicular section is A B C. Draw the diagonal D C. In B C take any number of points, e, through which draw the lines e f parallel to B D, cutting the diagonal line in the points f. From the points e draw the lines e g perpendicular to B C, cutting the curve A B in the points g; and from the points f draw the lines f b perpendicular to D C. Make all the lines f b equal to the lines e g; and through points D, b, h, ** I, draw a curve, and C D I will be the diagonal section required.

This process may easily be reversed, by having the angular section given. In the same manner are the sections of figs. 2 and 3, No. 1, to be found, which, from what has been said, are plain to inspection.

In order to give a clearer idea of these solids, their elevations are shown at No. 1.

**Prob. XI.**

To find the covering of a cylinder, such as may be generated by a rectangle.

Make a rectangle, one of whose dimensions is the length of the axis, and the other the circumference of the base of the cylinder.

**Example.—** A B C D (fig. 4, No. 1), is the elevation of a cylinder, G, (No. 2), the base. The side D E, of the rectangle C D E F, is made equal to the circumference of G, and the breadth C D is the height of the cylinder.

If C D E F be wrap round the cylinder A B C D, the edge E F will coincide with C D, D E with the base A D, and C F with the base B C; this is so evident that it wants no demonstration.

**Prob. XII.**

To find the covering of a cylindrical ungula, having the base of the cylinder; and the axis-section perpendicular to the inclined section of the ungula.

Let A B C E F G, (fig. 5) be half the circumference of the base. Divide it into the equal parts A, c, e, g, & c.; and let D E F G be the axis-section, whose base D G is placed parallel to A B, the edge D E in a straight line with the extremity A, and G F in a straight line with the extremity B. Draw the lines c b parallel to D E, cutting the inclined line E F in the points b. Produce D G to L. On G L make the distances G n, n n, m, &c. and n L, equal to B c, c e, e g, &c. Draw the lines n k parallel to D E, as also I L; and the lines b k, as also I E, perpendicular to it. Through all the points k to I draw a curve, and G F I L will be half the covering: for imagine the part D E F G to represent the ungula, and the covering F G I L wrap round F G D E; then, because that all the distances G n, n n, m, &c. are equal to B c, c e, e g, &c., the points n will fall upon those of e, which are represented by o in the elevation; and because that all the figures o b k n are parallelograms, all the lines n k will be equal to the lines o b, and the lines n k will fall upon those represented by o b, and the points k will fall upon those of b, and the part F G I L will cover half the ungula represented by F G D E.

**Prob. XIII.**

To find the covering of the curved superficies of a cone, such as may be generated by the revolution of a right-angled triangle about one of its perpendicular legs.

With a radius equal to the slant side of the cone describe an arc. Make the length of this arc equal to the circumference of the base. Draw two right lines from the centre to each extremity of the arc, then the sector comprehended by the two radii and the arc will be the curved superficies required.

**Example.—** Let A (fig. 6) be the base of the cone; B D C the
the elevation, which also represents a section of the cone through the axis.

On E is a centre, with the slant side D C, describe an arc C E. Make the arc C E equal in length to the circumference of A. Join D E and D C, and the sector E D C is the covering required.

For C being equal to the circumference of the base, when D E C is bent round the cone D B C, the straight line E D will meet C D, and all the points on the arc C E will coincide in the same plane with the base B C, since the superficies of the cone may be conceived to be divided into an indefinite number of isosceles triangles, whose vertex is the point D, and whose bases are in the base of the cone. The sector D E C may be conceived to be divided into as many isosceles triangles, which, when bent round, will respectively coincide with those of the cone.

**PROB. XIV.**

To cover a conical unguia, the cone from which it is a part being such as may be generated by the revolution of a right-angled triangle about one of its perpendicular legs, a section through the axis at right angles to the plane of the inclined section of the cone being given.

Let A B C D (fig. 7) be the section given. Produce A D and B C to meet it in E. Bifect the vertical angle A E B by E I, cutting A B at K. On the centre I, with a radius A K or K B, describe a circle F M G N. Draw the diameter F G parallel to A B. Divide the semi-circumference F M G N into any number of equal parts, F o, o o, o &c. Draw the lines o p parallel to E I, cutting A B in the points p; the lines E p, cutting D C in the points q; and the lines D r, q r, q &c. parallel to A B, cutting B E in the points r.

Make all the distances B t, t t, t t, &c. on the arc A B, equal to F o, o o, o &c. Draw E B, E r, E t, E r, &c. on the centre E, with the radius E r, describe arcs, cutting the lines E t in the points t. Draw the curve line C F E, &c. and B C L H will be the covering required: for the sector E B H will be the covering of the whole cone; B t t t, &c. will coincide with the base; the lines E r will coincide with the lines E p, and all the lines r t will fall upon r p.

**PROB. XV.**

To cover a solid generated by the revolution of a semi-polygon, the section through the axis being given.

Produce any side A B (fig. 8) to meet the axis produced in C. On C as a centre, with the radius C A and C B, describe arcs A E and B D. Draw the radius E D C, and A E D B will cover a part of the frustum of a cone, represented by A B G F, as is evident from what has been said.

**PROB. XVI.**

In a solid, whose parallel sections to the base are all similar figures, and whose base is a regular polygon, there are given the base and the perpendicular section to find the covering of one of the curved sides.

Let A B C D E (Plate III. figs. 1, 2, and 3) be the base, F G H the perpendicular section, G F its base, drawn from the centre F, perpendicular to the side A E. Draw the curve G H into any number of equal parts G I, II, II, &c. Draw the lines i f parallel to A E, cutting F G in the points k, and F E in the points l. Produce F G to P, making G P equal to the arc G H, and divide G P into the same number of parts in the points m, as G H is divided into the points l. Draw the lines m m n at right angles to G P, and the lines l n parallel to it; or make the lines m n equal to k l, and through the points n draw a curve; then A P E will be the covering of one of the curved superficies required.

If G H F be a quadrant, each edge of the covering will be the same as that of a cylindrical angle of the same diameter, cut at the same inclination as the angle F E G.

From what has been said it will be easy to conceive that any of these coverings must fit the surface they are made for. If the section G H F be raised upon the base G F until it becomes perpendicular to the plane A B C D E, and the covering A P E bent round; the points m will coincide with those of i, and the lines m n will fall upon the lines k l.

There is another geometrical method of finding the superficies of a solid in plano, much more convenient in practice. The data for this method are the length of the curve of the perpendicular section; the figure of the perpendicular section; one of the terms or sides of the base of the solid. This rule is as follows: on the given term or side describe a figure similar to the perpendicular section of the solid, the term or side being the base of the similar section. Produce the vertical edge of the similar section indefinitely from the base. Upon this indefinite line let the length of the curve of the perpendicular section divide this line and the curve of the similar section both into the same number of equal parts. Through all these points draw lines parallel to the side or term of the base of the polygon, those of the similar section to cut the perpendicular side. Take all the respective lengths of the lines, beginning with those next the base first of the similar section, and let them on the respective parallels in the same order from the base on each side of the line, cutting the parallels. A curve being traced through the points on both sides, will, with the base, be the boundaries required.

This is exemplified in figs. 4 and 5. A B C is the similar section to the perpendicular one; A B representing its base, B C its perpendicular, B D the length of the curve of the perpendicular rib, A E the side of the base of the solid. The manner of describing these coverings is plain to inspection. A B C (fig. 4) is for a curve of contrary flexure; A B C (fig. 5) is to answer a quadrant.

It may be remarked, that by whatever mode the curve of the perpendicular section is described, the same mode may be applied to describe the similar one A B C; if the outer edge of the perpendicular rib be a curve of contrary flexure, as in fig. 6, described from the summits of equilateral triangles, the similar rib A B C (fig. 4) may be described in the same manner. To find the height B C, find a fourth proportional to the base, the perpendicular height of the perpendicular rib, and the side of the base of the solid; that is, suppose F G H (fig. 7) to be the perpendicular rib, G H its base, G F its height. Make A B to B C, (fig. 4) as H G to G F, that is, H G: G F: A B: B C.

To demonstrate the truth of the above method, it is only necessary to shew, that if the lines i p (fig. 1) are drawn parallel to G F, intercepted by the line H F, all the lines k l, as they recede from G E, are proportional to the lines i p, as they recede from G F.

Draw H K (fig. 7) perpendicular and equal to H G. Join K G. Make H I equal to A B (fig. 4), that is, equal to half the breadth of a side of the base of the solid, and join I G. Draw L m, M n, N s, O y, P e, from the points L, M, N, O, P, in the curve F H, parallel to G H, cutting G F in the points v, w, x, y, z, and L M N B C D E P E, parallel to H K, cutting I G in the points V, W, X, Y, Z, G K in the points A, B, C, D, E, and G H in Q, R, S, T, U. Then, because of the parallelograms G L Q, G W M R, G X N S, G y O T, and G e P U; G Q.
G Q, G R, G S, G T, G U, are respectively equal to v L, w M, x N, y O, z P; and because of the similar triangles KHG, EUO, U T D, S C G, B R G, and A Q G, and because HK is equal to H G; U E, T D, S C, R B, and Q A, are respectively equal to U G, T G, S G, R G, and Q G; therefore U E, T D, S C, R B, and Q A, are respectively equal to z P, y O, x N, w M, and v L. Now H I, U Z, T Y, S X, R W, and Q V, are to one another as H K, U E, T D, S C, R B, and Q A; therefore H I, U Z, T Y, S X, R W, and Q V, are as P z, O y, x N, w M, and v L; but A B, c d, e f, g h, i k, l m, (fig. 4.) are to one another as P z, O y, x N, w M, and v L; therefore H I, U Z, T Y, S X, R W, and Q V, (fig. 7.) are also as A B, c d, e f, g h, i k, l m, (fig. 4.); but H I is equal to A B, (fig. 4.); therefore A B, c d, e f, g h, i k, l m, are equal to H I, U Z, T Y, S X, R W, and Q V.

From what has been said, the geometricalian will soon perceive that the coverings A D E (figs. 5 and 6.) are what is called the figure of the frustum.

Example.—Let A B C (fig. 8. N° 1, and fig. 9. N° 2) be the generating plane, A C its axis, B C its base, B E D half the base of the fold, B f j j f . . . . . D the curve line of the section; take the equidistances B f, j j, f f, &c. and on the centre of the base B, describe arcs cutting C B, the base of the frustum, in the points g; draw the lines g b perpendicular to B C, cutting the curve in the points b. Make I K, (N° 2. fig. 9.) equal to B f, j j, &c. and let the points I, in I K, be thence which correspond to f, j j, &c. (fig. 9. N° 1.) Draw perpendiculars I m to I K, equal in length to g b, N° 1, and the curve K m m . . . . . I, being drawn, will give the superficies of the frustum.

STEREOMETRY, \(\Sigma v r e f r o m G \), formed of \(\varepsilon f f o n s f o i d d\), and \(\varepsilon f f o n s m e f f o r e\), that part of geometry which teaches how to measure solid bodies, i.e. to find the solidity or solid content of bodies; as globes, cylinders, cones, vases, vases, &c.

The methods hereof see under the respective bodies; as GLOBE, SPHERE, CYLINDER, &c. See also GAUGING.

STEREOTOMY, formed from \(\varepsilon f f o n s f o i d d\), and \(\varepsilon f f o n s f e t t i o n\), is the science and art of cutting solids under certain specified conditions.

Stereotomy may be regarded as a branch of stereography, which is the science of solids in general. Mr. Hamilton has entitled his complete body of perspective, Stereography, which perhaps would have been more properly entitled Stereotomy, as the perspective representation of every object in nature is the figure of a pyramid or cone of rays. But as it has not been the object of the writers on perspective to state the rules for finding the sections of solids in general, under certain specified conditions of the cutting plane, nor of finding any other sections besides those of cones and pyramids, it is the express intention of this article to explain the general principles of the science for any given law, by which the surface of the solid may be constituted of straight lines, or that the surface may agree with the common section of two planes disposed in given positions. And as nothing of the kind has yet appeared, perhaps this attempt may be more acceptable, particularly as in its principles the whole art of dialling is included, and the mechanical arts of masonry and carpentry. The art of stone-cutting, the squaring and cutting of timbers, and the formation of hand-rails, depend entirely upon the sections of solids.

PROB. I. Plate I. Fig. 1.

Given the feet, A, B, of the intersection in space of two planes, having a given inclination, and the inclination, A C, of one of them in a given plane, Y; also the inclination of the common intersection of the two planes to the plane Y; to find the intersection of the other plane with the plane Y.

Make B A D equal to the inclination of the intersection of the two planes; from any point D, draw D E perpendicular to A D, cutting A B at E; make E B equal to E D; draw E C perpendicular to A B; make the angle C B F equal to the inclination of the planes, of which the feet of their intersection is A B; let B F meet E C in F; and join A F; then will A F be the intersection required.

Or thus: Through any point E, in A B, draw C E perpendicular to A B; make E A D equal to the inclination of the intersection; draw E D perpendicular to A D; make E B equal to E D; join E C; make the angle C B F equal to the inclination of the planes, which have A B for the feet of their intersection; let B F meet C E in F; and join A F; then will A F be the intersection required.

Demonstration.—Imagine the triangle A D E to be turned upon A E, until it becomes perpendicular to the plane Y; let the plane Z be turned upon C E, until E B fall upon E D; that E B will fall upon E D is evident, since E B, in revolving upon E C, will always be in a plane parallel to E C; and E D is also in a plane parallel to E C; E B must fall upon E D, and the point B upon D; and the plane A E D will be perpendicular to the two planes C E A and C E B; therefore A D will be perpendicular to the plane C E B; whence it is manifest, that C B F is in a plane perpendicular to the common intersection, and is the measure of the inclination of the planes.

PROB. II. Fig. 2.

Given I N, the intersection of a plane, W, with another plane, X, and their inclination, the feet, A, B, in the plane, X, of a line in space infilling at A, and the inclination of the line to the plane X; to find the section of the line in the plane W.

Through any point B, in A B, draw B S perpendicular to I N, cutting I N at E; make the angle B E F equal to the inclination of the plane; draw B G perpendicular to B S; make B G the tangent of inclination to the radius A B; draw G F parallel to B S; through A, draw any two lines A J and A K, cutting I N at J and K; make E S equal to E F; through S, draw V L parallel to I N; produce B S to P; make S P equal to F G; draw V P parallel to A K, and P L parallel to A J; and join K V and J L, cutting each other at a; and a is the section of the line in the plane W, as required.

For the imagine the triangles B E C and C G F in the same plane to be turned upon B E, so that their plane may be perpendicular to the plane X; then B G will be perpendicular to the plane X, and the point G will fall in the line in space; imagine also the plane W to be revolved upon I N, until E S fall upon E F, as is evident for the same reason as given in the first problem, and the point S will fall upon F; then the line V L will become parallel to the plane. In revolving the plane W upon I N, imagine the plane Y to revolve upon V L, at the same time, so that the plane Y may always continue parallel to the plane X; then V L will continue parallel to the plane W, and B S will continue parallel to A J; then, as in perspective, X is the original plane, W the plane of the picture, Y the vanishing plane, G or P the plane of the eye coinciding therewith, I N the intersecting line, V L the vanishing line, J, K, the intersecting points.
points, \( V L \), the vanishing point, and the original line would then be a visual ray; therefore, by the theory of perspective, \( a \) is the representation of the point \( A \).

**Prop. III.**

The same things being given, and the constructive lines remaining as in the preceding problem, as also the point \( a \), the section of the line in space; to find the seat of the line in the plane \( W \), and its inclination to the said plane.

Draw \( G O \) (fig. 3.) perpendicular to \( E F \), meeting \( E F \) in \( Q \); in \( E P \), make \( E T \) equal to \( E Q \), and join \( T a \); draw \( T R \) perpendicular to \( a T \); make \( T R \) equal to \( Q G \), and join \( R a \); then will \( T a \) be the seat of the line in the plane \( W \), and \( T a R \) its inclination to the said plane.

*Demonstration.*—For when \( E S \) is made to coincide with \( E F \), as in the last problem, the plane \( F C G \) will be perpendicular to the plane of the section \( W \); but the line \( F C \) being now in the plane \( W \), and \( Q G \) being perpendicular to \( F C \), \( Q G \) will also be perpendicular to the plane \( W \); but the point \( G \), that is \( R \), is a point in the line whose seat is \( A B \), and the point \( a \) is another point in the line whose seat is \( A B \); therefore, \( R \) and \( a \) are two points in the line whose seat is \( A B \): then join \( R a \), which will be the part of the line in space on the other side of the plane \( W \), and \( aT \) its seat.

*Scholium.*—This amounts to the same thing as the seat and distance of the eye being given with respect to the original plane, and the position of a point in the said plane; to determine the seat and inclination of the visual ray.

**Prop. IV.**

Two straight lines, \( A B \) and \( C D \), (fig. 4.) tending to an inaccessible point, being given, through a given point \( E \) to draw a third straight line, to tend to the same inaccessible point.

From any point \( A \), in \( A B \), draw a direct line, \( A E \), from \( A \) to the given point \( E \), cutting \( C D \) in \( C \); and through any other convenient point \( B \), draw \( B F \) parallel to \( A E \), cutting \( C D \) in \( D \); find \( D F \), a fourth proportional to \( A C \), \( C E \), \( B D \), and join \( E F \); then will the lines \( A B \), \( C D \), and \( E F \), tend to the same point of concurrency.

*Scholium.*—Sometimes happens, that a number of lines radiate from the same point, and that from a given point it is required to radiate other straight lines, so as to meet the radiations given in a given straight line: some or many of these radiations, according to their number, will be inaccessible; and though they may be all found by this problem, yet if the several operations are combined in one, much trouble will be saved.

Thus, let the radiations (fig. 5.) be \( A B, A C, A D, A E, A F \), tending to the straight line \( BC \); and let \( a \) be a given point, from which it is required to radiate other straight lines to meet or tend to the same points in \( BC \), with those drawn from \( A \). Join \( A a \), cutting \( B C \) in \( G \); and through any convenient point \( C \), in \( B C \), draw \( EF \) parallel to \( A a \); make \( C P \) equal to \( G A \), and \( C Q \) in \( B C \), produced to \( a \), equal to \( G a \); join \( P Q \). Now let \( A D, A E, \) meet \( C F \) in \( D \) and \( E \); draw \( D M, E N, F O \) parallel to \( P Q \), cutting \( B a \) at \( m, n, o \), make \( C d \) equal to \( C m \), \( C e \) equal to \( Cn \), \( C f \) equal to \( Co \); draw \( da, ea, f a \), which are the lines required. This might also be neatly effected by the proportional compasses; but the centred, invented by the author of this article (Mr. P. Nichollson), is much preferable. It is described under the article SCENORAPHY, but has of late been much improved, and made to set at the first time.

**Example 1.**—Given the meridian \( A B \) (fig. 6.) in the plane of the horizon \( X \), the latitude of the place, the intersection, \( I N \), of the plane \( W \), with the horizontal plane \( X \), and the inclination of the plane \( W \), to that of the horizon \( X \); to construct a dial in the plane \( W \).

In \( A B \), take any point, \( A_{1} \), for the foot of the fyle; then \( A_{1} B \) will be the fyle of the fyle, or of the line tending to the pole of the world: the fyle of the fyle is its inclination. Find \( a \) the representation of \( A_{1} \), that is, the fyle of the fyle of the dial in the plane \( W \), by the second problem: produce \( A_{1} B \) to meet \( I N \) in \( D \); draw \( D a \) in the dial-plane \( W \); then, by the third problem, find \( aT \), the fyle of the fyle in the plane \( W \), and the angle of elevation \( T a R \) : and by the first problem, find the intersections, \( U a, Y a, Z a, \&c. \) of lines passing through the fyle, making angles respectively of \( 15^\circ, 30^\circ, 45^\circ, 60^\circ, \&c. \) with the vertical plane passing through the meridian \( A B \); that is, with the plane whose intersection is \( T a \) : the inaccessible lines are also found by the last problem; and the dial is constructed as required. \( aT \) is the fyle of the fyle, whose intersection is \( T a \); \( T a R \) its inclination; \( aD \) is the 12 o'clock line; and \( U a, Y a, Z a, \&c. \) are the hour-lines. Another method of finding the sub-fyle is thus: produce \( G Q \) to meet \( P E \) in \( H \); join \( H A \), which produce to \( N \); draw \( N a \) the sub-fylter line.

Thus, upon one common principle, the sections of lines, planes, and solids may be found. The sections of folds are found by means of the sections of planes: the construction of a dial is but finding the sections of planes, whose positions are given. This method is, perhaps, of all others the easiest to consider and to construct.

**Example 2.**—Given the base, \( A N Q R \) (fig. 8.) of a pyramid, in the plane \( X \), and the whole foot, \( A B \), of one of its angular lines, the intersection, \( I N \), of the cutting plane \( W \), and the inclination of the planes \( W \) and \( X \); to find the section of the pyramid.

Find the vanishing line, \( V L \), of the plane \( X \), and the vanishing points, \( V \) and \( L \), of the lines \( A R, N Q, A N, R Q \); produce \( A R \) to \( K, N Q \) to \( M, A N \) to \( J, \) and \( R Q \) to \( L \), to meet the intersecting line \( I N \); join \( K V \) and \( M V \), also \( J L \) and \( L L \); then \( a n q r \) will be the section of the pyramid inscribed upon \( A N Q R \).

**Example 3.**—To find the section of a prism (fig. 7.), the same thing as before being given. Find the vanishing points, \( V \) and \( L \), of the lines \( A J \) and \( A K \), and the representations, \( K V \) and \( J L \), as before: draw \( L r \) parallel to \( J L \), and \( M n \) parallel to \( K V \), and \( q u a r \) will be the section of the prism required.

**Plate II. Fig. 3.** To find the section of a cuneiform or cono-cuneous, the same things as before being given, the base of the solid being \( a b c d e f g h \).

Let \( G a \) be the fyle of the plane, passing through the apex, and the centre of the base in the original plane, cutting the base of the solid in \( a \) and \( c \): divide each half on each face of the diameter, \( a e \), into any number of equal parts, as four: through the points of divisions draw lines parallel to \( a e \), which produce to meet the intersecting line; and let \( a e \) meet it in \( G \); then having drawn another series of lines at right angles, also to meet the intersecting, find the vanishing points, \( V \) and \( L \), of each of these series of lines: join \( G V \); from the intersecting points of the lines parallel to \( G \), draw lines parallel to \( G V \); also from the intersecting points of the other series of lines, draw lines to the vanishing point \( L \); then the figure \( a b c d e f g h \), formed by the intersections of these lines, will be the section of the cuneoid.

**Fig. 2.** Shews the method of finding the section of a cylinder upon the same general principle, only with this difference,
STEREOLOGY.

ference, that having found the vanishing points V and L, and the lines GV and HL; one set of lines is drawn from the intersecting points parallel to GV, and the other set is drawn parallel to HL; and by this means the figure abedfgb is the section of an oblique cylinder, whose base is FB.

Fig. 1 shews the section of a cone upon the same general principle, differing from fig. 2, in this respect, that, instead of the lines being drawn from the intersecting points parallel to GV and HL, they are drawn from the said points to V and L as vanishing points, and by this means form the section abedfgb of the cone.

In the same manner may be found the section of a cone, when the cutting plane is parallel to one of its sides, that is, to a plane touching one of its sides, and thus giving the parabola for its section; and when the cutting plane is parallel to any plane within the cone palling through its apex, and forming the section into a hyperbola.

Figs. 4, 5, 6, 7, are other methods, not differing in principle, but in the manner of laying them down, which is more convenient in the practice of Stereotomy.

IN is the intersecting line, IP the base of a plane perpendicular to the intersection IN, and PIE the inclination of the cutting plane; the point E is found as in the former cases; draw IN perpendicular to IE.

In fig. 4, IB is the line of the axis of a cone, whose section is thus found: for the sake of simplicity, divide the base, or its half, into equal parts, and draw one series of lines perpendicular to IN, to meet IN, and another through the same points perpendicular to IP, to meet IP; from these points, draw lines to D, to meet IE; and from these lines in IE, draw lines parallel to in; make IN equal to IN, np equal NQ, or draw n E, p E, q E; let the same distances on the other side of n in n produced from those points; draw lines again to E, and the figure abedfgb in the plane Z will be the section of the cone.

In the same manner, the section of a cylinder may be found by drawing lines parallel to the middle line GI, instead of being drawn to the point D. The truth of this method may be conceived by raising the plane Y upon IP, so as to be perpendicular to the plane X; then turning the plane Z at a right angle with the plane Y, so that n will fall upon IN, the point D will be the apex of the cone; then, if a set of planes be supposed to pass through the apex parallel to the intersecting line, and another set of planes to pass through the apex parallel to IP, and both sets through the same points (a, b, c, d, e, f, g, h) of the original figure, it will be evident that these planes will cut the sectional plane by their intersections with each other in the points, a, b, c, d, e, f, g, h.

Fig. 5 is an example of this method in a right cone, in which only one half of the section is shown.

Fig. 6 is an example in a cylinder, which only differs from the cone in the planes being parallel. Having found the middle line GD, and n E, as in the description of fig. 4, from the points of section in IP, draw a line parallel to GD, to cut IE; from the points of section in IE, draw lines parallel to IN, cutting n E; from the points p, p, p, q, q, &c. of section in n E, and upon the lines parallel to IN, make pb, pm, equal to pb or pm; make pe, pf, each equal to pe or pf; make pd, p, each equal to pd or p; make pe, pf, each equal to pe or pf; make pg, pb, each equal to pg or pb; then the points a and g, the extremities of the diameter, are the points of the extremities of the plane passing through ag, and consequently abedfgb is the section of the whole figure.

Fig. 7 shews the section by the same method, when the cylinder is a right cylinder.

PROB. V.

Given the plane X, the facts A, B, C, (fig. 8,) in the plane X, of three points on the surface of another plane Y in space, and the heights of the points in the plane Y, above the given plane X; to find the intersection of the plane Y with the plane X.

Draw the three parallel lines AD, BF, CE, through the points A, B, C; make AD equal to the height of the point whose foot is A; BF equal to the height of the point whose foot is B; and CE equal to the height of the point whose foot is C; join A, B, and produce it to H; join D, E, and produce DE to H; draw FG parallel to AH, and FH parallel to AB, and then FH be the intersection of the plane Y upon the plane X.

Demonstration.—Suppose AD perpendicular to AH, and consequently BF perpendicular to BG; then let the plane ADH be raised upon AH, until it becomes perpendicular to the plane X; and at the same time let the plane BFG be raised upon BG, until it becomes also perpendicular to the plane X; then, because the triangle ABD is similar to the triangle ADH, and since both the planes ADH and BFG are perpendicular to the plane X, and their intersections A and B, with the plane X, are parallel, FG will be parallel to D H; and because AD and CE are perpendicular to AH, AD and CE will be perpendicular to the plane X, and for the same reason BF is perpendicular to the plane X; therefore the points A, B, C, in the plane X, are the feet of the three points D, E, F, raised to the plane Y; and because FG and DH are parallel, the points in FG and DH are in the plane Y; therefore the points G and H, which are common to the plane X, and to the lines D H and F G, are also in the plane Y; and because the points G and H are common to both the planes X and Y, therefore the straight line GH is common to the planes X and Y; whence the straight line GH is the intersection of the planes X and Y.

PROB. VI.

Given the plane A B C, (fig. 9,) of three points on the curved surface of the segment of a right cylinder in the plane of the base X, and the heights of the points; to find the section of the cylinder.

Find the intersection GH, as in the fifth problem; let AC be the base of the plane of the segment, which is perpendicular to the plane X: draw AI and CK parallel to GH; and draw CL perpendicular to AI, cutting AI in L; make LI equal to the height upon the point A, and CK equal to the height upon the point C; and join IK. In the base ABC take any intermediate points a, b, c, d, &c.; and draw the lines af, bg, ch, di, ek, meeting IK at f, g, h, i, k; through the points f, g, h, i, k, draw fa, gb, ch, di, ek, perpendicular to IK; make JA, JB, JC, &c., respectively equal to LA, FA, GB, HC, &c., and join A K, and draw the curve AB, &c.; KA will be the section of the cylinder, as required.

Demonstration.—Imagining a series of planes to pass through the points A, B, C, D, E, C, parallel to GH, and perpendicular to the plane X of the base; also a plane to pass through LC perpendicular to the said plane X; then all these planes will be parallel to the axis of the cylinder, and the plane standing upon LC will be perpendicular to the planes passing through the points A, B, C, D, E, C, as well as to the intersection GH. Suppose, therefore,
fore, L C and I K to meet each other in P, P will be in the straight line G H; and if the triangle I P L be raised upon L P, until its plane becomes perpendicular to the plane of the base, and supposing the sectional plane, Y, to be turned round I K, until its plane becomes perpendicular to the plane of the triangle I P L, and upon the same side of the triangle I P L as the base L A B C; then, if the plane A I K be produced, it will meet the plane of the base in G H; for the plane L P I will then be perpendicular to the two planes L A B C and L A K, and will therefore be perpendicular to their common intersection G H. Therefore, A I K B is the section of a segment of the cylinder, as cut by a plane passing through three given points in the surface, as was to be shown.

STEREOTYPE PRINTING. This art having of late years come very much into use, we shall give a short sketch of its history, practice, and advantages.

The method of printing linen and paper-hangings has been known in the East from time immemorial. Printing on wooden blocks, which is the mode now used by paper-hangers, has been practised fifteen or sixteen hundred years in China. According to this plan, when an author means to print his work, he has it fairly transferred upon a thin and semi-transparent paper. Each leaf is then revolved upon a smooth block of hard wood, upon which the engraver cuts the characters in relief. There must, therefore, be a separate block for every page. About the close of the 14th century, the Italians, Germans, Flemings, and Dutch, began about the same time to engrave on wood and copper, but the previous advances had been gradual. The impressions in relief, upon monuments and altars, in the cloisters, and over church, porches, served as models for block-printing. The letters upon painted windows resemble those in the books of images. The invention of cards was probably an intermediate step; and it has been inferred, as well from edits civil and ecclesiastical, as from the figures on the cards, that these were first brought into use about the year 1376, to amuse, Charles V. of France. By the shape of the crowns, and the sceptres with the fleur-de-lis, it has been thought they were invented by the French; but the names of the suits rather imply, that they are of Spanish or Italian origin. At first cards were painted, but about the year 1400, they were printed from wooden blocks. To this we may directly trace the art of printing. The books of images, which form the next step, were printed on wooden blocks: one side of the leaf only is impressed, and the corresponding text is placed below, or on the side, or proceeding from the month of the figure. Of these scarce books, Lambins gives the following enumeration: 1. "Figura typica veteris atque antitypicae Novi Testamenti," which in Germany is called the Bible of the poor, because it was originally intended as an abridgment of the scriptures, for those who could not purchase, or who had not leisure to read the whole. There is a copy of this work in the Bodleian library, and another at Christ's college, Cambridge. 2. "Historia S. Joannis Evangelista, ejusque viarones evangelistae, ejusque viarones apocalyp- ticae." 3. "Historia fen Providentia Virginis Marie, &c." 4. "Ars moriendi." 5. "Ars memorandi notabilis per figuram Evangelicialium." 6. "Donatus, feu grammaticae in usum scholaram concripta." 7. "Speculum humanitatis.

It is almost certain, therefore, that from the cotton and silk-printing of the Indians, the Chinese block-printing, and the books of images just alluded to, and perhaps from the mode of writing among the bards, who cut their poems upon bars of wood, and which they call carving a book, the idea of stereotype printing is not of modern origin. That it was prior to the art of printing by moveable types there can be no doubt, since this latter mode of printing was first suggested by the Catholic, which was printed with wooden tablets, in a series, and composed in forms. This mode of printing, except in China, where it is still practised, was had aside soon after the invention of the common letter-press printing.

The history of the modern stereotype is involved in some obscurity. In the Philological Magazine is the following account: "Above a hundred years ago, the Dutch were in possession of the art of printing with fold or fixed types, which were in every respect superior to that of Didot's stereotype. It may, however, be easily understood, that their letters were not cut in so elegant a manner, especially when we consider the progress which typography has made since that period. Samuel and J. Leuchtermans, booksellers at Leyden, have fill in their possession the forms of a quarto bible, which were constructed in this ingenious manner. Many thousand impressions were thrown off, which are in every body's hands, and the letters are still good.

The inventor of this useful art was J. Vander Mey, who resided at Leyden about the end of the 16th century. With the assistance of Muller, the clergyman of the German congregation there, who carefully superintended the correction, he prepared and call the plates for the above-mentioned bible, in 4to. This bible was published likewise in folio with large margins, ornamented with figures, the forms of which are still in the lands of Elwe, a bookseller at Amsterdiam, also an English New Testament, and Schaaff's Syriac Dictionary, the forms of which were melted down: likewise a small Greek Testament, in 18mo. As far as can now be ascertained, Vander Mey printed nothing else in this manner; and the art of preparing fold blocks was lost at his death, or at least was not afterwards employed. The Dutch editor supposes, that the reason why Vander Mey's invention was dropped was, that the process was too expensive.

In the year 1781 was printed, by Mr. Nichols of London, a pamphlet, entitled "Biographical Memoirs of William Ged," including a particular account of his progress in the art of block-printing. The first part of the pamphlet was printed from a MS. dictated by Mr. Ged just previously to his death: the second part was written by his daughter, for whose benefit the profits of the publication were intended: the third is a copy of proposals, issued by Ged's son, in 1751, for reviving his father's art; and to the whole is added Mr. More's narrative of block-printing. It should seem from this publication, that in the year 1775, Mr. Ged began his scheme of block-printing. In 1777 he entered into a contract with a person who had a small capital, but who, alarmed at the supposed risk of losing the little which he had, abandoned the concern, after he had expended little more than twenty pounds. In 1779 he entered into a more promising partnership with a Mr. Fenner, Mr. Thomas James, a type-founder, and John James, an architect. Some time after a privilege was obtained from the university of Cambridge to print bibles and prayer-books; but it appears, that one of his partners was actually aware of the plan, and, to thwart the project, engaged such people for the work as he thought most likely to spoil it. One of his people who was entrutted with the secret, avowed, that all the books printed in stereotype had been purposely made incorrect, in consequence of which they were suppressed at the university, and the plates sent to the king's printing-office, and from thence to Caflon's foundry. "After much ill usage," says the writer
STEREOTYPE.

writer in the Philosophical Magazine, "God, who appears to have been a person of great honesty and simplicity, returned to Edinburgh. His friends were anxious that a specimen of his art should be published, which was done by subscription. His son James, who had been apprenticed to a printer, with the consent of his master let up the forms in the night-time, when the other compositors were gone home, for his father to call the plates from, by which means Saltill was furnished in 1736." A copy of this work is in Mr. Tilloch's possession, and also a plate of one of the pages from which it was printed. Another work was also printed from plates manufactured by Mr. Ged; this was the well-known book entitled "The Life of God in the Soul of Man," which has the following imprint; "Newcastle, printed and sold by John White, from plates made by William Ged, goldsmith in Edinburgh, 1742."

Fifty years after the invention of plate-printing by Mr. Ged, Mr. Tilloch tells us he made a similar discovery, without having at the time any knowledge whatever of God's invention. He was aided in bringing his discovery into practice by Mr. Foulis, printer to the university of Glasgow. They overcame every difficulty, and were able to produce plates, the impressions of which were as perfect and handier as those of the types from which they were cut. Though they had reason to fear, says Mr. Tilloch, from what we afterwards found Ged had met with, that our efforts would experience a similar opposition, we persevered in our object, and took out patents for England and Scotland, to secure to ourselves, for the usual term, the benefits of our invention; for the discovery, he adds, was as much their own, as if nothing similar had been practiced before. God's knowledge of the art may be said to have died with his son, whose proposals for reviving it, published in 1751, not having met with encouragement, he went to Jamaica, where he died. Owing to circumstances of a private nature, not at all connected with the stereotype art, the business was laid aside after some few volumes had been stereotyped and printed under the direction of Meffrs. Tilloch and Foulis.

Some time elapsed, when M. Didot, a French printer, applied the stereotype art to logarithmic tables, and afterwards to several of the most popular classics, such as Virgil, Horace, &c. and to various French publications. On this account, the French lay claim to the invention, but purely without even the appearance of justice. About the year 1800, Mr. Wilton, a printer in London, engaged with earl Stanhope, for the purpose of bringing the stereotype art into general practice. His lordship is said to have had some communications with Mr. Tilloch on the subject, and afterwards to have received the personal attendance of Mr. Foulis at his feast, at Chevening, in Kent, where the noble earl was probably initiated into the practical part of the operation, and for which, we have heard, he paid 700l. as a remuneration.

After some years application, Mr. Wilton, who at that time lived in the neighbourhood of Lincoln's-Inn-Fields, but who afterwards removed to St. Pancras, and carried on the business on a very extensive scale, announced to the public, that the genius and perseverance of earl Stanhope had overcome every difficulty; and that accordingly, the various procresses of the stereotype art had been so admirably contrived, combining the most beautiful simplicity, with the most defirable economy, the ne plus ultra of perfection, with industry, fidelity, and promptitude, done for the public, that looking forward to the happy period when an application of this valuable art to the manufacture of books would be the means of reducing the price of all standard works, at least thirty, and in many cases forty, per cent.

In 1804, Mr. Wilton offered, upon certain terms advantageous to himself, the stereotype art to the university of Cambridge, for their adoption and use in the printing of bibles, titel- and prayer-books. Some differences between the syndics and the printer caused the contract to be dissolved. In these disputes it is not our business to enter; it will be sufficient to add, that at present, at Oxford as well as at Cambridge, the stereotype art is adopted, and thousands of bibles, &c. issue annually from their presses, printed on that plan.

The practice of stereotype printing is readily described: a page of any work is let up in the usual mode of printing, (see the article PVENTORY,) from which a mould of platter, similar to plate of Paris, is taken off, and from this a plate in type metal, from which the stereotype print is worked. Of course the whole is let up in distinct pages, which are to be put together in the usual way before a sheet is worked at press.

It is evident, therefore, that the beautiful specimens of stereotype printing sometimes exhibited, and which have induced many persons to ascribe that merit to the art, does not in reality belong to it. A stereotype plate is a fac simile of the page from which it was taken, and consequently cannot exceed in beauty the original stamp. Stereotype, therefore, can give no additional beauty to printing; this depends on the taste of the letterfounder, and the care of the prelaid. Those who produce fine specimens of stereotype printing, could also give others equally good with the moveable types from which the plates are cast.

The metal of which the plates are to be cast is a compound of regula of antimony and hard lead, or tea-ches't lead. The general method of mixing the metal is to take one hundred weight of regulus of antimony, and break it into small pieces, separating from it all dust and dirt, and then add to it from five to eight hundred weight of hard lead, according as the metal is required to be more or less hard. The lead is to be melted over a slow fire, and when melted, and the fume taken off, the regulus is to be put in. To every hundred weight of lead may be added a pound or two of block-tin, but this is not necessary.

In casting the plates, as in every other casting, a mould must first be made, so as to form the counterpart of the original type. The substance required for this must be of a delicate texture when soft, as to be capable of receiving an impression from the finest lines; and when dry, it must be capable of bearing the action of melted metal. These qualities will be found in gypsum or platter of Paris. Gypsum in the rock, as it is called, which is the belt, is plentiful in Nottinghamshire. It has been observed, that this substance, when pulverized and mixed with water, soon becomes very hard, and will bear almost any degree of heat; but it contracts when exposed to fire, and is liable to warp. It is also extremely difficult to expel the air and moisture which it rapidly absorbs, and tenaciously retains. These are defects respecting the proces of casting, which require to be corrected by compounding it with other substances less absorbing than itself. But whatever be added to it must be capable of a fine surface, so as to preserve a perfect polisle on the plate to be cast. The following processes have been recommended: dissolve a quantity of common whiting in a quantity of water, and make it into a paste, and of the confid of some substance which is generally used in white-washing. Mix the plaster with this solution, and it will contract but little from the heat; the air and the moisture will be expelled with greater ease, and
and the mould will not be so liable to crack as the plaster would alone.

In making a perfect mould for the page to be cast, a frame of cast-iron must be prepared, nearly half an inch wider and longer than the page or pages locked up in the chases. The frame determines the thickness and strength of the mould, and requires to be nearly an inch deep. To this must be added four cubic pieces of metal, whose height should be exactly four-fifths of the height of the letters.

On the height of these, the thickness of the stereotype plate depends. The pages in the chases are now to be laid flat upon the moulding table, and the letter, if necessary, is to be placed down to an even surface. In the openings of the four corners of the page are to be placed the four pieces of metal, on which the frame is to rest when laid over the page.

To prevent the adhesion of the plaster, it will be necessary to oil the face of the page with a soft brush; then take a quantity of the white-wash into a wooden bowl, and add to it so much fine plaster as will make it into a thin paste. When reduced to an equal consistency, apply it to the face of the letter with a painter's brush, so as to fill every cavity, and then pour on the remainder of the plaster to fill the frame. When beginning to harden, strike off the superfluous plaster with a straight metal rule, and the back of the mould will be smooth and regular. The mould is next to be separated from the page, and to be dried in an oven.

In casting the plates, the dried mould is to be laid in a pan about two inches deep, with the face upwards, and a small moveable ferew is to be placed at each side or end of the pan to furnish a press on the frame which contains the mould, and prevent the rising up, and the metal is applied over the mould in the pan, and carried to the oven, in which it should remain from one to two hours, to acquire an equal degree of heat; for on the principle of equal temperature between the metal and moulds, the success of the operation wholly depends. And unless the oven be kept sufficiently hot to raise the temperature of the moulds to that of the melted metal, the experiment cannot succeed.

Such is the fineness of the composition of the moulds, and such the accuracy of the process, that plates may be cast from the finest engravings as perfect as the copper-plate itself, and might be worked in the same manner, could it be cleaned after each operation with the same facility, and if the metal did not discolour the paper. Wood-cuts, ornaments, &c. are cast in the same manner, perfectly correct. The art has also been applied to the printing of music.

When the pages are returned from the foundery, they require to be thoroughly cleaned; for if the oil be not removed, it cannot only be disagreeable to distribute and compose, but the dirt which adheres to it will spoil the next mould to be made from it; hence it is necessary that the letter be thoroughly cleaned with boiling water and a brush, which increases the expences attached to this art very considerably.

After a plate has been cast, a few small imperfections will frequently be discovered; such as that the eye of the e, or similar letters, may have been full of dirt when the mould has been taken; of course the plate will exhibit those parts filled with metal, which now require to be corrected. A workman, called a picker, takes the plate, and after clearing it of all superfluous metal, pulls a proof, marks the defects, and proceeds to make the requisite alterations in a manner that will now be easily understood. If, in the course of the work, any damage be done to the plate, or any letter or word be broken, the picker cuts it out, and inserts its place a

Brought forward                        £  s. d.
Coll of the first five hundred, second, and of each subsequent five hundred, will be
38l. 5s. 3d.                            119 1 0

Common printing                        386 17 9
Balance against stereotype, after four years 50 13 3
The next edition of four thousand copies by common printing will cost as before 336 4 6
Ditto on stereotype eight times 38l. 5s. 3d. 306 2 6
Balance in favour of stereotype in the second edition 30 2 6

Hence it appears, that it will require more than ten years to clear the expense of the plates only, and after that it will yield a profit of 30l. 2s. 6d. on every subsequent edition of 4000 copies.

From the foregoing estimate, and several others given by the same author, which are not more favourable to the new mode of printing, other advantages must be looked for than those which result from pecuniary savings; but new discoveries may render the process still more economical than it is at present: thus, if the pages could be cut to the true size, that might go to press, and be worked with the same ease and expense as movable type; and if a substitute could be found for oiling and brushing the pages so as not to wear the type, or increase the labour of the compositor, more decided advantages would result from the introduction of stereotype: such as the following.

II. On books published in parts or numbers. Purchasers frequently take in the early parts and leave off, by which the fets become broken and uneven, and a great loss is incurred by the wafte of paper. This might be prevented by stereotype, which so remarkably facilitates the perfecting any parts or numbers that are found deficient.

2dly. On new books of doubtful sale. The plan of casting plates would not involve an expense of more than fixspence for an octavo page, besides the metal, which will still retain its value. So that a hundred, or a large number of copies, might be struck off to ascertain the opinion of the public. If it did not sell, the fets on a work of 20 sheets would not be more than about 8s., besides the composition; but if 500, or 750 copies were printed in the common way, and not sold, the loss would be from 30l. to 40l.

3dly. The principal advantage is unquestionably on stock books, whether bibles, prayer-books, or school-books, particularly works of arithmetic, and other branches of mathematics. There, by means of the stereotype, may be brought to perfect accuracy; and having once attained to that standard, may be kept on without the possibility of deviation: for this excellence, the public would not grudge even an extra price.

STEREOXYLON, in Botany, from $x_{2}$, hard and fold, and $x_{2}$, wood, a name given by Ruiz and Pavon in their Flora Peruviana, to the genus which has long before been called Linnaeus Escallonia, (see that article,) in honour of one of their distinguished botanical countrymen. Of this prior appropriation of the genus, they seem not to have been aware. Poiret, however, in Lamarck's Dictionary, v. 7, 424, has followed their error, and described eleven species of the genus in question, all natives of Peru or Chili, in cold, moist, shady, sometimes very elevated situations.

STERILE LAND, in Agriculture, those sorts which are unproductive in consequence of their particular nature and qualities; or which contain only small portions of nutrient soluble matters in their compositions.

In the examination of the constituent parts or matters of sterile lands, in the intention of ameliorating and improving them in regard to their fertility, any fort of component material, which is known as a cause of barrenness or unproductiveness, should be well and carefully attended to and considered; and if the whole of their composition can be nicely compared with that of some good and productive lands, in nearly the same situation and vicinity, the differences in the component substances of them may, in different instances, point out the most proper and ready methods of improving them.

Where lands of this sort become so in consequence of their stiff clayey nature, they may be improved and brought into a productive situation by the use and application of sandy, earthy, calcareous, marly, and other similar matters. Where lands are deficient in fertility, on account of their abounding too much in calcareous matter, they may be greatly improved and rendered more fruitful by the putting of sandy or clayey materials upon them. Where lands are unproductive, in consequence of abounding too much in sandy matters, they may be improved in their texture and other qualities, as well as rendered more capable of producing good crops, by the applying clay, clayey marle, and earthy vegetable materials to them. The application of peaty or turfy matters over the surfaces of light burning sandy lands, has been found to be attended with immediate and permanent good effects in many instances. Where lands are sterile in their nature, from containing too great quantities of ferruginous, ochry, or saline, irony, and acid matters in their compositions, they may be greatly benefited in their productiveness by the use of quicklime in suitable proportions.

In lands of otherwise good qualities and textures, which were infertile from containing too large proportions of the sulphate of iron, it has been found that they have been rendered productive, by having quicklime laid over the surfaces of them, as that substance has the property of converting this sort of sulphate or vitriolated iron into a manure, which serves as the food of the plants upon them.

Where lands become infertile from the deficiency of earthy, vegetable, or animal matters, the obvious means of removing it is the free use of suitable substances of the manure kind in proper proportions. Where the excesses of vegetable or other such matters causes improprieties in the growths of the crops, it is capable of being reduced readily by the practice of burning, or of being altered and improved by the suitable application of proper earthly materials of different kinds.

Where boggy, peaty, moory, or marshy lands are to be improved in their fertility and productiveness, the first steps to be taken for the purpose are mostly those of properly inclining and drawing off the superabundant moisture or wetness, both of which greatly contribute to these ends; and the latter promotes the growth of all sorts of nourishing kinds of plants, by the removal of injurious stagnant moisture. Some soft black peaty kinds of land, which have undergone this beneficial action, are not unfrequently produced into fertile and productive, merely by the application of sandy or clayey matters over their surfaces in due proportions; and repeating them as there may be a necessity. Where such peaty lands
lands are of a four acid nature and quality, or contain fer-
roginous, ochry, and saline matters, the use of lime, or other
calcareous materials in sufficient quantities, is indispensably
necessary for bringing them into a proper state of culture, and
for rendering them productive, either in the arable or
grafs state. When they abound with ligneous matters, and
different coarser vegetable products, which prevent their being
made productive, they are to be removed or reduced by
burning the superficial parts; in which last case, the ashes
thus afforded may supply earthy materials suited to the
improvement of the texture and other qualities of such
lands.

In short, in this business the farmer should cautiously fol-
low, as much as he possibly can, the lessons and methods held
out to him by nature, in her means of improving different
lands of this sort; and the result of his labours will be the
rendering them permanently more beneficial by their in-
creased fertility; by their requiring less expense in dressings
afterwards; and by the value of the lands being for ever after
greatly augmented.

The particular nature and caufes of sterility in lands,
have been stated and explained in speaking of soils. See
Soil.

STERILITY, formed from sterilitas, of sterilis, barren,
the quality of a thing that is barren; in opposition to
fertility.

Sterility was held a grievous affliction by the wives of the
ancient patriarchs. Nature has annexed sterility to all mon-
frous productions, that the creation might not degenerate.
Hence the sterility of males, &c.

Women frequently become sterile after a miscarriage, or
a difficult labour, by reason the uterus, or some other of the
genital parts, are injured thereby.

STERIPHA, in Botany, so named by Dr. Solander
from eiperiph, in allusion, perhaps, to the mean and dry
integument of its fruit, which, though at first sight resembling a
berry, proves unprofitable, in that respect, to the gatherer.
—Gartn. v. 2. 81. t. 94. —Clafs and order, Pentandria
Dignia.

This is no other than DICHONDIA of Forster. (See that
article.)

Gartn. speaks of it as a very distinct and singular
genus, having the habit of Silphoria europea, but in the
number of its parts of fructification, nearly agreeing with
Scherbera. Now it happens that the Scherbera alluded to is,
as we have said in its proper place, merely a Cucurbita,
growing on a Myrtis. Whether Solander or Gartn. made
this allusion to it, they could only have in view its artificial
characters and place in the Linnean system, for the plant
itself was, at that time, unknown to them.

STERIS, a Linnean name, of whose meaning or application
we have no information; nor is it a matter of any con-
sequence, the plant which bears this name, S. javana,
Linn. Mant. 8. and 54, being the fame with Naana zeylanica,
Linn. Sp. Pl. 327, and in fact a species of Hydrangea.
See that article; p. 4.

STERKE, J. F. X. Abate, in Biography, first chapell-
master to the elector of Mentz, was born at Wurzburg in
1743, went into Italy at the expense of his patron in 1781,
where he chiefly resided at Rome and Naples, in which cities
he was much esteemed for his amiable character. He formed
his style on the taste of the Italian school, to which he has
constantly adhered.

Besides many compositions for the harpichord and piano
forte, which he produced in Italy, he composed at Naples
the opera of "Farnace."

In 1782 he returned to Germany, and the next year
published at Vienna, we think his best and most pleasing work,
" Six Sonatas for the Piano Forte or Harpichord, accom-
panied by a Violin and Violonecello obligati, dedicated to his
XVII." These sonatas, when well accompanied, are ex-
tremely interesting and amusing. The abbe Sterkel there, as
in all his compositions for keyed instruments, has manifested
that he did not visit Italy improbably; his productions,
though not very laboured or learned, are full of spirit, taste,
and pleasing pallages; and he has not only collected all the
vocal flowers of the greatest opera-fingers of the present
times, but scattered them liberally through his works. His
violin accompaniments generally consist of pallages of effect,
and such as give importance to the player. Indeed his pieces,
though not very original, are left tinturied with Bachifm,
or Haydnism, than those of his countrymen who have not
visited Italy; and though left solid, and left his own propri-
erty than those of many modern composers, yet they are more
easy to execute, and more intelligible to unlearned readers.
We have been assured by some of his scholars, that he played
on the clavechord and piano forte, with such taste, expression,
and chiaro-fofo, as few performers, except Emanuel Bach,
ever arrived at.

STERLING, a term frequent in the English commerce.
A pound, shilling, or penny flearing, signifies as much as a
pound, shilling, or penny, of lawful money of England, as
fettled by public authority.

Antiquaries and critics are greatly divided as to the origin
of the word flearing. Buchanan fetches it from the castle of
Striveling, or Strirling, in Scotland, where a small coin was
anciently struck; that in time, according to him, came to
give name to all the reit. Camden derives the word from
caterling, or ceterling; observing, that in the reign of King
Richard I. money coined in the exult parts of Germany
began to be of especial request in England by reason of its
purity, and was called ceterling money, as all the inhabitants
of those parts were called ceterlings; some of whom, skilled
in coinage, were soon after, vis. in the reign of King John,
sent for to perfect the English money, or reduce it to its
due fineness, which was thence forwards denominated from
them, flearing, or caterling, or ceterling: not, says Camden,
from Striveling in Scotland, nor from fiella, a flat, which some
dream to have been coined upon it; for in old deeds, the
English species are always called nummi catularum, which im-
plied as much as good and lawful money, &c. Clarke, in his
connexion of the Roman, Saxon, &c. Coins, p. 80, obser-
vies, that the Saxon or English pound was called the pound flear-
ing, because their ancestors brought it from the most eafier
parts of Europe, the flores of the Exuame; and that they
called it libra feterlingorum, the pound caterling or flearing,
to distinguish it from the Roman pound, which, to preserve
the same distinction, was called libra occidentis, or the weftern
pound. Sommer, again, derives the name from the Saxon
fleere, a rule or standard: intimating, that this, as to weight
and fineness, was to be the common standard of all current
money.

In Stow, and some other of our ancient writers, flearing,
or caterling, is also used for a certain coin, in value amount-
ing nearly to our silver penny; and on some occasions we
find the fame word flearing used in the general for a piece of
money, it being observable, that for a good while together,
there was no other coin but pennies, with which flearings or
eaterlings were become synonymous: much as, among the
ancients, the words denarius and nummus were used.

STERLING, in Geography, a plantation in Kennebec county,
and
STE

and state of Maine, N.W. of Hallowell.—Alfo, a township
of Connecticut, in Windham county, 44 miles E. of Hartford;
containing 1,101 inhabitants.—Alfo, a township of
Franklin county, Vermont, containing 1,223 inhabitants.—
Alfo, a town of Worcester county, in Massachusetts, in-
corporated in 1781, and containing 1,472 inhabitants; 62
miles N.E. from Worcester.

STERLINGVILLE, a post-town in Granville county,
North Carolina; 267 miles from Washington.

STERLITAMATZK, a town of Ruffia, in the go-
vernment of Upha. N. lat. 54° 40'. E. long. 53° 54'.

STERN, a Ship, denominates her posterior face; or that
part which is presented to the view of a spectator, placed
on the continuation of the keel behind. It is terminated
above by the taffarel, and below by the counters; it is
limited on the sides by the quarter-pieces; and the inter-
mediate space comprehends the galleries and windows of
the different cabins.

STERN, among Hunters, is the tail of a wolf, or a grey-
hound.

STERN-CHAPEL, See CHASE.

STERN-PIFF, aboard a Ship, some fastenings of ropes, &c.
behind the stern of a ship, to which a cable or hawser may
be brought or fixed, in order to hold her stern to a whale,
&c.

STERN-FRAME, in Ship-Building, the strong frame of
timber, composed of the stern-post, transoms, and faftion-
pieces, which forms the back of the whole stern.

STERN-LADDERS, are made of rope and tree-nails, and hang
over the stern of ships, to come on board by in very rough
weather.

STERN-MOFT, in Sea Language, usually denotes that part
of a fleet of ships which is in the rear, or farther aft-tern,
as opposed to head-moft.

STERN-PIT, in a Ship, a great timber let into the keel at
the stern of a ship, somewhat fiberglass, into which are fasten-
the after-planks; and on this poft, by its pintle and gud-
geons, hangs the rudder.

It is usually marked, like the stem, (which see,) with a
scale of feet from the keel upwards, in order to ascertain
the draught of water at that part of the vessel. The dif-
ficulty of procuring a stern-post of sufficient breadth in one
piece, has introduced the practice of fixing an additional
piece behind it, which is strongly bolted to the former. The
barges, which support the rudder, are accordingly
fixed to this latter, which is also tenoned into the keel, and
denominated the back of the poft. It is half the breadth
of the stern-post at the keel, but diminishes gradually to-
wards the upper end, where it is one-third narrower.
The stern-post is strongly attached to the keel by a knee,
of which one branch extends along the keel, being scarfed
and bolted to the dead-wood, and fore-locked under the
keel, while the other branch inclines upwards, and cor-
responds with the inside or fore-part of the stern-post, to
which it is also bolted in the same manner. Falconer.

STERN-SHEDS, that part of a boat which is contained
between the stern and the aftmoff, or hindmost part of the
rowers. It is generally furnished with benches to accom-
modate the passengers. Falconer.

STERN-WAY, in Sea Language, the movement by which a
ship retreats, or falls backward, with her stern foremost.

STERN-WAY, To make. See Make.

STERNA, the Term, in Ornithology, a genus of birds of the
order Anseres, of which the generic character is: Bill
fulminate, straightish, pointed, a little compressed, without
teeth; nostrils linear; tongue pointed; wings very long; tail
mossily forked. Twenty-four species of this genus are enu-
merated by Gmelin: they are mossily inhabitants of the ocean,
and feed on fishes. Many of them are found on the shores of
large lakes and rivers. Four of the species are common to
our own country. They breed among small tufts of
rushes, and lay three or four eggs of a dull olive colour,
fotted with black. The birds belonging to this genus are
at all times clamorous and gregarious, but more particu-
larly in the spring of the year, during the time of nesting.
At this period they assemble in large flocks, and their ac-
ivity seems greatly increased, for they repeat with eag-
rel their sharp piercing notes so frequently, that persons
cannot approach the place where they breed without being
almost stunned with their noise. With us the terns are
migratory, leaving our shores regularly on the approach of
winter.

Species.

CASPIA. The Caspian tern has its body above of a
plumbeous-ash; beneath and neck white; the bill is scarlet;
the frontlet and legs are black. It is found, as its specific
name denotes, on the Caspian sea, and is nearly two feet in
length. It frequents the sea-shores and banks; feeds on
small fish and sea-animals, hovering over the water, and
frequently darting into it for its prey. The bill is red;
rids dusty; tail short, forked; tail-feathers tip with
black; the legs are brownish. There are three varieties:
1. Crown black, spotted with white; tail-feathers with
brown bars. It inhabits Bombay, and is twenty-one inches
long; its bill is red; and legs black. 2. Crown black;
head-head sub-crested; outer tail-feathers white from
the middle to the tip; the bill is yellowish; and the legs
black. It inhabits China, and the Sandwich islands.
3. The bill in this is white; frontlet varied black and
white; ears black; back and wings cinereous; quill and
tail-feathers tip with black.

CAYANENSI S; Cayenne Tern. Cinereous; the feathers
edged with reddish; beneath they are white; the hind-head
is black. It inhabits Cayenne, and is sixteen inches long.

SURINAMENSI S; Surinam Tern. Bill, head, neck, and
breast, black; back, wings, and tail, cinereous; belly
whitish; legs red. It inhabits Surinam, and is about
fifteen inches long.

FULIGINO S A; Sooty Tern. Black; beneath, checks,
front, and shafts of the quill and tail-feathers, white. It
inhabits the Atlantic and Antarctic seas, and is sixteen
inches long. The bill and legs are white; the eggs yellowish,
with brown and violet spots; outer tail-feathers white,
except at the tip.

AFRICA NA; African Tern. White; bill and legs
black; crown, wings, and tip of the tail, spotted. It is
an African bird, and is about the size of the S. fuligino-
sa. The crown is spotted with black, the wings with brown,
and the tail with white; quill-feathers blueish-ash.

STOLIDA; Noddy. Body black; front whitish; eye-
brows black; bill and legs black; the hind-head is cin-
ereous. It is fifteen inches long; found chiefly within the
tropics; is clamorous; seldom goes far from shore, and
always reste at night. It builds on rocks; and its eggs
are excellent food.

PHILIPPINA; Philippine Tern. Claret-grey; cap white;
band through the eyes, wings, tail, bill, and legs, black.
It is found on the shores of the Philippine islands; and
is about twice as large as the common fwalow.

SIMPLEX; Simple Tern. Above plumbeous; beneath,
crown,
crown, greater and middle wing-coverts, white; band behind the ears and quill-feathers black. A variety has the bill and legs black. It inhabits Cayenne; and is fifteen inches long. The bill and legs are red; some of the wing-coverts edged with brown.

**NITELICA;** Egyptian Tern. Cinereous; beneath white; head and neck with blackish spots; orbits black, dotted with white. It inhabits Egypt; and is above the size of a common dove. The bill is black; and the legs of a flesh colour.

*CASTALCA;* Sandwich Tern. White; back and wings hoary; cap black; front with white spots; quill-feathers blackish, with a white shaft. The bill is black, but yellowish at the tip; the legs are black; wings longer than the tail; the egg is of an olive-brown, with purplish and crowded spots; it is full eighteen inches long, and is found on the Kentish coast, generally appearing about Romney in the middle of April, and leaving the country in September. It is rather common at Sandwich, where it was first noticed by Mr. Boys. There are two varieties of this species: 1. Tail hardly forked; body variegated; ears with a black spot. 2. Above black, varied with paler colours; beneath white; tail forked; bill and legs black. This last is found in Finland.

**HIRUNDIO;** Common, or Greater Tern. The two outer tail-feathers are half black and half white. There is a variety that has black legs; outer tail-feathers entirely white. The greater tern is about thirteen inches from the tip of the bill to that of the toes; its breadth, when the wings are spread, is about two feet. It is of a slender but elegant form, which is increased by the beautiful plumage with which it is adorned. The back is covered with a grey mantle; the breast is of pure white, elegantly contrasted with a large black spot upon the crown of the head, resembling a hat; the bill and legs are red. Early in the spring this species arrives on our own coasts, and sometimes is seen in a considerable way from the shore, in the interior parts of the country, hovering about the lakes and rivers. They are observed by sailors during the whole passage from Britain to Madeira. They are the most active fithers of all the aquatic tribes; insatiabley darting upon the prey which they observe from a great height in the air. After having dived and caught the booty, they as suddenly ride again to their former elevation.

The action of the stomach which this tribe exhibits is amazingly powerful; the fish being so completely digested in their stomach, they swallow them whole, as is proved by the number of bones which they vomit after feeding. Those parts of the food that are nearest the bottom of the stomach are dissolved, and make way for the rest, which soon undergoes the same process.

Immediately after the arrival of this species of the tern, the pairing feaston commences; during which each female chooses a warm bed of fand, where the deposits three eggs, of a size far superior to what might be expected from a bird of her dimensions. The eggs of the tern are of different colours, some grey, others brown, and some of a greenish hue. The manner in which their eggs are hatched is as singular as their external appearance, for it is accomplished chiefly by the heat of the sun. If the weather be dry and warm, the female seldom hatches by day, but resumes her maternal functions regularly about the time that the influence of the sun begins to decrease.

The young are not all protruded at the same time, but in the order in which the eggs were laid; and at the interval of a day between each of the three birds. The young terns are no sooner protruded from the shell, than they leave the nest, and follow the parent bird, who supplies them with small morsels of the fish upon which they themselves feed. During the whole period of incubation, the parent birds display great solicitude for the safety of their eggs and their young. Should a person at this period approach their nest, both parents dart down from the air, and flutter about him, uttering all the while the most piercing screams, expressive at once of their fear, anxiety, and rage. These parental care from cafe; the young soon become capable of pecking their own food when provided for them. For a few days they are fed by the mother's bill; afterward, what food the parents provide, they below without even alighting upon the ground. Fond of indulging in their aerial excursions, they drop down the food upon their young, that are waiting below to receive it.

Terns are provided with very large wings, and from this very circumstance the young are not soon able to fly, their wings not being strong enough to accommodate them for flight. In this circumstance they resemble the swallow, which remains longer in the nest than any bird of its size, and leaves it more completely feathered. During this period of nonage, the parent terns continue to shower down plentiful supplies of food to their young, who at a very early period begin to dispute for their prey, displaying that inatiable gluttony which characterizes their race. The colour of the first plumage is a whitish-grey; the true colour is not obtained till after the first moulting.

**PAVAYENSIS;** Panayan Tern. Beneath white; crown spotted with black; wings and tail brown; beneath pale. This species inhabits Panay, and is the size of the last. The bill and legs black.

**CINERA;** Cinerous Tern. This species is cinereous; the head and chin are black; the lower tail-coverts and upper edge of the wings white. It inhabits Italy, and is thirteen inches long. The bill is black; legs red; chin sometimes spotted with white.

**ALBA;** White Tern. Entirely white; the bill and legs white. It inhabits the Cape of Good Hope.

**OSCELA;** Brown Tern. Above brown, beneath white; head black; wings variegated with brown and cinereous. This is probably the young bird of a former species.

**NIGRA;** Black-headed Tern. Body hoary; head and bill black; legs red. It inhabits Europe; and is a very small bird.

**Australis;** Southern Tern. Cinereous; beneath grey; front yellowish-white; the quill-feathers are white. It inhabits the Nativity islands; and is from seven to nine inches long. The bill is black; the legs blackish; and the connecting membrane tawny.

**Sinensis;** Chinefe Tern. White; back, wings, and tail, cinereous; crown with a black band reaching as far as the nape. It inhabits China; and is about eight inches long. The bill is black; the legs tawny.

**Metopoleucus;** Hooded Tern. Head and neck black; back blackish, hoary; wings cinereous; front, body beneath, and tail, white. It inhabits Russia and Siberia; and is about nine inches long. The bill is yellow, and red at the base; the legs are of a fine fawn-colour.

**MINUTA;** Lesser Tern. Body white; back hoary; front and eye-brows white. It is found in divers parts of Europe and America; and is the size of the last.

**Sterna;** Steriata; Striated Tern. White; hind-head and nape black; body above and wings with transverse black streaks. It inhabits Zealand. The bill is black; the legs are of a lead colour.

10 town belly tail makes collection Wreathed purity very
tiny, Yorkshire, Anatomy,
always so far difficult, that Albinus describes them as two muscles. They are continued together above, and attached to the apex and outer surface of the manubird process, to the manubird portion of the temporal bone, and to the superior curved line of the occiput. The internal portion commences by a strong tendon, rising in front of the muscular fibres: the clavicular part originates by short aponeuroses. The upper extremity terminates by a broad strong aponeurosis, common to both parts; thicker in front than behind. All the muscular fibres go obliquely between the aponeuroses.

The sternocleido-mastoideus, by drawing the manubrid process forwards, rotates the head and the atlas on the axis, so as to turn the face to the opposite shoulder; in which effect it concurs with the opposite splenius, and oblongus inferior capitis. It will then incline the head and neck on the sternum. When the two act together, the head is not rotated, but bent, with the neck, directly forwards on the sternum.

This operation of the sternocleido-mastoideus is more particularly observed in the recumbent attitude of the body; the head and neck are then raised in direct opposition to their gravity, and the recti and obliqui abdominis contract to fix the sternum and ribs, and thus to render the contraction of the sternocleido-mastoideus more effectual. In the erect attitude, the weight of the head naturally inclines it forwards.

STERNO-CLEIDO-MASTOIDEUS, in Surgery. For an account of the operation of dividing this muscle in cases of wryneck, see Torticolis and Wryneck.

STERNO-COSTALIS, in Anatomy, a muscle passing between the sternum and ribs. See INTERCOSTAL Muscles.

STERNO-HYOIDEUS, a muscle of the larynx. See DEGLUTITION.

STERNOMANTIS, in Antiquity, a designation given to the Delphian priests, more usually called Pythia.

STERNOMANTIS is also used for any one that had a prophesy- ing demon within him.

STERNO-MASTOIDEUS, in Anatomy. See STERNO- CLEIDO-MASTOIDEUS.

STERNOPTYX, in Ichthyology, a genus of fishes of the order Apodes, of which the generic character is as follows: Head oblong, teeth very minute; no gill-membrane; the body is compressed, without apparent scales; breast carinate, folded; belly pellicul. A single species only is mentioned by Gmelin, v. 2.

DIANA. This is found in the American seas: it is small, compressed, truncate before, narrowed and silvery behind. The eyes are large, and of an amber colour: the mouth is perpendiculat; the tongue thick and rough; the upper lip is short, lower perpendicular, with four semi-circular depressed cavities from the ridge, and three others under the aperture of the gills; the aperture is oblique, with soft covers; the folds of the breast form a pellucid ridge; the back is of a greenish-brown colour, gibbous behind the fin, with a double ridge diverging towards the notials; it has no lateral line; the dorsal fin with an oblique, strong, spinous, immovable ray, joined to which is a membranous very finely toothed at the edge: pectoral fins of a fine amber colour; tail bifid.

STERNESTEIN, in Geography, a town of Bavaria, with a ruined citadel, which gives name to a county. The county lies dispersed in the Upper Palatinate, and the town is situated 17 miles N. of Namburg.

STERNUM, in Anatomy, the breast-bone. It is the flat piece occupying the middle and front of the chest, and receiving the cartilages of the ribs in a series of small cavities on each side. See the description of the chest under the article Lung.

STERNUM, Fractures of, in Surgery. See Fracture.

STERNUM of Birds. See Anatomy of Birds.

STERNUTATIVE, or STERNUTATORY, such substan-ces as palfes the quality of exciting sneezing.

It is not by the sneezing which they excite, however, that these substances are useful medicinally; but by producing a discharge of fluids from the orifices of the membranes lining the nostrils, by which some kinds of diseases of the head are relieved. In this quality they are more com- monly denominated erubes, which fea. See also Sneezing.

STERTOR. See SNEEZING.

STERZINGEN, in Geography, a town of the county of Tyrol, celebrated for its manufacture of sword-blades; near it are silver-mines; 10 miles N.W. of Brixen.

STESICHORUS, in Biography, a Greek lyric poet, was born at Himera, in Sicily, and flourished about the year B.C. 612, being a person of some consequence in his native city; and he is said to have died in the year B.C. 556. His works were numerous, and much esteemed by the ancients. They were composed in the Doric dialect, but they have all perished, except a few fragments, amounting to 50 or 60 lines, printed in the collection of Fulvius Urbinus, Ant. 1568. The general character of his writings is represented as consisting in force and dignity. Horace speaks of "Stesichorus grave suum;" and Dionysius says that he possessed all the excellencies and graces of Pindar and Siko- monides, and that he surpassed them both in the grandeur of his subjects, in which he has well preserved the characteristics of manners and persons; and Quintilian represents him as having displayed the fulness of his genius by the election of weighty topics, such as important wars, and the actions of great commanders, in which he has sustained with his lyre the dignity of epic poetry. Accordingly, Alexander the Great ranked him among those who were the proper subjects of princes. To him we owe the first introduction into the ode of the triple division of strophe, antistrophe, and epode, which were called in a Greek proverb "the three things of Stesichorus," from which he is said to have derived his name, as signifying "place of the chorus," which was before "Tifias." Suidas. Moreni.

STETTEN, in Geography, a town of Germany, in the margraviate of Anspach; 8 miles N.N.W. of Anspach.

STETTIN, in Geography, a town of Hither Pomerania, situated in the midst of lakes, built in the 14th century by Duke Ratibalis IV., as a defence of the frontiers against Prussia; but it has never flourished; 45 miles S.E. of Col- berg. N. lat. 53° 42'. E. long. 16° 38'.

STETTIN, or Old Stetin, a town of Anterior Pomerania, and capital of that part which belongs to Prussia, situated on the Oder, which it divides into four branches. The town is large, handsome, and well fortified; and contains several manufactories, together with a dock for the building of ships. Its trade with England, Holland, France, Spain, Denmark, Germany, Prussia, Danzig, Mecklenburg, Lubeck, and Hamburg, is very con- siderable. It contains five parishes-churches, a college of phy- sicians, a board of health, a chamber of commerce, a court of admiralty, &c. and about 20,000 inhabitants. It fur- rendered to the French in 1806; 12 miles W.N.W. of Starzard. N. lat. 53° 29'. E. long. 14° 44'.

STEUART, Sir James, in Biography, the only son of Sir James Stuart, bart., solicitor-general of Scotland to queen Anne and George I., and grandson of Sir James Stewart, lord-advocate of Scotland in the year 1692; was
STEVEN'S, a short navigable river of America, which rises born in 1712, and after a regular course of education at Edinburgh, devoted himself to the study of the law. In conformity to the fashion of the times he undertook a foreign tour, and having spent five years abroad, returned to his native country, an accomplished gentleman, in 1740. About three years after his return he married lady Frances, the daughter of the earl of Wemyss, and retired to his seat at Colneyhe. Having formed an acquaintance with the Pretender at Rome, he renewed his connection with him at Edinburgh in the year 1745, but the hopes of the exiled prince being frustrated, sir James removed to France, and remained at Sedan until the year 1754. In the following year he removed to Flanders, and began to communicate to the public the fruits of his literary labours. In 1757, during his residence at Frankfort-under-the-Maine, he published "A Vindication of Newton's Chronology," and having settled in the same year at Tubingen, in Germany, he there published his "Treatise on German Coins," in the German language. This was followed, in 1761, by "A Dissertation on the Doctrine and Principles of Money, as applied to the German Coin;" and in the same year he so far made his peace with the British government, as to obtain for his son a competency in the English service. From Tubingen he removed to Antwerp, but on an excursion to the Spa, he fell under suspicion, and being arrested by the French, was sent prisoner to the fortress of Charlemont. A remonstrance having been presented to the British cabinet, and peace being established, sir James regained his liberty. Under assurances of protection in his native country, he settled at Colneyhe in 1763; and in this retirement he probably finished his work entitled "Inquiry into the Principles of Political Economy," on which he had bestowed the labour of eighteen years. In 1769 he again presented to the public, under the name of Robert Frame, "Considerations on the Interests of the County of Lanark." His full pardon passed the great seal in 1771; and in the following year he printed the "Principles of Money applied to the present State of the Coin of Bengal." He also wrote "A Plan for introducing an Uniformity of Weights and Measures," published after his death; and engaging in metaphysical speculations, he published "Observations on Beattie's Essay on Truth," "Critical Remarks on the Atheistical Fallacies of Miraband's System of Nature," 1779; and soon after, "A Dissertation concerning the Motive of Obedience to the Law of God." He died in November 1780, at the age of 67, leaving one son, sir James Stuart Denham, bart. a general in the army, and colonel of the 12th dragoons. His collected works were printed at London in 1805, in five vols., 8vo.

STEUBEN, in Geography, a county of New York, esteemed from the S. part of Ontario in 1796, and so named in honour of baron Steuben, an officer in the revolutionary armies. Its form is regular, being about 40 miles square; and it is bounded N. by Ontario county, E. by the southern part of Seneca county, or by Seneca lake, and by Tioga county, S. by the state of Pennsylvania, and W. by Allegany county. Its area is 16,141 square miles, or 1,050,240 acres; and it is situated between 42° 40' and 42° 36' N. lat., and 7° 51' and 3° 50' W. long. from New York. Its towns are Addison, containing 369; Bath, with 1,616; Canisteo, with 656; Danville, with 666; Painted-Post, with 954; Pultney, with 1,038; Reading, with 1,210; Trumbrburgh, with 2,021; and Wayne, with 1,025 inhabitants; amounting in the whole to 7,746. This county is 203 miles N.W. from New York. Its surface is hilly, if not mountainous. Near the rivers its aspect is not inviting, except that the alluvial flats are in some parts very extensive and rich. The upland plains have a rich variety of deciduous trees, and extensive tracts of a rich and fertile soil, principally argillaceous or a warm mould. This county, the small town of Reading excepted, was included in the cession of New York to Massachusetts, and is principally peopled by farmers from the eastern states. The agriculture is improving; and the eastern people have brought hither their habits of household industry, from which the clothing is chiefly produced. The capital is Bath. This county has 443 electors, and sends one member to the house of assembly.

STEUBEN, formerly Naugatuck, a town of the district of Maine, in the county of Washington, at the S.W. corner of the county. Naragutag river runs through its N.E. corner. It contains 552 inhabitants.—Alto, a small fort in the Indiana territory, situated at the rapids of the Ohio, a little above Clarksville.—Alto, a township of New York, in Oneida county, taken from White-town, and incorporated in 1792. In 1795, the towns of Floyd and Rome were taken from this township. The western branch of Mohawk river rises here, and the centre of the town is about 12 miles N.E. of Fort Schuyler, and 32 N.W. of the mouth of Canada creek.

STEVENSON, E.L.E., a post-town of Jefferson county, in the state of Ohio, situated on the W. bank of the Ohio, a few miles W. of the Pennsylvanian W. line, and containing 1,617 inhabitants; 312 miles from Washington. N. lat. 40° 17'. W. long. 5° 30' from Philadelphia.

STEVE, a town of Sweden, in East Bothnia; 35 miles E.N.E. of Gamlan Carleby.

STEVEN'S Klint, a mountain of Denmark, in the island of Zealand, near Heding.

STEVENAGE, a village in the hundred of Broadwater, and county of Hertford, England, was anciently a market-town, and named Steigne, or Sienne, and Siennebraugh. The manor was given by Edward the Confessor to Welfinh, and was thereto annexed, till Henry VIII. converted the abbey to a bishop's see. After its dissolution by Edward VI., Stevenage, with Ashwell, and other manors in this county, became by grant the property of the fee of London, to which they have ever since belonged, with the exception of a short period in the consuime reign of queen Mary. It received, through the influence of Montaine, bishop of London in the time of James I., the grant of a weekly market, and three annual fairs. In the fifth year of William and Mary, a charter of confirmation was granted, with liberty to alter the market-day to Friday; but the continuity of the towns of Baldock and Hitchin has greatly tended to the decay of this. Stevenage contains of one large, and several lesser streets, with a free school, and a small church, containing a nave, chancel, and aisles; a chapel on each side the chancel, with a tower at the west end. The population of this place, as returned in 1811, amounted to 1,302, and the number of houses to 308. The petty feoffees for Stevenage division are held here.

About three quarters of a mile southward from this place, on the east side of the high road, are six large barns, some of which have been superficially opened, but nothing of consequence has been discovered: they appear to be composed of gravel and fine clay; and have been thought, from the titles of Dane-end, Mundane, &c., which occur in this part of the county, to be of Danish origin. Stevenage is pleasantly situated on the high North road, 12½ miles N.W. by N. from Hertford, and 31¼ miles N.N.W. from London. Beautes of England and Wales, vol. vii. by J. Britton and E. W. Brayley.

STEVEN'S, a short navigable river of America, which
ripcs in the district of Maine, within a mile of Merry Meeting bay, with which it is connected by a canal lately opened.

STEVENSBURG, a port-town of Virginia, in Culpeper county, on the road from Philadelphia to Staunton. It contains from 40 to 50 houses, and an academy. The inhabitants are mostly of Dutch extraction; 10 miles N. by E. from Strasburg, and 90 from Washington.

STEVENSIA, in Botany, is said to have been so named by M. Poiteau, a French botanist, in compliment to Dr. Edward Stevens, American consul at Hfipaniola, or St. Domingo, who had rendered many important services to the French in that island; but whether he possessed any skill in botany does not appear; neither is he recorded to have afforded any particular patronage to this science.— "Poiteau Ann. du Mus. d'Hilft. Nat. v. 4. 235." Poiret in Lamarck Dict. v. 7. 439.—Claf and order, Hexandria Monogyna. Nat. Ord. Rubiaceae, Juili.

Gen. Ch. Cal. Perianth superior, of one leaf, in two deep, lanceolate, deciduous segments. Cor. of one petal, tubular, slightly silky externally; tube cylindrical, the length of the calyx; limb in five, sometimes seven, oblong, ciliate, spreading, somewhat reflexed segments. Stam. Filaments none; anthers inverted into the upper part of the tube of the corolla, and equal in number to the segments of its limb, oblong, straight, two-lobed, of two cells. Pet. German globose, inferior; filly erect, the length of the tube; stigmas two, spreading. Peric. Capsule globose, coated, of two cells and two valves, separating at the top, the partitions from the inflexed margins of the valves, which at length split longitudinally into two parts. Seeds numerous, minute, oval, a little compressed; encompassed at the upper part with a membranous wing; tapering and pointed at the base. Receptacle central, hemispherical, forming the division between the two cells.

Eff. Ch. Calyx superior, in two deciduous segments. Corolla tubular, with five or seven segments. Anthers filiform in the mouth of the tube. Capsule of two cells, with many winged seeds.

1. S. biaulifolia. Box-leaved Stevensia. Poiteau Ann. du Mus. d'Hilft. Nat. v. 4. 235. t. 60.—Native of the northern part of Hfipaniola. An upright branching shrub, ten or twelve feet high; the wood very hard; bark ash-coloured, full of cracks. Young shoots covered with a wifed rein. Leaves opposite, stalked, oblong, acute at each end, about an inch and half in length, rigid, smooth, shining above, pale and reticulated beneath. Footstalks short, connected by an undivided sheathing stipula. Flowers axillary, solitary, white, fragrant, on stalks the length of the footstalks. Bracteae at the base of the calyx, in four divisions, two of which are short and obtuse, the two intermediate ones lanceolate and twice as large, sometimes leafy. We know this plant only from the descriptions of the authors above cited.

STEVENSWAERT, or Fort of St. Etienne, in Geography, a fortress of France, in the department of the Roer, situated on the E. side of the Meuf, built in the year 1635: besieged and taken by the allies in 1702; 30 miles N. of Liege.

STEVENTOWN, a township of New York, in Weftchester county, bounded W. by York town, and N. by Dutchess county, containing 1,573 inhabitants.

STEVER, a river of the principality of Munster, which runs into the Liptpe at Hattern.

STEVIA, in Botany, was named by Cavanilles in memory of Peter James Steve, or E Reeve, an eminent physiologist of Valencia, and professor of botany in that university, towards the middle of the 16th century. He is said to have published some valuable works, and to have left in manuscript a dictionary of the plants of the country where he resided.—Cavan. Ie. v. 4. 32. Wild. Sp. Pl. v. 3. 1774. Ait. Hort. Kew. v. 4. 510.—Clafs and order, Syngenesia Polygama-epiitalis. Nat. Ord. Composite disfoides, Linn. Corymbifera, Julii.

Gen. Ch. Common Calyx simple, oblong, or several, nearly equal, leaves, in a simple row, Cor. compound, uniform, disfoid. Flores all uniform, perfect, fertile, funnelf-shaped, with a five-leaved spreading limb, not numerous. Stam. Filaments in each floret five, capillary; anthers united into a cylindrical tube. Pet. German oblong; style thread-shaped; stigma two, long and slender. Peric. one, except the permanent upright calyx. Seeds solitary to each floret, oblong; down chaffy, or partly bristle. Recept. small, naked. Eff. Ch. Receptacle naked. Down chaffy. Calyx cylindrical, of a simple row of leaves.

Obs. This genus is distinguished from Eupatorium and Ageratum, by its simple row of calyx-leaves. From the former, moreover, the chaffy head-down keeps it clearly distinct.

1. S. lineare. Linearis Stevensia. Willd. n. 1. Cavan. Ic. v. 4. 32. (Ageratum lineare; ibid. v. 3. 3. t. 205.)—Stem shrubby. Leaves simple, linear, entire. Seed-down of five lanceolate scales.—Native of New Spain, flowering in the garden at Madrid, from August to November, in the open ground. The stem is two feet high, branched, glaucous and smooth, like the rest of the plant. Leaves scattered, on short stalks, entire, obtuse, narrow, an inch and half long, the lower ones often opposite. Flowers pale rose-coloured, terminal, corymbose, not numerous. Bracteae foliary, at the base of each partial stalk, linear-lanceolate. Calyx three-quarters of an inch long. Scales of the seed-down spreading, linear-lanceolate, acute, whitish, about the length of the downy seed.

2. S. Eupatoria. Three-ribbed Stevensia. Willd. n. 2. Ait. n. 1. (Muifelia Eupatoria; Sprengel in Tr. of Linn. Soc. v. 6. 152. t. 13.)—Stem herbaceous. Leaves lanceolate, nearly entire, three-ribbed. Flowers crowded. Seed-down of short scales, with intermediate bristles. Native of Mexico. Brought from the Madrid garden, by the late marchioness of Buie, in 1798. A hardy perennial herb, flowering from July to September, but of no striking appearance. The stem is two feet high, inclined or spreading, round, leafy, its branches terminating in numerous small corymbose flowers, of a reddish hue. Leaves rather above an inch long, shining, dotted, occasionally ferrated towards the point. Willdenow describes three obtuse scales, with as many intermediate bristles, in the crown of each seed; which answers to Sprengel's figure, but the latter describes five bristles.

3. S. falecifolia. Willow-leaved Stevensia. Cavan. Ic. v. 4. 32. t. 354. Willd. n. 3. Ait. n. 2.—Leaves lanceolate, ferrated; tapering and entire at each end. Seed down of two awl-shaped bristles. Native of Mexico. Its seeds were sent to the writer of this, from the Madrid garden, in 1803. This is a greenhouse herbaceous plant, flowering in August and September, about two feet high. Leaves two or three inches long, smooth; glaucous beneath. Flowers corymbose, more copious, but much smaller than in the first species; the flowers flesh-coloured, with a red tube. Seeds slender, each crowned with two very narrow, rather spreading, bristles.

Jacq. Hort. Schovenbr. v. 3. 28. t. 300.)—Leaves linear-lanceolate, most forked towards the point. Seed-down of three short scales, with intermediate bristles.—Native of Mexico. We received it from the rich garden of the late Rev. Mr. Watts, of Ashill, Norfolk. It is a hardy perennial, flowering in autumn, about the size of the last, but its leaves are smaller and more abundant; flowers larger and white, in level-topped, corymbose panicles. The three long rough bristles which crown the seed are membranous at the base, connected by a membranous crown at the base, agreeing in structure, and, we doubt not, in number, with the same part in our second species.

5. S. pedata. Compound-leaved Stevia. Cavan. Ir. v. 4. 33. t. 356. Willd. n. 5. Ait. n. 4.—Leaves pedate, entire. Seed-down of several short equal scales.—Native of Mexico. Its seeds were received from Madrid, with those of the third species, in 1803. This proves a hardy annual in our gardens, flowering from July to September. The stem is two or three feet high, a little downy, striated. Leaves seven, halved, entire, elliptic-lanceolate, roughish; the middle one an inch and half long; the lateral ones gradually smaller. Flowers white, small, but of more numerous florets than most of the species, with violet anthers. Seed crowned with about ten, equal, short, obtuse scales.

STEVIN, Simon, in Biography, was born at Bruges after the middle of the 16th century, but the year of his birth is not ascertained. He was held in great estimation by Maurice, prince of Orange, whole own talents led him to respect the mathematical and mechanical acquirements of Stevin, and he was employed in Holland as an inspector of the dykes. He seems to have been the first person who discovered the true proportion between the power and the weight on an inclined plane, which he accurately determined in all the different cases. In hydrostatics he was also no less an adept than in mechanics; and to him we owe the discovery of the famous paradox, that a fluid contained in a tube decreasing upwards, acts with the same preliure on the base as if the tube were every where uniform. He was also the inventor of a sailing boat, which was moved entirely by the impulsion of the wind, and with such velocity, that it conveyed passengers from Scheveling to Putten, through a distance of about forty miles, in the space of two hours. Although the exact form of this vessel is not much known, it excited general attention. Grotius, who was a passenger in it, wrote a poem in reference to it, intituled "Iter Currus Velferti," and he has made it the subject of more than twenty epigrams; in one of which are the following lines:

"Ventivolum Tiphys deduxit in sequora navem; Jupiter in tellas atereamque domum. In terrre fleum virtus Stevinia: nam nescit Tiphym tuum fuerat, nec Jovis itud opus."

It is also asserted by Swertius and Valerius Andrascs, that Stevin could raise any weight with a small power, by a simple machine, called by the latter "pantactor." Stevin died at Leyden, according to Weidler, in 1633. His works are, "A Book of Arithmetic in French," printed by Plantin at Antwerp in 1565, 8vo, and republished with his Algebra in Flemish, in 1605; "Problematum Geometricorum, Lib. V," 4to. 1; and various other treatises in Flemish, translated into Latin by Snellius, under the title of "Hyponemata Mathematica," Lugd. Bat. 1608, 4 tomo. fol. of which is a French edition, with curious notes and additions by Albert Girard, 1634, 6 vols. fol. The first contains arithmetic and algebra, with tables of interest; the second, cophomorphics, that is, the doctrine of triangles, geography, and astronomy; the third, practical geometry; the fourth, statics; the fifth, optics; and the sixth, ephemerides, fortification by fluxes, and general fortification. One of his treatises relates to the finding of harbours, and is intitled in the French edition "Du Trouve-l'Port, ou la Maniere de trouver les Havres," which was translated by Grotius into Latin verse, 1599, 4to. Montucla says, that none of Stevin's works contain any new things, except his Mechanics; but Dr. Hutton informs us, that his improvements in algebra were many and ingenious. Hutton's Dict. and Mathematical Tracts. Montuc. Weider Hist. Art. Wilkinson's Math. and Phil. Works. Gen. Biog.

STEW, a small kind of fish-pond, the peculiar office of which is to maintain fish, and keep them in readiness for the daily uses of the family, &c.

The fish bred in the large ponds are drawn out, and put in here. For two large ponds of three or four acres a-piece, it is advisable to have four flews, each two rods wide, and three long. The flews are usually in gardens, or at least near the house, to be more handy, and the better looked to. See Fish-Pond.

In the construction of flews or ponds, the sides of them should be cut down sloping, carrying the bottom in a continual decline from end to end, so as to have a convenient mouth, as horse-ponds have, for taking out nets in drawing for fish; and if there be room enough, a mouth may be made at both ends, and the deepest part be in the middle, by which means the net may be drawn backwards or forwards, and the fish not have such shelter as is given by a depth under a head. And besides, the fish delight to come upon the shoals, and probably thrive better. These may chiefly be referred for carp, but not absolutely; and where tench and perch increase and prosper, smaller flews may be made to serve them apart, and take them when wanted, without disturbing the other fish. See Fish.

In general, the strongest and best fish, where it can be done, are faved and preferred for being put into the flews, in order to be brought forward, and got ready more quickly for the table.

In places near the sea, there are frequently salt-water flews formed for keeping various kinds of sea-fish. It is noticed in the account of the state of the agriculture of the county of Essex, that the flews for sea-fish in Foulness island, in that distric, are extremely well contrived, and answer the purpose in a complete manner. The fish for them are, it is said, caught in weirs, on the extensive sands, which run out several miles on the coast there, and then, when plentiful, deposited in these flews, where they are afterwards dragged for, as wanted, with a small net, as in flews of the fresh-water kind. See Fish-Ponds, and Pond Fisheries.

It is material in all sorts of flews, that there be some thing of the house kind near to or connected with them, for the safety and securing of the fish, as well as for the purpose of ornament in some cafes. Different flews may in this way be made to be partially covered and divided by them; and by having perforations opened through the dividing parts, the waters of the different ones may flow through and communicate with the whole. They may also have trap-door openings for each of the different flews, made to be locked and fastened, as that no perch, except the owner, can have the means of opening them, and getting at the fish, without being liable to detection.

These sorts of contrivances may be beneficially had recourse to in most cafes, as preventing all risk of depredations being committed; and in some cafes, where the flews are connected with the refidences of men of fortune, they may have such forms and shapes given them, as may render their
their effects highly ornamental; besides serving as habitations for old domestics.

Different sorts of fish, besides being preferred, are often raised and fed to very great sizes in lochs.

Stews, or Stews, were also places anciently permitted in England, to women of professed incontinency, for the profit of their bodies to all comers. These were under particular rules and laws of discipline, appointed by the lord of the manor. See Southwark.

The word is probably borrowed from the French, glasse, hot-baths, in regard prostitutes are wont to prepare themselves for prevalent acts by bathing.

Steward, or Seneschal, an officer, of whom there are various kinds; thus called from the Saxon sican, stead, place, or room; andward, kepper, q. d. a deputy, or person appointed in the place of another. See Seneschal.

Steward of Great Britain, Lord High, is the first and highest officer of the crown; as having the power of what we call a vice roy, the Danes, &c. flatholders, and the Swedes, reichs drifite, q. d. vice reg. Chamberlayne.

Common lawyers call him magnus Anglei senzeichnet.

His office, as exprest in an ancient record, is to super- vide and regulate the whole kingdom, both in time of peace and war, immediately under the king, and after him, an authority so very great, that it has not been judged safe to trust it any longer in the hands of any subject.

The office was hereditary and permanent in the family of the dukes of Lancaster, till the time of Henry IV. since whom it has only been made pro hac vice, occasionally: as to officiate at a coronation; at the arraignment and trial of some noblemen for treason, or other great crime. And it hath been the constant practice (and therefore seems now to have become necessary) to grant it to a lord of parliament, else he is incapable of trying such delinquent Peer.

During his stewardship he bears a white staff in his hand, and the trial, &c. ended, he breaks his staff, and with it his commission expires.

Steward, Court of the Lord High. See Court.

Steward of the Household, Lord, is an officer, to whom the state of the king's house is committed, to be ruled and guided at his discretion. See Household and Lord Steward.

Steward, Court of Lord. See Court. See also Marborough Court.

Steward of the University, Lord High. See University.

Steward of a Ship of War, an officer appointed by the purser to distribute the different kinds of provisions to the officers and crew, for which purpose he is furnished with a mate and proper assistants.

He hath an apartment for himself in the hold, which is called the steward's room, built on the larboard side of the after-platform, nearly aft.

Steward, Matthew, D.D. in Biography, professor of mathematics in the university of Edinburgh, was the son of the Rev. Dugald Stewart, minister of Rutheney, in the isle of Bute, where he was born in the year 1717. As soon as he left school in 1734, being intended for the church, he was entered at the university of Glasgow, where his application and proficiency engaged the peculiar notice and friendship of the two eminent professoors, Dr. Hutchen an and Dr. Simson. The latter especially, perceiving probably in young Stewart talents and propensities of study resembling his own, initiated him betimes in the sublime speculations of the ancient geometry, to which he afterwards manifested a very decided attachment. As his views required his attendance on the lectures at Edinburgh, in 1741, Dr. Simson recommended his favourite pupil to the celebrated Maclaurin, whose lectures he attended, and by which he finally profited. At this time he kept up a regular correspondence with professor Simson, communicating to him the progress of his studies, and his geometrical discoveries, which were even at this time various and important, and receiving in return interesting information with regard to the Lozi Plan and Purisms of Euclid. Both the professor and the student prosecuted their investigations of these abstruse subjects in different directions, but with similar success.

The result of Mr. Stewart's enquiries was the discovery of those curious propositions, which he published in 1746, under the title of "General Theorems," and which gave him a high rank, at an early age, among eminent geometers. Whilst he was engaged in these speculations, he had entered into the church, and under the patronage of the earl of Bute and the duke of Argyle, he was presented with the living of Rosneath; and in this retired situation he had discovered the greater part of the fore mentioned propositions. But the death of Maclaurin, in 1746, afforded an opportunity for his being advanced to the mathematical chair in the university of Edinburgh, so that he became the successor of that eminent mathematician and philosopher in September, 1747.

His new office produced some change in the direction of his mathematical studies; and led him to make an application of geometry to those problems, for the solutions of which the algebraic calculus had been employed. The first specimen of his successes in this way was the resolutions of Kepler's problem, founded on a general property of curves, which, perhaps, had never been before observed. This was published in the second volume of the "Essay of the Philosophical Society of Edinburgh," for 1756. The first volume of the same collection contains some other propositions, relating to the subject of porisms, and which are demonstrated with all the elegance and simplicity peculiar to the ancient analysts. Attached to the geometry of the ancients, Mr. Stewart had formed a plan of introducing its strict and simple mode of demonstration into the higher parts of the mixed mathematics; and in the prosecution of this plan he compos'd his "Treatis Physical and Mathematical," which were published in 1761. Mr. Stewart, in the first of these tracts, lays down the doctrine of centripetal forces in a series of propositions demonstrated, the quadrature of curves being admitted, with the utmost rigour, as not requiring the previous knowledge of mathematics, except the elements of the geometry and of conic sections. Accordingly this tract may be regarded as the bell elementary treatise of physical astronomy extant. In the three following tracts the author proposed, in the same method, to determine the effects of those forces which disturb the motions of a secondary planet; and from these it was his design to deduce, not only the theory of the moon, but the sun's distance from the earth. But his declining health did not allow him to pursue the arduous investigation of these subjects. In the year 1763, when the result of the observations of the transit of Venus had been unsatisfactory to all astronomers, Dr. Stewart determined to apply the principles he had laid down to this subject; and accordingly in this year he published his "Essay of the Sun's Distance," where, from actual computation, the parallax of the sun was found to be no more than 6.9', and consequently his distance nearly 29,875 semi-diameters of the earth, or about 118,541,428 English miles, a distance so much exceeding all former estimates as to excite surprise, and to produce a severe examination of the principles on which the calculation was founded.
founded. This "Elfay" was the last work which Dr. Stewart published; but he declined engaging in any controversy on the subject. Some months before he published his "Elfay," he presented to the public another work adapted to promote the study of the ancient geometry, and entitled "Propositiones Geometricae more Varietatem demonstrat." By his constant use of the geometrical analysis he obtained many valuable propositions, several of which have found a place in the writings of Dr. Simson. Soon after the year 1763, the health of Dr. Stewart began to decline, and he was unable to encounter the fatigue of the duties of his office. He therefore retired to the country in the year 1775, and never resumed his labours in the university. In 1775 he had the satisfaction to see his son, Mr. Dugald Stewart, elected joint professor with him; and when mathematical studies ceased to be his business, they were still his amusement. Having at an early period of his life admired the analogy between the circle and hyperbola, his attention, during the leisure of his advanced life, was directed to this subject, and he left among his papers some curious approximations to the areas of both. At length the fate of his health would not allow him to prosecute study even as an amusement; and he closed his honourable life in the month of January, 1785, at the age of 68 years. Dr. Stewart's application had been from his youth most intense and continued; his mental faculties possessed an extraordinary vigour; and his memory was so tenacious, that he retained his discoveries, and he rarely wrote out any of his investigations till it became necessary to do so for the purpose of publication. When he discovered a proposition, he put down the enunciation with great accuracy, and on the same piece of paper constructed very neatly the figure to which it referred; for every thing else he trusted to his memory. Although he was very industrious, he read few books. After the academical labours of the winter were concluded, he spent the summer at a delightful retreat in Airlair, where he found leisure to prosecute his favourite researches. Translations of the Royal Society of Edinburgh.

W. T. STEWART, in Geography, a county of the district of Welf-Tennet, in America, containing 4,262 inhabitants, of whom 779 are slaves.

W. T. Stewart's Island, a cluster of small islands in the South Pacific ocean, discovered by captain Hunter in the year 1791, and so named in honour of admiral Keith Stewart. S. lat. 8° 26'. E. long. 153° 18'.

W. T. STEWARTIA, see Stuartia.

W. T. STEWARTON, or Stewart-town, in Geography, a town in the district of Cunningham, and county of Ayr, Scotland, is seated in a pleasant and fertile district, on the banks of the river Annach, at the distance of six miles N. from the town of Irvine. From a comparative view of the population reports of 1801 and 1811, it appears that Stewarton has greatly increased in houses and inhabitants during the intermediate eleven years, as at the former date, there were 447 houses and 2,657 inhabitants; and at the latter, the number of houses was 484, and that of inhabitants 3,049. The town and parish seem to have derived their name from the royal and unfortunate family of Stuart, who had a manor here at a remote period, and part of it still remains. The principal trade of the town is the manufacture of bonnets, which was continued for upwards of a century past to a great extent. A general post-office is here established. Here is a weekly market, and several well-attended fairs. The general appearance of the parish is flat, with a gentle descent towards the sea; and it is decorated with extensive plantations. The soil is chiefly strong clay; and lime-quarries abound in great plenty: its extent is upwards of ten miles in length, and some places about four in breadth. — Carlisle's Topographical Dictionary of Scotland, vol. ii. 4to. 1813. Gazetteer of Scotland, 8vo. 1806. Sinclair's Statistical Account of Scotland, vol. ix.

S. T. STEWARTSTOWN, a palt-town of the county of Tyrone, Ireland; 77 miles N. by W. from Dublin, and 5 miles N. from Dungannon.

W. T. STEWARTSTOWN, a town of America, in the county of Coos and Haste of New Hampshire, containing 186 inhabitants.

W. T. STEYR POINT, a cape on the coast of Labrador. N. lat. 58°. W. long. 61° 40'.

W. T. STEYERBERG, a town of Germany, in the county of Hoya; 9 miles S.W. of Nienburg.

W. T. STYLL, a town of the duchy of Berg, lately belonging to the abbey of Ellen; 2 miles S.E. of Ellen. N. lat. 51° 22'. E. long. 7'.

W. T. STEYNING, a borough-town in the hundred of Steyning, rape of Bramber, and county of Sussex, England, derives its name from the Steyne-street, an ancient road, which passed through this part of the country. In the population return for 1820, it is stated to have contained 219 houses, and 1,174 inhabitants; but in 1811, the houses only amounted to 187, and the inhabitants had increased to 1,210. Here is a weekly market on Wednesday; a monthly one for cattle, and three annual fairs. It is seated at the foot of a lofty hill, near the river Adur, and is formed by four transeverile streets.

Steyning is a borough by prescription, and returns two members to parliament, elected by the householders and inhabitants, who do not receive alms, within the borough, amounting to 80. The municipal government is vested in a constable, who is on such occasions the returning officer; and is appointed at the court-leet of the lord of the manor. The members of this place were formerly elected in conjunction with Bramber, and intermitted till 31 Henry VI.; but at present each town is entitled to return two representatives, although one part of Bramber is in the centre of Steyning, and a part of Steyning interdicts Bramber in a similar manner. See Bramber.

W. T. STEYNING, a borough by prescription, and returns two members to parliament, elected by the householders and inhabitants, who do not receive alms, within the borough, amounting to 80. The municipal government is vested in a constable, who is on such occasions the returning officer; and is appointed at the court-leet of the lord of the manor. The members of this place were formerly elected in conjunction with Bramber, and intermitted till 31 Henry VI.; but at present each town is entitled to return two representatives, although one part of Bramber is in the centre of Steyning, and a part of Steyning interdicts Bramber in a similar manner. See Bramber.

The church is an edifice of great antiquity, but of this building only the nave remains. It contains some very curious specimens of early Norman architecture. The tower is of flint and stone, with buttresses at the corners. About the middle of the 16th century, a free grammar-school was founded in this place, and endowed with lands to provide for the salary of the master. There have been also of late years extensive barracks erected here for infantry.

At a very remote period, a Benedictine priory for monks existed in this town, founded by Edward the Confessor; the church, which appertained to this establishment, and which is supposed to be that already noticed, contained the sacred relics of St. Cuthman, and of Ethelwulf, father of Alfred the Great.—Beauties of England and Wales, Susex, by F. Shoberl, vol. xiv. Carlisle's Topographical Dictionary of England, vol. ii. Representative History of Great Britain, by T. H. B. Oldfield, vol. iii. 8vo. 1816.
STI

separated from Stiria, it was added to the country above the Ets, and since deemed merely a seignory. It has often suffered much by fire; 28 miles W. of Vienna. N. lat. 48° 17'.

STERYE, in Geography, a town of Austria; 4 miles W. of Vienna. N. lat. 48° 17'.

STEYRSPERG, a town of Austria; 5 miles E. of Glaggitz.

STEZZANO, a town of Italy, in the department of the Serio; 3 miles S. of Bergamo.

STHANUS, in Mythology, a name of the Hindoo god Siva, by which he is frequently designated in the celebrated poem the Purana. See Siva.

STHENIA, from σθένος, strength, a word of great import in the Bronzonic theory of medicine, implying an inflammatory diathesis, and standing in opposition to ασθενία, or debility, to one of which that ingenious but mistaken pathologist ascribed all diseases incident to the living body. See Excitability.

STHENUS, in Antiquity, a festival of Argos, supposed to be kept in honour of Minerva, tunique as Σθενας, from σθένος, strength.

STHENUS, in Mythology, denoting powerful or strong, one of the epithets of Jupiter; as Σθενας, or rebull, was one of the epithets of Minerva.

STILE, a word used by some of the old authors for pebbles found on the sea-shore.

STIBIUM, among the Romans, a low kind of table-couch, or bed of a circular form, which succeeded to the trichina, and was of different sizes, according to the number of guests they were designed for. They were called hexaedra, octaedra, or enneaedra, according as they held six, eight, or nine guests, and so of any other number.

STIBIUM, in Geography, a town of Pomerelia; 30 miles S.S.E. of Dantzic.

STIBILIA, a term used by some to express the antimonial medicines.

STIBINUS, in Geography, a town of the duky of Stiria; 7 miles N.N.W. of Graz.

STIBINUS, a term used by St. Jerome, and others, to express the false black colour which the ancient Jews, and other eastern people, gave to their eye-brows with stibium, or antimony.

STIBIUM. See Antimony.

STIBINUS, in Geography, a town of Bohemia, in the circle of Koniggratz; 24 miles N. of Koniggratz.

STICA, a name given by some authors to all external afferent glands used in hemorrhages.

STICA, in our Old Writers, a copper or bullion haephtic coin, of the value of half a farthing, four of them making an elfing. This small piece was only known in Northumbria, and in the later period of that kingdom. See Penny, and Skeatta.

STICHOGRAPHIA, εικοσιγραφία, in Antiquity, a fort of divination by verses (commonly those of the Sibylline oracles), which being wrote on little pieces of paper, and thrown into a well, the first drawn out was supposed to contain the will of the gods. See Sortes.

STICHEOMETRY, formed of εικοσι, twenty, and μετρος, a measure, in Scripture History, a catalogue of books of sacred literature, to which is added the number of the verses which each book contains.

STICHOS, a name given by the old writers to a pectoral confection, the principal ingredient of which was the herb marrubium, or horehound.

STOCK of Eels, a quantity or measure of twenty-five. A bond of eels contains ten picks, and each pick twenty-five eels. Stat. Weights and Measures.

STICKADES, in Botany. See Cassidiony.

STICKELSTA, in Geography, a town of Norway, in the province of Drammen; 46 miles E.N.E. of Drammen.

STICKHAUSEN, a town and citadel of East Friadland, founded by the Hambourgers about the year 1435, as a security against pirates, and afterwards still farther fortified; 18 miles E.S.E. of Emden. N. lat. 53° 14'.

STICKLEBACK, in Ichthyology, a name given by us to that small fish called by authors the several names of spinacia, Spinax, and punigius pescis; also pisculus After pisculus aculeatus, and the like; and finally, by Arcted, by the much more expressive name of gaferolarius, expressing that great singularity it has in the bony structure of its belly.

The common stickleback, or gaferolarius aculeatus of Linnaeus, is distinguished by arteries by the name of the gaferolarius with three spines on the back; and by this character it differs from the other species of this genus.

It is a very well-known fish, and is found everywhere in new-dug ditches, &c. where no body can perceive how it comes. Hence the vulgar have an opinion, that it breeds there equivocally and of itself, without the help of parents of its own kind, and that from it all other fishes are bred.

These are idle opinions: the smallest animalcule is not produced in putrid matter otherwise than by the egg of a parent animal: this origin will, therefore, hardly be believed of larger, and, as they are called, more perfect animals. These small fish are far from peopling ponds with other fish, that they are very great devourers of the spawn of larger fish, and do infinite mischief in ponds.

These are found nowhere in such great quantities as in the fens of Lincolnshire and Cambridgeshire, and some of the rivers flowing from them. At Spalding there are, once in seven or eight years, amazing flocks that appear in the Wold, and come up the river in the form of a vast column. These are supposed to be the multitudes that have been washed out of the fens by the floods of several years, and collected in some deep hole, till, overcharged with numbers, they are periodically obliged to attempt a change of place. The quantity is so great, that they are used to manure the land, and trials have been made to get oil from them. See Phil. Trans. N° 225. For the characters of this and the other species, see Gasterosteus.

It is observed in the Norfolk Report on Agriculture, that these little fish, which are caught in immense quantities in the Lynn rivers about once in seven years, have been bought as high as eight-pence a bushel. The favourite way of using them now, is by mixing them with mould, and carrying them on the land for turnips. Great quantities have been carried to Marham, Shouldham, and Beachwell. Mr. Fuller, there, is reported to have laid out 400l. for them in one year: they always answer exceedingly. And Mr. Rogerfon, of Narborough, has gone largely into this husbandry, laying out 300l. in one year, at from 6d. to 10d. per bushel, besides carriage from Lynn: he formed these into comports well by turning over, and carried them on for turnips: the success was very great. There can be no doubt but that these small fish afford a good animal manure.

Matters of this kind constantly afford a most efficacious manure, and should mostly be applied in the fresh state, though
though in limited proportions, according to the nature and condition of the land. When sifted with good rich earthy fulvities, as above, they are probably in the best line of application for the production of arable crops. The operation of such fulvities, as marlure, is readily elucidated and explained. The limy parts of them, the writer of the work on "Agricultural Chemistry" considers as principally confiding of gelatine, which, from its light flake of cohesion, is quickly soluble in watery fluids; and, besides, the fatty matter which constitutes different internal parts of them, readily becomes useful in the same way. Their fibrous matter contains all the elementary matters of vegetable fulvities, that are particularly wanted for this use.

Little fill of the pricklyback, thornback, and other similar kinds, may also probably be employed in the same way, with equal benefit and advantage, where they can be had in sufficient quantities.

STICKLER, in our Old Writers, an inferior officer, who cuts wood within the king's parks of Clarendon.

STICKNA, in Geography, a town of Bohemia, in the circle of Prachatitz; 3 miles S. of Strakonitz.

STICKS, Foot, in Printing, slips of wood that lie between the foot of the page and the chafe, to which they are wedged fast by the quoins, to keep the form firm, in conjunction with the file-kicks, which are placed at the side of the page, and fixed in the same manner by means of quoins. See Reglet.

STICTA, in Botany, from robus, robustus, alluding to the minute impressions on the under side of the frond; a name given by Schreber to one of the sections into which he proposes to divide the Linnæan genus of Lichen, and which is now received as a genus by itself, like Stereocaulon, Spiloma, &c. (See those articles.) — Schreb. Gen. 768. Achar. Meth. 275. Lichenogr. 86. t. S. f. 1—8. Syn. 520. Clasf and order, Cryptogamia Alga. Nat. Ord. Lichenet.

Eff. Ch. Shields orbicular, flat, bifidule, with an elevated border of the fulvity of the frond, scattered. Frond coruscous; downy beneath, fringed with little bald pits.

One of the most handsome of this natural order, found on old trees in various parts of the globe. The species in the Synopses of Acharius amount to twenty-two, of which seven are British; but the last in this list, S. lyriatica, is not attainted with doubt, and another is certainly misplaced, as we shall mention hereafter. We select a few of the most remarkable exotic, in addition to our native species.

S. flabellina. Ferny Sticta. Ach. Syn. n. t. (Lichen Ficus; Swartz in Linn. fil. Meth. Mufc. 36. t. 2. f. 2. Platima Ficus; Hoffm. Pl. Lich. v. 3. t. 55.) — Frond somewhat falked, glaucous-grey, doubly pinatifid; strongly ribbed, tawny and almost smooth beneath, with bordered pits. Shields reddish-brown; their border entire. — Found on trunks of trees in New Zealand, from whence Mr. Menzies brought our specimens. The fronds are three or four inches in length, or height, for we know not whether they grow erect or horizontally, and consist of numerous, very elegant, rounded, finetted, finely pinatifid lobes, lying over each other. The upper surface is quite smooth, even, and veinless, of a pale greenish-greyish grey-colour, beprinkled with small, slightly elevated, flat, shields, red when young, then chefant-coloured; their border tawny, finely ribbed, following the inner edge. The under side of the frond is yellowish or tawny, paler towards the extremities, and scarcely downy, except about the remarkably strong, brown, elevated, central ribs, which run down into a fort of channelled common falk. The pits, cyphelle, have an elevated polished border, raised above the smooth back of the frond, not funk, as usual in other species, amongst down or pubescence.

S. corniculata. Fringed Sticta. Ach. Syn. n. 2. Meth. 276. t. 5. f. 1. — Frond dilated, greenish-white, with wedge-shaped, somewhat forked lobes; piousy beneath, with cup-shaped pits. Shields tawny-red, fringed, like the frond, with radiating black hairs. — Gathered by Dombey on trees in Peru. One of his specimens was given us by M. L'Héritier, a remarkably handsome species, larger than the last, spreading in broad imbricated matts, and distinguided by the conspicuous large red fields, bordered with black spreading hairs. The pits of the under surface are, in fact, pale brown elevated cups, imbedded in dense piony pubescence of the same hue.

S. crocata. Yellow-veined Sticta. Ach. Syn. n 6. (Lichen crocatus; Linn. Munt. 310. Dickf. H. Sicc. falc. 4. 24. Engl. Bot. t. 2110.) — Frond roundly lobed, dilated, cellular, glaucous-brown, with bright-yellow powdery cracks and margins; brown and piousy beneath, with minute bright yellow pits. Shields dark-brown, with an entire border. Native of rocks, and trunks of old trees, in the Highlands of Scotland, as well as in the Eall and West Indies. The dark hivy hue of the wrinkled cellular frond, is strikingly contrasted with the lemon-coloured powder, which lies from all the cracks, edges, and warts. The piousy down of the under side is nearly as dark, though some what reddish; and the pits, though very small, are rendered conspicuous by their bright lemon-colour. We never saw the shields. — Acharius misapplifies to this the synonymy of Dilenninus that belongs to the following.

S. aurata. Golden-edged Sticta. Ach. Meth. 277. Syn. n. 7. (Lichen auratius; Engl. Bot. t. 2359. Platima crocatum; Hoffm. Pl. Lich. v. 2. 52. t. 38. f. 1—3. Lichenoides lacunofum rutulum, margnibus flavis; Dill. Mufc. 549. t. 84. f. 12.) — Frond finituated, roundly lobed, nearly even, of a bluing reddish-glaucus light brown; the margin wavy, bearing golden coloured powder; brown and downy beneath, with bright-yellow pits. Shields . . . Native of trees in St. Helena and the West Indies, possibly also of Devonshire; but the authority for the latter depends upon unmarked specimens, found in Mr. Hudson's British herbarium. This was first finituated from the leaf, by the writer of the present article, in Engl. Bot. v. 53. There can be no doubt of its being abundantly different, the paler redder colour of the upper side, and want of veins, wary cracks, or cellular depressions, are sufficient characters. The margin is more timid and wary, with a rather more golden than lemon-coloured powder, which line also appears in the inner fulvity of the frond, when broken, and in the minute pits of its brown under fide. Nothing is known of the fields.

of the earlier botanists, and given rife to the name. The
colour of the upper surface, when fresh and moist, is a rich
bright green, verging towards olive, or brown by age or
drying. It is very prominent reticulations, usually smooth,
are occasionally rough with warts, or rather minute fibres.
The under side is downy, pale-brown; in an early flat
quite even, though marked with broad, oval, perfectly
smooth, and rather shining, spaces, apparently analogous to
the pits of other species, and therefore, in our opinion, justi-
fying the removal of this plant to the present genus, with
which it, no doubt, in every other respect, strictly accords.
These spaces become afterwards tumid, and very prominent,
between the downy depressions, which answer to the ribs,
or reticulations, above. The shields are frequent, for the
most part seated on the margin, more rarely on the ribs of
the disk, flat, of a chestnut-brown, with a narrow border
disappearing with age, when also the shields sometimes
tumid and convex. The resemblance of this plant to the
lungs, has caused it to be used, in a decoction with milk,
to cure coughs. It is bitter, astringent and mucilagi-
ous, like the famous Iceland Mofs, Lichen ifandicus of
Linnæus, and may therefore agree with that species, in
whatever virtues the latter may possess.

S. fribulatus. Pitted Sticta. Arch. Syn. n. 13. (Par-
melia fribulatus; Ach. Meth. 219. Lichen fribulatus;
Lichenioides pulmonium villosum, superficie fribul-
cteta; Dill. Mufc. 216. t. 20. f. 114.)—Frond
dilated, roundly lobed, crenate, deeply cellular, obfolutely
reticulated, glaucous, with grey mealy warts; brown and
villous beneath, with pale, ovate, smooth spaces. Shields
small, scattered, chestnut, with a roughish border.—Found
in the mountainous parts of Europe, on trees and mossy
rocks, but rarely in fruticisation. We met with it in this
state, but sparingly, near Luss, on the beautiful shore of
Loch Lomond. This has much broader rounder lobes than
the foregoing, spreading loosely in large patches; the pale
glaucous colour likewise marks it at a distance; and the
surface, though deeply cellular, is scarcely rubbed or reti-
culated. Grey mealy warts, looking like a sort of moulds-
iness, occur towards the edges of old plants; and the fsiels,
when present, are feated more towards the central part of
each lobe. The under side is clothed with dark-brown
fpongey down, vanishing near the edge, and interpersed
with oval, whitish, very smooth spots, evidently of the nature
of real Dryinea, though rill to much resembling what we
have described in S. pulmonacea, as to confirm the genus
of that species.

Syn. n. 20. (Lichen limbatus; Engl. Bot. t. 1104.
Lichenioides, Dill. Mufc. 10. t. 26. f. 100, varietas far-
ifoba, B.C.)—Frond roundly lobed, glaucous-brown, smooth;
grey and powdery towards the margin; downy beneath,
with white cup-shaped pits. Shields brown, with a dark
border.—Native of shaly mossy rocks, and about the roots
of trees, in Scotland, Wales, Oxfordshire, and, according
to Acharius, in Switzerland. We have a specimen with nu-
merous shields, which are extremely rare, from Mr. Hudson's
herbarium, and another from M. Ménzies. Much smaller
than the last, each plant rarely exceeding two inches in
diameter, and consisting of a few concentric, lax, rounded
fronds. Its very prominent reticulations, and brown by age
or brown fattin, with scarcely any depressions and reticulations;
the margin only, often tumid and reflexed, being rugged,
and covered with grey mealy warts, proceeding from cracks
in the cuticle. The under side is even, of a nearly uniform
light brown, finely downy, besprinkled with small, white,
frond-like, white-bordered pits, sunk in the down. Shields small,
whitish, with a broad base; their disk dark-brown, at first
conceal, with an elevated, smooth, thick border, but soon
becoming flat, or slightly convex, almost black, the border
affirming the fame hue. This border is not sufficiently ex-
name the shields, and hence the former supposed this very
difficult species to be the male, or "powder-bearing plant," of
what we shall next describe, both having been for the
first time clearly determined in the Engl. Bot. from spe-
cimens collected and fluided with no small care and at-
tention.

n. 21. (Lichen fuliginosus; Dickl. Crypt. fusc. t. 12.
Engl. Bot. t. 1103. Lichenoides fuliginosum et pulv-
tentium, fuscules rubiginosis; Dill. Mufc. 108. t. 26. f. 100,
A.)—Frond roundly lobed, dark greenish-grey, rough with
blackish granulations; downy beneath, with white cup-
shaped pits. Shields red-brown, with a pale border.—More
frequent than the last on rocks, as well as trees in old dark
woods, in the alpine countries of Europe. Acharius says
it grows also in France, America, and the island of Bourbon.
We have it from Cornwall, Wales, and Wightmoreland.
The size and habit of this plant agree with the last, but the
present species is distinguished by the innumerable dark
warty granulations of its upper surface, and the want of
those grey, dense, mealy warts, which distinguish S. limbata.
The under sides of both species are similar. The little
fronds of the present, very rarely met with, are more elevated;
at first reddish, with a pale tumid border; then convex and
dark brown, their border disappearing. This has been very
erroneously considered as a variety of the following.

Pl. Lich. v. 21. t. 4. f. 2. Lichenoides polychichides,
villosum et feelrum, peltis parvis; Dill. Mufc. 199. t. 27.
f. 101.)—Frond deeply lobed, bluntly cut, divaricated,
greenish-brown, somewhat uneven and granulated; downy
beneath, with white pits. Shields marginal, vertical, con-
vea, dark-brown.—Abundant in the mountainous woods of
moss parts of Europe, clothing the ground in loose extensive
tufs, intermixed with moss, under the shade of rocks or
old decaying trees; but the fruticisation is among the
greatest botanical rarities. We have seen it however in
Dr. Hope's collection, who received his specimen from Dr.
Burges of Dumfriesshire: Dillenius and Hoffmann have
also delineated similar ones. The fronds spread much more
widely than those of S. limbata or fuliginosa, and are longer,
though narrower and much more divided, with abrupt
divaricated segments. Their upper surface is usually
smooth and even, of a greenish rusby brown, scarcely to
green as in Hoffmann's plate. Sometimes it is obfuscely
cellular, and besprinkled with dark granulations, like those
of fuliginosa; with which species likewise the under side
accords, the pits being those of a true Sticta. But the
shields, as represented by authors, appear very different from
every known species, being more like the petes, or targets,
of the genus Pelidea, and falted, like most of them, on
marginal elongated portions of the frond. (See Pelidea.)
Whether they are orbicular and bordered in a young state,
smoothly has not obseived. If so, this ambiguity needs it
would prove a genuine Sticta; but otherwise it would, as a Pe-
leida, overturn the importance of the cyphella for generic
distinction. Indeed this importance is much weakened by

Vol. XXXIV.
S. pulmonacea and verdicula, in which these pits are so imperfectly defined; to lay nothing of Parmelia glauculiace, Ach. Syn. 195. (Lichen glauculiace; Engl. Bot. t. 2935) and other species, in which they dilutely, though not occasionally or sparingly, occur.

We beg leave, further, to observe that S. obvoluta, Ach. Syn. n. 19, has no character of the present genus, but, though villous on both sides, seems naturally of the tribe called Cerraria.

STEICHOWITZ, in Geography, a town of Bohemia, in the circle of Beraeus, in the Muldaw; 10 miles S.E. of Beraeus.

STIEGE, or Stige, in Commerce, a term of reckoning used in Germany, containing 20 pieces.

STIENTA, in Geography, a town of Italy, in the department of the Lower Po; 9 miles N. of Ferrara.

STIEPANO, a town of Bohemia, in the circle of Kaurzin; 15 miles S. of Kaurzin.

STIERNHIELM, George, in Biography, a learned Swede, was born in Dalecarlia, in the year 1598. Enjoying the friendship of Burkus, tutor to Gustavus Adolphus, he made great progress in literature and the sciences. Upon his return from a tour into foreign countries, he was appointed lecturer on moralities in the Gymnasion newly founded at Velleros; but destined for a wider sphere of usefulness and reputation, he was appointed, in 1630, alderman in the court of justice at Dorpat; and in the following year was ennobled. In 1639 he occupied an important office in Livonia, where it was his fate to be regarded by the ignorant and superstitious populace as a forcerer, because he employed microscopes, and other philosophical instruments, to aid him in the investigation of the secrets of nature. In 1648 he was advanced to the high lation of vice-president of the court of justice at Dorpat; but being obliged to fly from the Russians, who threatened this place, the vessel in which he embarked was wrecked in its passage; and though he escaped himself, he lost all the property which he had preserved from the ravages of the Russians. When he arrived at the capital, he was penniless and almost naked; but he was soon relieved by the munificence of some steady friends. Queen Christina treated him with respect, and nominated him antiquary of the kingdom; entailing him also with the care of the public records, and conferring on him the title of "Culos Regni." In 1658 he was appointed by Charles X. provincial judge of Drosteheim, in Norway; but when Drosteheim was restored to Denmark, he became, in 1661, a member of the council of war; and when the college of antiquities was established at Upsal, in 1666, he was appointed director. He died at Stockholm in 1672, at the age of 74. Stiernhelm was a man of great learning, and excelled in an extensive knowledge of languages. All languages, in his opinion, were derived from the Scythian, which he maintained to be older than the Hebrew itself. By command of queen Christina, he was obliged, in her presence, and in the public hall of the academy of Upsal, to hold a disputation on this subject with professor, afterwards bishop, Terfehus. His taste for poetry led him to an acquaintance with the principal compositions of the ancient poets; and his own verses are said to be still read with pleasure. In consequence of his extensive knowledge of mathematics and arithmetic, he was employed to regulate the Swedish weights and measures. Regardless of wealth, he was often reduced to such distress as to be under a necessity of writing to the chancellor Oxenhius, requisitioning public relief. When his friends regretted his poverty, they received for answer, "Bone mentis comes et paupertas. Aut philosophum aut divitem operet vivere." He preferred the former; and always feemed contented, cheerful, and happy. Being asked on his death-bed what epigraph should be inscribed on his tomb, he replied, "Vixit, dum Vixit, latum." Although he was a man of unquestionable virtue and integrity, he did not escape calumny. In matters of philosophy, he thought freely and boldly; but it does not appear that he ever wrote any thing contrary to that respect which is due to the Supreme Being, or to the principles of true religion. Among his numerous works were, "Magog Araméez Gothicus, five origines Vocabularum in Linguas pane omnibus, ex Linguæ Svecica veteri," a work printed at Upsal in 1640, but never completed; "Leges Velthrogothicæ antiquæ, cum Praefatione et Indice Vocabularum obfusciorum," Stock. 1662; fol.; "Uphilias, seu Verbo quatuor Evangeliorum Gotica, Litteris Latinis quam Gothicæ editis F. Junesium, cum Verfionibus paralleliis, Svecogothica, Islandica, et vulgata Latina," &c. 1671; ibid. 4to.; "Epitola ad Olaus Verelium de Origine Vocabularum Gothi et Svedi," prefixed to Hervara Saga; "Antichveriæs, litteræ de Originiis Sveo-Gothicæ," Holm. 1683; 8vo. The "Archimedes Reformatæ" of Stiernhelm, on trying metals by water; and his "Linea Carolina," are incontrovertible proofs of his deep knowledge in mathematics and natural philosophy. It appears that he had both these microscopes and tables, which were very rare in Sweden at this time. He was well versed in languages, history, and the northern antiques. His memory is particularly venerated on account of his being the father of true poetry in Sweden. He determined, as his biographer says, to throw aside that restraint which words of the fame at the conclusion of the lines carry with them, and to try whether ingenious thoughts would not please as much in Swedish verse without rhyme, as in the poetry of the Greeks and the Romans. The attempt completely succeeded in hexameter or heroic verse, and Stiernhelm's "Hercules" is and will continue to be a master-piece. Gen. Bong.

STIERNHOK, John, a learned Swede, was born in 1576. After travelling in foreign countries from 1620 to 1624, he was appointed lecturer of jurisprudence and the political sciences at Velleros; and in 1640 made professor of jurisprudence in the newly established academy at Abo. In 1658 his flight became bad, and he laboured under this infirmity until his death, which happened at Stockholm in 1675; and yet two years before this event he went to Holland, and visited the Hague, Leyden, Amsterdam, and several other parts, without any affluence. He was the author of various esteemed works, among which was "De Juris Sceuomin et Gothorum vetulio Libri duo," Holm. 1672; 4to. Gen. Bong.

STIE, the quality by which a ship is enabled to carry a sufficient quantity of sail without the danger of overfetting. Vessels having this quality, arising from their construction, will certainly fail fatter than others, which, in order to carry the fame quantity of sail, require to be builded. The illibors of many ships, however perfect in their construction, may be materially injured by an injudicious mode of lollowage; although, on the contrary, this defect in the construction can be seldom rectified, to any considerable degree, by the lollowage. See Ship-Building and Stowage.

STIFF Joints in neat cattle, a disease of these parts, which is often troublesome and very hurtful to them. It is most probably of the rheumatic kind, and not unfrequently termed joint felloen by the country people. It affects, for the most part, such old milch cows as are near calving, or such young cattle as are much exposed in the
the held in the spring of the year. It commonly arises from too great exposure to cold winds and moisture, and generally takes place in such animals as have been kept in a state of poverty and starvations for the winter season, on their being suddenly turned out in the early summer months, and greatly exposed in low damp situations to the severity of the north and easterly winds.

The appearances of it are, that the joints become particularly affected, and sometimes swelled; and there are great pain and weakness. For two or three days at first, the animals only appear stiff in the joints; which afterwards often begin to tumefy and enlarge, without any signs of an active inflammatory state; a cold inactive tumour con- sequently takes place about the articulations, which is attended with a great stiffness, that not unfrequently spreads and extends itself over the whole body, so that the beast is scarcely able to rise when laid down, without being in some measure afflicted. Such cattle as labour under this complaint often suffer greatly from the severity of the pain in the parts, and from the lassitude and incapacity of stirring which attend it.

On the disease first making its appearance, the beast should be removed, and be taken to some proper building of the cow-house kind, which is rather which is situated in moderate warmth, and much use in the removal of the complaint. Here proper remedies should be given, such as calomel and gum guaiacum, in pretty full doses, as from half a dram, to a whole dram and upwards, of the former; and from half an ounce, to an ounce and more, of the latter, in powder, made up with the tincture of opium and balam of copaiva into the form of a small ball. This may be given once or twice in the day, in a hornful or two of warm ale. And afterwards, recourse may be had to guaiacum, in combination with Peruvian or oak bark, camphor, and fumach feeds, in the proportions of from one to two ounces of the gum, bark, and feeds; and from one and a half to two and three drachms of the camphor; the whole being formed into a fine powder, and given as above. One or two ounces of the spirit of turpentine may also sometimes be given in a quart of thin oatmeal gruel with great benefit.

The use of strong stimulating applications rubbed externally on the swellings of the joints, which are so strongly recommended by some, are seldom probably to be had recourse to, as they may be attended with danger in many ways.

Where the disease puts on an active state, and is accompanied with fever and much pain, as well as swelling in the joints, as occasionally is the case; it will be necessary and proper to have recourse to opening mild purgative remedies, as there may be occasion, with the balls and powders given in such a manner as may be suitable.

By the proper use of these means, the beasts will most likely soon get well of such lassitude in their joints.

But cows and other neat cattle sometimes have lamenesses and flinfinenes, which appear to be at one time in the fore-quarters, and at another in the hind ones; and which are attended with considerable pain. These often proceed from hard driving, or other similar causes, and not from the same causes as the above; but in these cases, too, the calomel-ball, as well as such remedies of the bark kind as have been advised above, will be found useful.

Stiff Joints in lambs, a disease or affection in these parts of them, which mostly takes place during the hot summer season, as about the month of June, coming on with a flinfinnes in the different joints of the extremities, and sometimes feizing several lambs in the same flock at the same time. It is commonly supphed to be occasioned by the low state or condition of the ewes to which they belong; but it is more probable that it arises from the sudden change of colds and damp which are liable to take place, and to which they are particularly exposed at this period of the year. At such times, however, the lambs are believed to be disposed to grow fat, and, for want of proper and sufficient nourishment, to become flinted, and to have their joints stiff and swelling out; they, however, for the most part, recover from the complaint. It is most likely a disease of the rheumatic kind, which, when it does not readily go off, may cause the use of calomel with a little opium in the form of a small ball, to the ex- tent of from a scruple to half a dramh, once or twice in the day, or a small spoonfull or two at a time of the spirit of turpentine.

STIFFLE, or STIFFLE, the name of a disease in the patella, or knee-pin, in a horse or other animal, which part it properly signifies. A lameness in the stifle is caused by those accidents that produce it in all other joints. When a horse is lame in this part he generally treads upon his toe, and cannot set that heel to the ground. Some strains in the stifle are violent, and swell pretty much; but Gibbon affirms, that he hardly ever knew any of them incurable, unless bad methods had been tried in the beginning. They commonly may be cured by cooling saturnine applications, such as have been prescribed for the shoulder strains; but if the swelling be very large and puffy, which sometimes happens, recourse must be had to fomentations, to take off inflammation. Sometimes, however, impojishments follow: in such cases, and when these break and run, there is commonly an end of danger.

STIFF, in Etching. See Etching.

STIGLIANO, in Geography, a town of Italy, in the Patrimonio; 9 miles E. of Civita Vecchia.—Alfo, a town of Naples, in Basilicata, celebrated for its baths; 24 miles S.S.E. of Acerenza.

STIGMA, in Medicine, a minute red speck in the skin, without any elevation of the cuticle, of the same nature as petechia, from which they differ only in magnitude.

STIGMA, in Botany and Vegetable Physiology, an essential part of the Pistillum (see that article) in flowers, being the organ defined to receive the pollen, the action of which upon the stigma causes the fertility of the seeds. (See fertilization of Plants.) For the accomplishment of this important purpose, the part in question is so situated as to receive the pollen, and so formed as to retain it; whilst a peculiar moisture, secreted, more or less copiously, by the stigma, occasions the particles of the pollen, hitherto kept dry, to burst, and discharge their elastic contents, more immediately subservient to the end designed. When the pollen is of a glutinous quality, as in Orchidea and Conotera, the same moisture must be supposed to act as a menstruum, performing the same thing in a slightly different mode.

The shape of the stigma is either simple, being little more than a mere point; or it is capitate, like a pin's head, as in the Primrose. In the ringen flowers the two stigmas are tapering, but of the mall simple structure, devoid of all evident pubescence, so that it is hard to understand which is the efficient part; while in most graces the stigmas are amply branched or feathery, to detain the pollen. So in many of the mallow tribe, a great degree of pubescence, and abundance of vifid moisture, are evident in these organs; their rich purple or scarlet colour contrasting with the large yellow pollen, whose burbling, or explosion, may almost be seen by the naked eye. The stigma of the Ama- ryllis formosiflora is furnished, as Linneus observes in his
Dilertation on the Sexes of Plants, with a large drop of clear fluid, which is protruded in the day time, so as to seem in danger of falling to the ground. 'To this the pollen adheres, rendering it turbid or striated, in which state it is re-absorbed towards evening into the style. The concave stigma of the Violet gapes to receive the pollen; that of the Martynia is said to be irritable, closing from the stimulus of the pollen, which by that means it more freely retains. That a vital principle is inherent in the stigma, at least till the ends of its formation are answered, we learn from an observation of Linnæus, in the Dilertation above alluded to. He found that this organ, in female plants of Hemp to which no pollen had access, remained for a long while green and vigorous, as not having had the vital principle exhausted; while the stigma of every blossom which had been impregnated, evinced the completion of that operation, by fading and withering away. Almost every flower, when carefully examined, confirms the truth of this remark. In those cafes where the styles remain, to form a crown, or hooks, afiliting in the dispersion of the seeds, the stigmata will generally be found decayed or separated. See Germen and Stylus.

STIGMANTHUS, in Botany, a name of Loureiro's, formed of repyn, the stigma, and wies, a flower, in allusion to the unusually large size of that organ. — Loureir. Cochinch. 146. — Clafs and order, Pentandria Monogynia. Nat. Ord. Rubiaceae. Julf.

Gen. Ch. Cal. Perianth superior, of one leaf; tube short; limb in five deep, long, very slender, segments. Cor. funnel-shaped, with a long tube; limb in five deep, ovate-oblong, spreading segments. Stam. Filaments five, very short, inserted below the segments of the corolla; anthers oblong, reflexed (we presume between the segments). 

Per. Germen inferior, roundish; style thread-shaped, longer than the corolla; stigma ovate, furrowed, very large. Peric. Berry dry, compressed, tuberculated, of one cell. Seeds numerous, oblong, angular, bony.

Ell. Ch. Corolla funnel-shaped. Stigma furrowed, very large. Berry dry, crowned by the calyx, of one cell, with many bony seeds.

1. S. cympaeus. Cay luim rong of the Cochinchine.—Native of woods and hills in Cochinchina.—A large, branching, climbing, fawls, within tendrils or thorns. Leaves opposite, lanceolate, entire, smooth. Flowers white, in very large, axillary and terminal, cymes.

Loureiro hints the affinity of this plant to Muffenda, from which he says, it differs chiefly in its feed-selv and stigma. We cannot refer it to any known genus, but it seems to range near the Solena of Willdenow. See that article.

STIGMAROTA, from figma, and rota, a wheel, alluding to the large, orbicular, toothed stigma. — Loureir. Cochinch. 633. — Clafs and order, Diastea Polyandria. The name is bad, and of the genus itself we have not sufficient materials to form an opinion. Loureiro gives the following.

Ell. Ch. Male, Calyx in four or five deep segments. Corolla none. Stamens thirty.

Female, Calyx in five or six deep segments. Corolla none. Stigma wheel-shaped, fix-clerk. Berry fleshy, with fix seeds.

The species are two.

1. S. Jangomas. — Stem arborescent, with branched spines. Stalks scattered, many-flowered.—Cultivated, and perhaps wild, in Cochinchina. This the author confounds as Jangomas, Bunt. Jav. 111, and Spina Spinorum, Rumph. Amboin. v. 7. 36. f. 1. 1. He the foregoing rightly observs, that the latter synonym can have no reference to Curifa spinorum, Linn. Mant. 559.

2. S. africana. — Stem shrubby, with simple spines. Flowers solitary, terminal.

STIGMATA, in Natural History, the apertures in different parts of the bodies of insects communicating with the tracheæ, or air-vesels, and serving for the office of respiration.

Nature has given to these minute animals a much larger number of tracheæ and bronchia, than to us. We have the ramifications of the trachea reaching no farther than into the break, whereas, in the bodies of these insects, we find them extended through the whole, and finely and admirably interwoven with one another. We have but one mouth to respire by; and the organization of the parts, indifferent to respiration, is very admirable in us; but in the insect class, the mouth or openings to breathe at, are much more numerous, and the organization much more complex. All the two-winged and four-winged flies, which have a single or undivided corselet, to which their legs are all fixed, have also four stigmata in that corselet, two on each side. They have them also on the rings of their body, but those on the corselet are the most considerable.

Of the four on the corselet, the two anterior ones are usually the largest. The best way to find them, in the generality of flies, is to examine them first in the larger species of the bumble, where they are very distinct and plain, and after their situation is well known in that species, they will be much the more readily found in the cell.

These stigmata of the corselet, as well the anterior, as the posterior, are oblong, and placed obliquely to the length of the body; that end of them next the head is more elevated than the other, and their size is sufficiently large to render them visible, especially the first pair. Each of those seems not a little to resemble a fea-muscle with its feel a little open, or is somewhat like the opening of an eye. It is also surrounded by two eye-lids, proportionally thick; and beside these, which make its outer circumference, one may discover two others within, which are bordered with hairs, and which, when elided, often quite shut up the opening.

The colour of the stigmata often is some help also to us for the discovery of them; they are very frequently different in colour from the corselet; some are yellowish, others of a coffee colour, or some degree of a fellow colour, in flies whose corselet is brown, or black, or blueish.

Flies have, besides these, several stigmata also in the rings of their bodies, perhaps in every one of them, though common those in the two or three first are only to be dilligence; these are not like those of the corselet, but are round, usually a little eminent above the rest of the surface, and resembling pin's heads; they are not easily discovered, because they are not only small, but usually hid by the folds, or commissures of the rings. They are usually two on each ring, placed on the two opposite sides, and partly under the belly.

Malpighi first discovered, that those eighteen openings, which are placed nine on each side of the caterpillar, and which are called by the name of stigmata, serve to give respiration to this class of animals. M. Reaumur repeated his experiments, and made several new ones; and he concluded that those apertures serve only for the inspiration of the air, which the caterpillar afterwards expired through the whole superficies of its body, because he could never observe that any bubbles of air were ever driven out of these stigmata: but Mr. Bonnet, on the contrary, having seen bubbles of air coming out of these openings, was led to infer that the inspired air was also respired or discharged through these same orifices; and he is of opinion that no part
part of it is expired through the pores of the body. From several experiments he also inferred, that of the eighteen stigmata with which the caterpillar is furnished, the two anterior and the two posterior ones are of greater use for respiration than any of the others. Phil. Trans. vol. xlv. p. 300, &c.

STIGMATA, in Antiquity, certain marks impressed on the left shoulder of the soldiers when lifted. See STIGMATIZATION.

STIGMATA were also a kind of notes, or abbreviations, consisting only of points, disposed various ways; as in triangles, squares, cradles, &c. STIGMATA is also a term introduced by the Franciscans to express the marks, or prints, of our Saviour's wounds, said to have been miraculously impressed by him on the body of his faithful follower, St. Francis.

A solemn feast was hereupon appointed to be annually celebrated in memory of the miracle, called "the feast of the stigmata of St. Francis," and a peculiar mass or office was composed for the same.

An archi-confraternity was erected on the same occasion, by Fred. Pizzi, a Roman surgeon, in the year 1594. STIGMATICI, among the Romans, were fervants marked in the face for fame crime.

STIGMATIZING, among the Ancients, was inflicted upon slaves as a punishment, but more frequently as a mark to know them by; in which case it was done by applying a red-hot iron, marked with certain letters, forming the name or some peculiar character belonging to their masters, to their foreheads till a fair impression was made, and then pouring ink into the furrows, that the inscription might be the more conspicuous.

Soldiers were branded in the hand with the name or character of their general.

After the same manner it was customary to stigmatize the worshippers and votaries of some of the gods. The marks used on these occasions were various; sometimes they contained the name of the god, sometimes his particular ensign, as the thunderbolt of Jupiter, the trident of Neptune, the ivy of Baechus, &c. or they marked themselves with some mystical number, by which the god's name was described. To these three ways of stigmatizing St. John is supposed to refer. (Rev. chap. xiii. ver. 16, 17.) Theodoret is of opinion, that the Jews were forbidden to brand themselves with stigmata, because the idolaters, by that ceremony, used to confound themselves with their false gods.

Among some nations, stigmatizing was considered as a distinguished mark of honour and nobility. In Thrace, as Herodotus tells us (ib. x.), it was practiced by none but persons of credit, nor admitted by any but persons of the meanest rank.

The ancient Britons are also said to have imprinted on the bodies of their infants the figures of animals, and other marks, with hot irons. Potter Arch. Greek. tom. i. p. 64, &c.

STIGSIO, in Geography, a town of Sweden, in Angermanland, seated on a river which runs into the gulf of Bothnia; 8 miles W. of Hernosand.

STIKKESHOLM, a place on the south coast of Iceland, situated at the extremity of a small peninsula, close to the sea, amid shrubry precipitous rocks, some of which are columnar. Near the i throm, which is pilled in entering this peninsula, is a hamlet, called "Helgafell," or the Holy Hill, from its situation on an eminence, with which certain superflitious ideas and usages were anciently connected. On this spot was established one of the earlist of those settlements which the Norwegian emigrants made upon the coasts of Iceland. The access to Stikkeholm affords several fine views of the "Brecie-Fiord," which is here completely flooded with small rocky islands, amounting in number to about 150. Many of these islands contain great numbers of cinder-ducks. The houses are large, and, as well as the flore-houses and cottages, belonged (1810) to Mr. Thorlacius, a native of the country, and reputed the richest man in Iceland. Before the war between England and Denmark, Stikkeholm was a place of considerable trade. The fishery, which begins earlier than in the Faxfiord, was very productive. During the early part of Sunday, the occupations of the people in this place were suspended, and many of them went to the neighbouring church at Helgafell; but at six o'clock in the evening, the flore-houses were again opened, and the inhabitants of the place, refuming their common drestes, went to work as usual. This is also the cafe in every part of the country. The fabbath of the Icelanders, according to the ecclesiastical law of the island, begins at six o'clock on Saturday evening, and terminates at the same hour on Sunday. The females of the family at Stikkeholm, as well as those of the higher classes of people in other places, did not sit at the table, when the travellers, to whose account we now refer, were eating their meals. The master of the house always saluted his lady, when he rose from the table.

Mackenzies Travels in Iceland in 1810.

STILL de Grain, in the Colour Trade, the name of a composition used for painting in oil or water, and is made of a decoction of the lycium, or Avignon berry, in alum-water, which is mixed with whiting into a paste, and formed into twisted sticks. It ought to be chosen of a fine gold yellow, very fine, tender, and friable, and free from dirt.

STILAGO, in Botany, Linn. Mant. 16. Jull. 443. Schreb. Gen. 608. 836. Wildk. Sp. Pl. v. 4. 714. Mart. Mill. Dict. v. 4. Ait. Hort. Kew. v. 5. 367., was so called perhaps from the supposed permanency of its style. The name and the genus, however, require to be abolished, the characters, except that of the berry from Rumphius, having been taken from a specimen in the Linnean herbarium, which proves merely the male plant of Antidesma alexiteria. (See Antidesma.) Indeed the Stilago diaandra, Roxb. Coromand. v. 2. t. 166, most evidently agrees in genus with his Antidesma pakefenus, t. 167. We cannot account for their being kept separate by the learned editor, who well knew what Stilago was. Still more wonderful is it that Noeli talia, Riche Hort. Malab. v. 4. t. 56, should be quoted by Wilkensow, without any remark, for both Stilago Buxius and Antidesma alexiteria. We cannot deny the accidental propriety of this citation, they being, though the author did not know it, one and the same plant.

STILARO, in Geography, a river of Naples, which runs into the gulf of Squillace, N. lat. 38° 21'. E. long. 16° 50'.

Gen. Ch. Cal. Perianth inferior, double; the outer of three lanceolate, spreading, pointed leaves; inner of one leaf, tubular, five-toothed, at length hardened. Cor. of one petal, tunnel-flaped; tube the length of the calyx; limb
limb in four or five linear-lanceolate, nearly equal, deep segments. **Stam.** Filaments four,awl-shaped, inserted into the throat of the tube, longer than the limb, somewhat unequal in length; anthers heart-shaped, obtuse. **Pist.** Germ. superior, ovate; style thread-shaped, the length of the filaments; stigma acute. **Peric.** none, except the inner calyx becoming cartilaginous, inclosing the feed, and falling off with it. **Seed** solitary.

Some plants are said to bear only male flowers.

**Eff. Ch.** Calyx inferior, double; the outer of three leaves; inner five-toothed, cartilaginous. Corolla funnel-shaped. Capsule of one cell and one valve, separating entirely from the base. **Seed** solitary.

1. **S. pinifera.** Fine-leaved Stilbe. Linn. Mant. 305. Wild. n. 1. Thunb. Prodr. 29. (S. veitita; Berg. Cap. 30. t. 4. f. 6. Selago pinifera; Linn. Sp. Pl. 876.)—Leaves lanceolate, pungent, revolute. **Spikes** erect. Limb of the corolla hairy.—Native of the banks of rivulets, at the Cape of Good Hope. It seems unknown in the gardens of Europe. Commelin’s *Vaterianella*, Hort. Amst. v. 2. t. 110, surely can have nothing to do with this plant. The stem is shrubby, with many straight, round, upright branches, densely clothed with whorled, spreading, ascending, rigid, pale, lanceolate, revolute, entire, smooth leaves, half an inch or more in length; dotted above; on short broad Raliks. Spikes terminal, sterile, solitary, erect, oblong, with a bract under each flower, reeling the leaves, but shorter and broader. We have never seen the flowers in perfection, which Bergius describes as white.

We are not without suspicion of his having, as well as Linnæus, confounded two species, one with longer whitish hairs upon the corolla, and shorter less pungent leaves, than what his plate represents.

2. **S. cernua.** Drooping Stilbe. Linn. Suppl. 441. Wild. n. 2. Thunb. Prodr. 29.—Leaves prismatic, abrupt, with a small point. Spikes drooping. Limb of the corolla smooth.—Gathered by Thunberg, at the Cape of Good Hope. The leaves are only four in each whorl, not fix, as in the foregoing. Their form is triangular or prismatic, with a fleshy rib. **Spikes** shorter than the lal, recurved, with much larger flowers, whose limb has only four segments, all smooth, lanceolate, and acute.

3. **S. ericoides.** Heath-leaved Stilbe. Linn. Mant. 305. Wild. n. 3. Thunb. Prodr. 29. (Selago ericoides; Linn. Mant. 87.)—Leaves ovate. Spikes erect. Limb of the corolla smooth.—Native of the Cape of Good Hope. A much smaller shrub than either of the preceding, with small leaves, like some Heath or Thyme, imbricated in four rows, ovate, thick, smooth, with a fleshy lanceolate keel, lodged in a furrow. Spikes short and erect. **Flowers** apparently purplish. **Calyx** fringed with white wool. No figure is extant of this or the last, nor have they appeared in any garden.

**STILBITAE.** In Mineralogy. See ZEOLITE.

The French mineralogists, after Haiy, have divided the mineral called zeolite into two species, metotype and filbitæ. The latter is often called nacy zeolite, being distinguished by its nacy infusc. The properties of this mineral will be described, with the other varieties of zeolite, under that article.

**Eff. Ch.** Seeds, or seed-cailes, naked, imbodied collectively in a black substance, flowing from the branches of trees.

This cannot but seem a very doubtful genus of the vegetable kingdom, though not more obscure than the *Chase* of Linnæus, or the *Hydatid* of Hunter, amongst animals. Peron. remarks that there is no *fisbaula*, or capillary receptacle, as in *Spilaria* (see that article): and that a compound microscope is necessary for the determination of the different shapes of these minute granular bodies, which he knows not whether to call *feed-waffles*, or feeds, or perhaps buds, all forming, to the naked eye, one uniform black mass. He defines six species.

1. **S. afterofera.** (S. afterofera; Hoffm. Germ. v. 2. t. 13. f. 3.)—Cafes foliated.—This appears in the form of variously-shaped black spots, under the cuticle of trees, and is found, under a high magnifier, to contain numerous, compact, radiated bodies, composed of oblong pods, crossing each other, and divided internally into three or four cells.

3. **S. ovata.** Perf. Obs. Mycol. fasic. 1. 31. t. 2. f. 2. (S. pyriformis; Hoffm. Germ. v. 2. t. 13. f. 2.)—Cafes? or feeds? ovate.—On the trunks of beech. The shape is exactly oval, but no distinct partitions, or cells, are discernible, according to Peronson, though Hoffman’s figure seems to express them.

4. **S. angulata.** Perf. Syn. n. 4.—Seeds minute, ovate, inclining to cylindrical.—Intermediate between the last and the following, nearly agreeing in minuteness with the latter.

5. **S. microspora.** Perf. Obs. Mycol. fasic. 1. 31. t. 2. f. 1.—Seeds minute, unequally ovate, rather acute at each end.—On branches of beech, or the bark of *Betula alba*, &c. Various in form, roundish, ovate, or oblong, delibuted of partitions.

6. **S. fihrofera.** Perf. Obs. Mycol. fasic. 1. 31. t. 1. f. 6.—Seeds minute, globose.—Found on the same of the Common Reed, *Arrundo phragmites*, appearing to have run out of filitures in the Straw, and sometimes collected in round spots.

**STILBUM.** From στενος, shining, a genus of fungi, which Fison can in his *Synoplia*, p. 608, thus defines.

**Eff. Ch.** Little, flaked, muceo-like fungi; with a roundish folid head, at first warty or gelatinous, becoming generally opaque, or turbid, as it ripens.

He defines sixteen species, found on rotten wood, of which the most conspicuous and remarkable is the first.

**S. birutum.** Perf. Dips. Meth. Fung. 39. Hoffm. Germ. t. 10. f. 2.—Permanent. Stalk yellowish, rough with straight upright hairs.—A pretty species, found rarely on rotten trunks of trees. This is among the largess of its genus, and may even be dried and preferred. The brightly aspected of the falk, one or two lines in height, readily distinguishes it.

We cannot perceive why this genus may not be comprehended under MUCON. See that article.

**STILE, and Stilus.** See STYLE.

**Stile** in Rural Economy, the name of a well-known contrivance for the admission of foot-passengers, without permitting the flock of the inclosures to get through. Stiles are made in very different forms and manners, in different districts, according to the nature of the materials, situations, and purposes for which they are intended. But they may be more clearly understood, by a short description of them. Where liones are in use, a file of a very simple construction is formed, by having at the bottom a thin flat stone set up edge-ways, to prevent sheep, and other small animals, getting out; and above there is a long cord stone or bar fixed, to prevent horses or cattle jumping over. Another file of a simple construction, and which is well calculated
calculated for situations where the traffic is not great, is formed by having flapping-frames fixed in the sides of the wall. In the Corinithian flute, the foundation is a fluted wall, in which a gap is left, and flutes are laid across a ditch of some depth, made lengthways in the gap; the foot-paftengers step on the flutes, but four-fooled animals mfs through and fall into the ditch.

Where wood is employed in forming flutes, they have many different forms, according to the nature of the situations, and the ingenuity of the workmen who construct them. Common flutes of this fort are made with two framed pieces of timber let upright, part of them parallel to each other, leaving sufficient space for a perfon to pass between them; and by a fort of upright railing set firmly into the ground, with steps fixed through it towards the bottom part, by means of which the paftengers are enabled to get over. There is likewise the wallet flute, which has somewhat the form of a small gate, swinging between two other similar frames, which are let fall into the ground in an angular manner; and the regular flue-form, with a rail.

It is probable, too, that there are other different kinds and forms in use in different places.

STILES, in Carpenter, denote also the upright pieces which go from the bottom to the top in any window, or the like.

STILLFRIED, in Geography, a town of Austria; 7 miles N.E. of Weikendorf.

STIL, an island in the Grecian Archipelago. N. lat. 37° 25'. E. long. 22° 49'.

STILICHIO, in Biography, a commander who distinguished himself in the decline of the Roman empire, was of Vandal origin, and the son of an officer of cavalry in the service of the emperor Valens. Brought up to arms, he rose rapidly through various gradations to the post of master-general of the cavalry and infantry of the Roman, or at least of the Western, empire. He accompanied Theodosius in all his wars, and maintained the Roman dignity in ratifying a treaty with the king of Persia. On his return, he married Serena, the niece and adopted daughter of Theodosius. Although Rufinus, who was the confidential minister of Theodosius, was jealous of Stilicho, and wished to depress him in the estimation of the emperor, he was counteracted by the influence of Stilicho's wife; so that he was with the emperor at the time of his death in 395, and entrusted by him with the guardianship of his two sons, Arcadius and Honorius. The latter, who had the Western empire for his share, appointed Stilicho for his prime minister; and he began his administration by renewing the ancient alliances of the Romans with the German nations, and established peace. In 397, Stilicho restored to the succour of Greece, which was ravaged by Alaric. Having either neglected or betrayed his trust, by suffering Alaric to escape, he was obliged to withdraw from Greece, and was declared at Constantinople a public enemy, with confiscation of all his estates in the East. Stilicho exerted himself with vigour in recovering Africa, which had revolted from the Western empire; and acquired new influence by the marriage of his daughter, Maria, to the young emperor, Honorius;—an union elegantly celebrated by Claudian, the perpetual panegyrist of Stilicho. When the timid Honorius was alarmed by the irruption of Alaric into Italy in the year 403, and was disposed to quit Milan, the seat of his government, and to retire to one of the Gallic provinces, Stilicho opposed this disgraceful measure, and collecting a powerful force, vanquished the Goths at Pollentia, and obliged them to retreat; neverthelefs Alaric, breaking through the passage of the Apenines with his cavalry, spread an alarm that reached even Rome, to that Stilicho advised the purchase of his retreat from Italy with a sum of money. When Alaric had finally departed, the policy of Stilicho was publicly arraigned for suffering him to escape. In 405, Italy was again invaded by a vast multitude of barbarians, who penetrated as far as Florence, laid siege to the city, and reduced it to great distress. Stilicho hallowed to the relief of the beleaguered, who forced the barbarians, forced them to surrender, and put to death their commander, Radagaisus, who had been taken prisoner. Although Italy was again delivered by Stilicho, Alaric still remained at the head of new levies of Goths, and other barbarian warriors. Stilicho, either from motives of personal ambition, or of late necessity, entered into a negotiation with Alaric, by virtue of which he was declared master-general of the Roman armies in Illyricum. Whilft Stilicho was forming a purpose of leading an army of Romans and Goths to Conflantinople, and concurring with Alaric in making an extravagant demand upon Ravenna, the feeble-minded Honorius was connecting himself with a new favourite, who succeeded in impressing the mind of the emperor with alarms of the treasonable intentions of Stilicho. Honorius determined to visit the camp at Pavia; and soon after his arrival at it, a pretext was formed for massacring all the friends of Stilicho, who occupied distinguished posts in the army and state. Stilicho received intelligence of this measure at Bologna; and a council, which he summoned, advised him to march immediately, and revenge the slaughter of his friends. Whilft he was hesitating, a Gothic chief rushed into his camp, killed his guard, and penetrated into his tent, whence he had but just time enough to escape. Flying to Ravenna, he took sanctuary in a Christian church; but being deceived by count Herachian, who appeared at the gates with a body of troops, and confiding in his oath that he meant only to secure him, surrendered himself into their hands. Upon this the treacherous count produced an order for his immediate execution, to which he submitted with a firmness becoming the military character which he had acquired. His son Eucherius was soon after apprehended, and put to death; and his daughter Thermantia, who had succeeded her father in the imperial bed, was divorced. Stilicho's surviving friends were cruelly tortured, in order to procure the confession of a supposed conspiracy against the emperor; but they suffered in silence. This catastrophe occurred in the year 408. The apparent piety of Olympus, the new favourite of Honorius, has induced the ecclesiastical historians to treat the memory of Stilicho with great severity; but Zosimus, though upon the whole not favourable to him, acquits him of the treason laid to his charge; and the poetry of Claudian eulogizes him as the hero of his age. Univ. Hist. Gibbon's Rom. Hist.

STILL, the name of an apparatus used in distillation. See Distillation and Laboratory. See also Alum, Bic, Retort, Worm, &c.

Dr. Lewis has contrived a still, adapted to his portable furnaces, which is sufficient for the purposes of an experimental laboratory. The body of the still is a wide copper pan; and, for distillation in a water-bath, another vessel of the same figure is received into it almost to the top, the space between them being nearly filled with water. Both these vessels are of the same width at the mouth, and either may be used as a still equally with the other: either of them serves also, on other occasions, as an evaporating pan, a boiler for experiments in dyeing, and other like purposes.

All the parts are made of thin copper plates, and well tinued on the inside with pure tin. In consequence of their thinness,
thinneth, they admit of some alteration of their figure about the edges, so that though they should not be perfectly round, they are readily accommodated to one another, and sit close; the juncture is easily made perfectly tight, by applying round it narrow slips of moistened bladder, which are more convenient than lathing, as being readily stripped off when the operation is finished. A short pewter pipe, with a pewter flapper fitted to it, for returning the distilled liquor, or pouring fresh liquor occasionally into the still, without the trouble of unluting and separating the vessels, is inserted into the top of the head, which, in these kinds of instruments, is the most convenient place for it. For separating, by distillation, spirituous from watery liquors, or the rectification of spirit of wine, the head is caulked, by inferring between it and the brash, a thin copper pipe about two feet long. A worm and refrigeratory are necessary, as for the common still; and a glass head is requisite for some ues, particularly for the distillation of vinegar, and such other liquors as would corrode a copper one, and impregnate themselves with the metal; in which case, the ufe of the metallic worm also is to be avoided, and the glafs or flone-ware receiver joined to the pipe of the head.

Lewis's Com. of Arts. p. 9, 10.

**Still-Bottoms**, in the **Dilillery**, a name given by the traders to what remains in the still, after the working of the wath into low wines.

Those bottoms are procured in the greatlest quantity from the malt wath, and are of no much value to the distiller in the fattening of hogs, &c. that he often finds them one of the most valuable articles of the business. They might also be put to other ues, such as the affording of a large proportion of an acid spirit, an oil, a fuel, and a fixed ual; and with some address, and good management, a vinegar and a tartar. Another very advantageous ufe of them, is the adding of them to the next brewing of the malt for more spirit: the increafe of the produce from this is more than could easily be conceived. It also more readily dispofes the new wath to ferment, and gives the spirit a vinofity that it cannot have without it; the proportion, in this cafe, can never exceed that of a fifth or sixth part of the whole quantity of the liquor employed. The liquor left behind in the still, after the rectifying of the low wines into proof spirit, is also caulked by some by the name of still-bottoms; but this is little more than mere phlegm, or water impregnated with a few acid, and some oily parts, not worth separating, ufed for curiosity. The liquor left in the still, after the rectifying of the proof spirit into alcohol, is also of the fame kind.

The bottoms of molasses spirits seem calculated for many ues. It is very probable that the vinegar-makers would find their account in trying them, and the strong and lafiting yellow colour with which they tinge the hands may recommend them to the dyers. A small proportion of them, added to the new treacle to be fermented, greatly promotes the operation, and increases the quantity of spirit.

The bottoms of the wine spirit, that is, the remainder after distilling the spirituous part from damaged wines, or wineless, may be brought to afford Mr. Boyle's acid spirit of wine, and that substance called by Becher the molia flantia vini. A parcel of tartar may also be procured in very great perfection; and the laft remainder may be converted into excellent and genuine salt of tartar. The liquor may otherwise be serviceable in making vinegar and white lead.

**Still-House.** The Dutch have much the advantage of us in the structure of their still-houses, and have every thing in great readiness and neatness. The general rules in building these houses should be these:

1. The first caution is to lay the floor slop, not flat, where any wet work is to be performed: it should also be well flagged with broad stones, so that no wet be detained in the crevices, but all may run off, and be let out at the drains made at the bottom and sides.

2. The stills should be placed above and on that side of the still-house to which the floor has its current. The largest stills in Holland, for their greatest works, are of these monolithic size which are constructed in England, but much more manageable and convenient, as seldom containing more than six or eight hogsheads; and with such stills a single hand will perform more business than with one of a much larger size. Fronting the stills, and adjoining to the back wall, should be a stage for holding the fermenting backs, and these being placed at a proper height, may empty themselves, by means of a cock and a canal, into the stills, which are thus charged with very little trouble.

Near this let of fermenting backs should be placed a pump or two, that may readily supply them with water by means of a trunk or canal, leading to each back. Under the pavement adjoining to the stills should be a kind of cellar, wherein to lodge the receivers, each of which should be furnished with its pump, to raise the low wines into the still for rectification; and through this cellar the refuse wath, or still-bottoms, should be discharged by means of a hole, or other contrivance. These are the principal things to be regarded in the erecting of a still-house for the original production of spirits; and if these rules are well observed, malt spirit will be made with little more trouble than molasses; for by this means the basins of brewing and cooling the wath, which, according to the method generally practised in England, takes up much time and trouble, is entirely saved; fermentation is carried on to a much greater advantage, and the quantity of spirit increased. Shaw's Essay on Distillery.

**STILLATIOUS Oils,** are such as are procured by distillation, in opposition to those got by infusion, exprefion, &c.

**STILLATORY.** See **Still-House.**

**STILLINGFLEET, EDWARD,** in Biography, a learned prelate of the English church, was born at Cranbourn, in Dorsetshire, in the year 1635; and, after preparatory education in the grammar-schools of Cranbourn and Ringwood, was elected in 1648 to St. John's college, Cambridge. Of this college he was chosen fellow in 1653, and presented to the rectory of Sutton, in Bedfordshire, in 1657, having previously received episcopal ordination from Dr. Browning, the deprived bishop of Exeter. In 1659 he published his "Trinitium, or the Divine Right of particular Forms of Church Government examined," hoping, by this publication, to remove the prejudices, and consolidate the attachment of those who were alienated from the church of England. In this treatise he maintains, that Chrit is not determined the form of the government of his church by any positive laws; that the apostles adapted it to the various circumstances of time, place, and persons; that episcopacy is lawful; that in the primitive church no invariable form of church government was adopted; and that the most eminent divines, at the Reformation, did not conceive any one particular form to be necessary. In a new edition of this work, in 1662, he annexed an appendix, concerning the power of excommunication in a Christian church. The Trinitium was highly commendable for its learning and moderation; but the author himself, as bishop Burnet says, desirous of avoiding the imputations of hostility to the church which
which it occasioned, retracted the book, and gave way to the humours of a high feat of people, beyond what became him, perhaps beyond his own sense of things. Whilst he was employed in performing the functions of a country pastor, he presented to the public a second work, of extensive learning and periphrastic style, which has been always esteemed one of the best defences of the Christian religion; and which was intituled "Origines Sacrae; or a rational Account of the Christian Faith, as to the Truth and divine Authority of the Scriptures, and the Matters therein contained," 1669. This work established his reputation as a writer, so far as he had a commission from Dr. Hanchman, bishop of London, to draw up a vindication of archbishop Laud's conference with Fisher the Jesuit; and the title of his work was, "A Rational Account of the Grounds of the Protestant Religion," 1664, folio; which Dr. Tillotson affords to be fully answerable to this appellation. So soon after, he was elected preacher at the Rolls chapel, and in 1665 presented by the earl of Southampton to the living of St. Andrew's, Holborn, and appointed likewise lecturer at the Temple. In 1668 he took his degree of doctor in divinity, distinguishing himself on the occasion by keeping an act in which he displayed great fluency in the Latin language, and logical acuteness. At the election of Charles II., to whom he was chaplain, he was nominated canon-residentiary of St. Paul's, to which preferment succeeded the deanship of London, and in 1678 the deanship of St. Paul's, which was his highest promotion during that reign. Whilst Dr. Stillingfleet was thus advancing from one dignity to another in the church, he was occupied in a variety of compositions on doctrinal and controversial subjects, more particularly directed against the Socinians. He also published a number of tracts against the Roman Catholics; one of the first was "A Discourse concerning the Idolatry practiced in the Church of Rome, and the Hazard of Salvation in the Communion of it," 1671; which produced a great number of answers and replies. Although much of his time must have been occupied in controversial writing, he found leisure to prefer to the public "A Letter of Resolution to a Peron unsatisfied about the Truth and Authority of the Scriptures" which was considered as an excellent piece of refutation. He also preached a sermon about the time of the Popish plot, the design of which was to unite the Differents in the common cause, and to induce them to abandon their separation from the established church, which involved him in a controversy with Baxter, Owen, and others, which were not likely to acquit him of his fundamental position; that, "peace, according to the judgment of divers among themselves, a conformity to our church's worship was not unlawful, by consequence their separation must be sinful and dangerous." To their strictures on his sermon he published a reply.

Dr. Stillingfleet extended his investigations far beyond the limits of theological and ecclesiastical subjects; and on occasion of the impeachment of the earl of Danby, he vindicated the right of bishops to vote in criminal cases, in a treatise on "The Jurisdiction of Bishops as capital Cafes," which proved his extensive acquaintance with parliamentary history, as well as statute and common law. A second work, published in 1685, and entitled "Origines Britannicae, or the Antiquities of the British Churches," gave an ample view of the origin and progress of Christian churches in Britain, since the first introduction of Christianity in the island to the conversion of the Saxons. In this research, Stillingfleet had been preceded by the learned archbishop Usher, in his work "De Ecclesiariarum Brittonicarum Primordiis," King James having instituted an ecclesiastical commission, summoned Vol. XXXIV.

Stillingfleet, who had long been prolocutor of the Lower House of Convocation, to appear before it; on which occasion he drew up a "Discourse concerning the Illegality of the Ecclesiastical Communion, in answer to the Vindication and Defence of it," which was not published till the year 1689.

At the Revolution, the services rendered by Dr. Stillingfleet to the established church were recompensed by the bishopric of Worcester, to which he was consecrated in October 1689; in which high station he was dubious in the discharge of the duties of his office, and in defending the rights of his order by his speeches in parliament. On the death of archbishop Tillotson, in 1694, the queen is said to have wished for the advancement of Stillingfleet to the see of Canterbury, but the Whigs opposed it, from an apprehension "that both his notions and his temper were too high." The bishop again engaged in controversial divinity against the Socinians and Unitarians; and in a treatise intitled "A Vindication of the Trinity, with an Answer to the late Objections against it from Scripture, Antiquity, and Reason," he introduced some animadversions on Locke's Essay on the Human Understanding, under an apprehension that the definition of subsistence, and the account of ideas contained in that work, were unfavourable to the doctrine of the Trinity. The cause was not decided late, who is thought on this occasion to have flurried a defeat. An edition of his 50 sermons appeared in 1707, folio.

Dr. Stillingfleet injured his constitution, which was naturally strong, by his tedious and sedentary life; so that repeated attacks of the gout terminated his life on March 27th, 1699, after he had nearly completed his 64th year. He had been twice married, and had several children, three of whom survived him. His remains were interred in the cathedral of Worcester, where a monument was erected to his memory, with a Latin inscription by his chaplain, the celebrated Dr. Bentley, in the high style of panegyric, part of which has been thought to exceed even the jilt encomiums to which this prelate was intitled. The bishop, who had a good portion, and a lofty temper, somewhat moderated by good sense and a knowledge of the world, had collected a noble library, which was purchased, after his death, by Dr. Marsh, archbishop of Armagh, as the foundation of a public library at Dublin. Biog. Brit.

STILLINGFLEET, BENJAMIN, grandson of the bishop of the same name, and son of Edward Stillingfleet, M. D., who left his father's favour by marriage, and afterwards taking orders, settled upon a living in Norfolk. Benjamin was born about the year 1702, and after a previous education at Norwich school, was entered, in 1720, at Trinity college, Cambridge, of which Dr. Bentley was then master; who, forgetting his obligations to the family, procured the rejection of young Stillingfleet, when candidate for a fellowship. We may naturally imagine that the disappointed candidate should feel resentment at such conduct, for which it is difficult to devise a sufficient apology. The subject of our memoir left college, and travelled to the continent; and upon his return, palled an unambitious life, which was chiefly devoted to the study of books and nature. Under the patronage of lord Barrington, he obtained the post of barrack-matter at Kenfigton. To Mr. Windham, of Felbrig, Norfolk, he was more substantially indebted, being often refuted at his house, and receiving from him an annuity, which was considerably augmented when he became Mr. Windham's executor. He is well known as the author of several pieces in prose and verse, particularly for an "Essay on Conversation," which was published in the first volume of Cc Dodo.
Stillingfleet.

Dodder's Collection of Poems; and also from a volume of "Miscellaneous Tracts," printed in 1759, and conflicting claims of discovery from Linné's Amoenitates Academica. To this work were annexed valuable "Observations on Grafs," and also a "Calendar of Flora," formed upon a suggestion of the Swedish naturalist, and adapted to this climate. The poet Gray, with whom he became acquainted, mentions him in one of his letters, dated in 1761, in the following terms: "I have lately made an acquaintance with this philosopher, who lives in a garret in the winter, that he may support some near relations who depend upon him. He is always employed, consequently, according to my old maxim, always happy, always cheerful, and seems to me a worthy honest man. His present scheme is to feed some perfons, properly qualified, to refine in Attica, to make themselves acquainted with the climate, productions, and natural history of the country, that we may understand Aristotle, Theophrastus, &c. who have been heathen Greek to us for so many ages." It is observed, that the term garret used by Gray is rather a disparagement of Stillingfleet's town-lodgings at a fodder's in Piccadilly, where he died in 1771, at the age of 69. He ordered all his papers to be destroyed at his decease. Gen. Biog.

This ingenuous, learned, and worthy man, was well acquainted with the theory of music by reading and meditation, and with the practice by hearing all the Bell performers in Italy during his travels, and intimacy with Mr. Price of Foxley, Mr. Tate of Mitcham, and Mr. Smith, the disciple and successor of Handel in carrying on the oratorios, for whom Mr. Stillingfleet wrote new sacred dramas, which he set and had performed in turn with the music of Handel.

His work, intitled "Principles and Power of Harmony," the most clear, agreeable, and interesting tract on a dark, obscure, and speculative subject that we know, is nothing more than a commentary on the theoretical writings of the celebrated Tartini. It has been often observed with truth, that theory and practice are more frequently at strife in music than in any other art. Tho' those who treat music merely as a science, without posseffing the practical part, are naturally contracted in their ideas, and ufeles for profefors: and, on the contrary, mere practical musicians, who have feldom had either education or leisure to qualify themselves on the fide of learning, produce nothing but crude and indigefled reveries, which a man of taste in literature difdains to read. That this has been the cafe with fome of the moft able practical musicians, we can, from our own knowledge, affert. They have the ambition of paffing for men of science; they speak of Greek writers without Greek; of arithmetical proportions without figures; of ratios without geometry; and equations without algebra. The late Dr. Pepusch, a man of great learning, and of universal reading in musical compositions, attempted to explain the Greek fyllem; but arithfute calculations being neceffary in the bufinefs, he had recourse to his friend De Moivre, who was no musician, and underflood the doctor as little as the doctor underflood Euclid: they never met without a quarrel; for as each would talk about what he did not understand, each must by turn have been abfur'd. The fame thing happened in France between the famous Rameau and d'Alembert; at Padua, between Tartini and Padre Colomba, his friend, the professor of mathematics in that university. The work of which we are now speaking, however, contains free reftrictions upon objections; as it was written by no half scholar or shallow musician; but by one posseffed of all the requifites for fuch a task.

In the author's commentary on Tartini's firft chapter, he explains clearly the now well-known phenomenon of a single string or found producing its own harmony, upon which Rameau has built his fyllem of a fundamental base. (See BARNE Fundamentals.) The author, in the history of this discovery, traces it no farther than the time of Merfennus, with whom he leaves it; but it seems to have been long known before his time, as the organ is constructed upon the fame principle; the fops of that instrument being proportioned to each other in the fame manner as the founds above-mentioned, which are generated by a single string or tone: when the fops, known by the names of the diapason, principal, 12th, 15th, and tierce, are drawn out, every single key of an organ gives the complete chord, as, when G only is fruck, and it is imagined that no other founds are mixed with it, wind is conveyed to the pipes G, g, d, g, b, &c.

But the principal phenomenon upon which Tartini builds his fyllem, was quite new, and discouvered by himself. It is that of the third found produced in the medium by the concurrence of two founds that can be sustained for any time upon one or two instruments, as trumpets, horns, flutes, hautbois, two violins, or one in double fops, two founds on the organ, with only the open diapason out, &c. a third found will be heard, which is its true fundamental base. See TERZO Suono, where these invisible bases will be specified to every interval, but chiefly those that are confonant.

Tartini's second chapter concerning the circle, its nature and signification in harmonics, Mr. Stillingfleet examines with great candour, and some pleafantry. It is in the third chapter that Tartini unfolds his musical fyllem, and treats of concords and discords, their nature and definition. The commentator's remarks on this chapter are very bold and luminous.

The fourth chapter of Tartini gives the origin of the musical scale and genera, their use and confquences. In our author's commentary upon this important chapter, he acquires himself with great dexterity, and proves that he is not only profound in the theory of found, but endowed with nice feelings, and of great experience and observation, with respect to practical music.

But though we admire the ingenuity of Tartini in tracing the origin of the octave in modern music, and think, with his commentator, that it is not implanted in our nature, as it is never sung by any people out of Europe (nor would it seem so easy and natural there, if it were not for the bells and church finging in almost every Christian town and village, which inquisitively teach intervals and the fcale to every one that has a voice and an ear from early childhood); we regard the gamut, and its octaves and scales, as the musical alphabet; and nature never teaches an alphabet to the natives of the most civilized and polished country any more than to fages.

Our author's praise of the harp, and wishes that there were better music for it than old and vulgar Welth tunes, would have been highly gratifying, had he lived a few years longer; for in 1771, when his book was published, a short time before his decease, the pedal harp had not been introduced or heard of in England. And it seems as if madame Crumpolzh made not only the firft great performer upon that instrument in our country, but the firft who had good music to perform, to f盛典 its powers; with which she had been furnished by her husband and master.

It is enough for us to make Stillingfleet in thinking more favourably of the ancient; Greek music and modes than late writers have done; and concerning Italian recitative, he gives from Tartini a curious account of its surprizing effects, with no other accompaniment than a base.
"In the year 1714, (if I am not mistaken,) in an opera performed at Ancona, there was, in the beginning of the third act, a passage of recitative, unaccompanied by any other instrument but the bafe; which railed, both in the profeflors and in the ret of the audience, such and fo great a commotion of mind, that we could not help flaring at one another, on account of the visible change of colour that was caused in every one's countenance. The effect was not of the plaintive kind: I remember well that the words expressed indignation; but of fo harsh and chilling a nature, that the mind was disordered by it. Thirteen times this drama was performed, and the fame effect always followed, and that too universally; of which the remarkable previous silence of the audience, to prepare themselves for the enjoyment of the effect, was an undoubted sign. This almost equals the miraculous powers related of the ancient Greek music. But this can never happen where the Italian language is not universally known to the whole audience.

A period of Tartini in favour of simple music, has suggested to his commentator a reflection which we cannot pass over in silence: as we are unable, implicitly, to subscribe to his opinion, that the tunes in the Beggar's Opera should be the standard of good melody, modulation, and harmony. It is true, that many of them are the tunes of our nurseries, to which our ears have been accustomed from our infancy; for this reason, perhaps, perhaps, the hundredth at the playhouse, will prefer them to any other music. In fo mixed and popular an assemblage as the audience of an English theatre, are not the majority ignorant of other music, and as likely to be prejudiced in favour of bad, as more refined ears in favour of a more polished and artificial kind of music; but would it not be the fame thing with painting, poetry, and sculpture? Would not a sign-poll, highly coloured, be preferred by the ignorant to a picture of Raphael; or a jovial and balderdash song to the E这场比赛 on Man, or Milton's Paradise Lost? Simplicity is an excellent and desirable thing in all the arts; but let it be an elegant simplicity, free from vulgarity and barbarism. Why should people of refined ideas, and, if you will too, delicate taste, be governed by the ignorant and unpolished, any more than thole last mentioned by the former? It has been well said, that authors and artists are the only people in this country who are not tried by their peers.

What Tartini says in favour of simplicity could never extend to such a medley of tunes of all nations being introduced into one piece, as those of the Beggar's Opera, which are made up of Scotch, French, Italian, Irish, and English; and is a lover of music to be thought affectingly refined, who wishes for something less hackneyed and vulgar? The music in the pope's chapel, with which our author was so enchanted, could never remind him of that in the Beggar's Opera. But the moderns, and modern music, are always to be abused; it was so in Plato's time; the custom has been continued by every writer on the subject; and every musician, who, like Timotheus, adds a new string to his lyre, will be said to endanger the flat; but about taste and prejudice, it has long been agreed, that there is no disputing; our habits and our feelings will ever be uppermost.

STILLINGIA, in Botany, was sent under that name to Linnaeus, by the celebrated Alexander Garden, of whom a biographical account may be found in its proper place. This genus is dedicated to Mr. Benjamin Stillingfleet, of whom we have made some mention in our account of Mr. WILLIAM HUDSON, and who is well known as the author of a popular book of "Tracts," relating to natural history, &c. partly translated from the writings of Linnaeus. He was an elegant scholar, an enthusiastic admirer of virtuous liberty, and a philosophical naturalist; intimately attached to the Price, Barrington, and Littleton families, as well as to some men of talents and cultivation in Norfolk. A MS. volume of his advice to the late distinguished politician Mr. Windham, we have seen in the Felbrigg library. — (See the preceding article.) — Linn. Mant. 19. Schreb. Gen. 646. Willd. Sp. Pl. v. 4. 588. Mart. Mill. Dict. v. 4. Ait. Hort. Kew. v. 5. 337. Walt. Carol. 239. Pursh 609. Jiff. 390.—Chas and order. Monocoty Monadelphia. Nat. Ord. Tricoceae, Linn. Euphorbia, Julii.

Gen. Ch. Male. Cal. Perianth feven-flowered, coriacous, hemisphorical; pitcher-shaped, entire. Cor. of one petal, tubular, funnel-shaped, gradually dilated upwards, much narrower than the calyx; its margin undivided, but fringed ia a jagged manner. Stamina. Filaments two, thread-shaped, twice as long as the corolla, spreading at the summit, very nightly connected at the bafe; anthers kidney-shaped, of two round lobes.

Female, at the bafe of the same spike, Cal. Perianth as in the male, but single-flowered. Cor. superior, shaped as in the male. Pet. Germen roundish, between the calyx and corolla; filyle thread-shaped; stigmas three, distinct, recurved. Peric. Capsule somewhat turbinate, bluntly triangular, three-lobed, of three cells, surrounded at the bafe by the enlarged calyx. Seed small, oblong, obliquely triangular, marked on the inner side with a transverse furrow.

Obí. The "two cup-shaped glands," which Schreber, after Walter, describes in the male flowers of the original species, appear to be either a bractea, or abortive calyx. They perhaps contain honey.

1. S. Jfloriaca. Wood Stillingia. Linn. Mant. 126. Willd. n. t. Ait. n. 1. Pursh n. 1. —Stem herbaceous, Leaves elliptic-oblong, obtuse, finely serrate.—Native of pine-woods on a barren soil, from Virginia to Florida, flowering in May and June. A greenhouse perennial herbaceous plant, flowering at Kew in July and August. The flowers are milky when broken, a yard high, round, smooth, leafy. Leaves scattered, on short stalks, elliptical, three inches long, smooth; paler beneath. Flowers yellow, in a terminal spike, resembling a catkin; the male flowers numerous. Linnaeus says this plant is esteemed in a specific verdoraceous.

2. S. Jflorír0s. Privet-leaved Stillingia. Michaux Boréal-Americ. v. 2. 213. Willd. n. 2. Pursh n. 2. —Stem shrubby. Leaves lanceolate, tapering at each end, entire.—In shady woods of Carolina and Georgia, flowering in June and July. Pursh.

3. S. febíerea. Poplar-leaved Stillingia, or Chinefe Tallow-tree. Michaux, ibid. Willd. n. 3. Pursh n. 3. Ait. n. 2. (Croton febíerea; Linn. Sp. Pl. 1425. Ricinus chinesinis febíerea, populi nigra folio; Petit. Gazoph. t. 24. f. 3. Euonymo affinis Sinanum, populi nigra folio, &c.; Pluck. Amath. 7. t. 350. f. 2.)—Stem arboreous. Leaves rhomboid, pointed, entire.—Native of China, in moist situations. Now said to be naturalized on the sea-coast of South Carolina, flowering in July and August. It has been known more than a century in our flves, or rather greenhouses. The habit is that of a Poplar, with smooth leaves, on longer slender stalks. Spikes terminal, dense, cylindrical. Male flowers with a roundish sepal or gland at each side of the calyx, analogous to what we have mentioned after the Eff.

C C 2 Ch.
STILPO, Ital. Style, in Music, a peculiar manner of finging, playing, or composing. In ancient ecclesiastical music, the styles of Palestrina, Tallis, and Bird, are venerable, and highly esteemed by masters, and all good judges of that species of composition. In oratorios, the styles of Handel, Leo, and Jommelli, are marked with an original art of excellence; the opera styles of Pergolesi, Hasse, Piccinni, Sacchini, and Paisiello; in symphonies, the elder Stamitz, the Mannheim school, Haydn, Mozart, and Vanhal at the Vienna school, are original; as are the quartets of Haydn; the quartets of Boccherini and Mozart; the harpsichord pieces of Domenico Scarlatti, Alberti, Schobert; the piano forte pieces of Emanuel Bach, Haydn, and Mozart; but the comic operas of this last must be inrolled among the first for genius, originality, and good composition, that modern times have produced.

Padre Martini says, there are three kinds of style for the imitation of young ecclesiastical composers,—the sublime, the middle style, and the inferior; all which may be perfect in their kind.

There is likewise a recitative style, Stilo di recitativo, Stilo madrispazio, Stilo semplice, and Stilo sinnemario. There are likewise national styles, such as the Venetian, Sicilian, Scots, Irish, and Welsh. All these national styles have characteristic marks or paffages, which an attentive and experienced hearer instantaneously discovers.

STILPO, in Biography, a Grecian philosopher, who was a native of Megara, flourished in the third and fourth centuries B.C., and is said to have died after the year 249 B.C. He is considered as belonging to the Megaric sect, and to have been a disciple of one of the successors of Eucleid of Megara. In his youth he is represented as having been licentious; but having corrected his natural propensities by the moral precepts of philosophy, he acquired reputation among philosophers, and became distinguished for his sobriety and moderation; and also for his eloquence and skill in dialectics. When Ptolemy Soter captured Megara, he presented Stilpo with a large sum of money, and invited him to his court; but the philosopher returned the greater part of the present, and chose to retire during Ptolemy's stay at Megara to the island of Zegen. When Demetrius, son of Antigonus, took Megara, the soldiers were ordered to spare the house of Stilpo, and to return any thing that might have been precipitately taken from him. The philosopher being required to give an account of those effects which he had lost, replied, "that he had lost nothing; for no one could take from him his learning and eloquence." To the conqueror he recommended himself by the pathetic manner in which he incited him upon the exercise of humanity. So great indeed was his fame, that when he visited Athens, the people ran out of their shops to see him; and even the most elegant philosophers of Athens took pleasure in attending upon his discourses. Nevertheless, he excited prejudice by not paying respect to the Athenian superlubitions, of which an instance or two occurred during his abode at Athens. Having asked a person, if Minerva, the daughter of Jove, was a deity? and being assured that she was, he rejoined, "but this before us (referring to the statue) is not the Minerva of Jove, but of Phidias, and therefore no deity." For this speech he was carried to the court of Areopagus, and ordered immediately to leave the city.
STI

When Crates put the question to him, whether the gods took pleasure in prayers and adoration? — experience having taught her several habitants, "you fool, do not question me on this subject in the public street, for when we are alone." But there is no proof of Stilpol's modality with respect to the existence of a supreme divinity. Some of his peculiar doctrines were, that species, or universals, have no real existence, and that one thing cannot be predicated, or ascertained, of another; and that in using the word "man," as an universal term, we speak of nothing; for the term signifies neither this man nor that man, nor applies to any one man more than another. In order to prove that one thing cannot be predicated of another, he said, that "goodness" and "man," for instance, are different things, which cannot be confounded by ascertaining the one to be the other: he further argued, that goodness is an universal, and universals have no real existence; consequently, since nothing cannot be predicated of any thing, goodness cannot be predicated of man. Some have supposed that Stilpol was not serious in this kind of reasoning, and that it was his intention merely to expose the sophistry of the schools. If he was serious, it could not be wholly without reason that Glycerus, a celebrated courtezn, when he was reproved by Stilpol as a corruptor of youth, retorted the charge upon him by saying, that he spent his time in filling their heads with sophistical quibbles and useless sophistries. Of moral topics, Stilpol is said to have taught, that the highest felicity consists in a mind free from the dominion of passion, a doctrine similar to that of the Stoics. He lived to a great age, and is said to have hastened his final departure by a draught of wine.

STILTON, in Geography, a village and parish in the hundred of Normenton-Cross, and county of Huntingdon, England. The houses are situated on the sides of the high North road, in a flat country. The population of this place in 1800 amounted to 592; and in the succeeding 11 years which occurred before the next report, it appears to have increased to 657 inhabitants and 197 houses.

This village is chiefly noted for a peculiar species of cheese, which obtained the name of Stilton from having been first sold here; but it is manufactured mostly in certain districts of Leicestershire. In a former part of this work, (see Cheese,) it has been described; but since the time of writing that article, (about 1805,) this cheese has become a more common article in the London markets, and is rendered at a cheaper price. The usual retail charge is now 1s. 6d. per pound. Each cheese is made of about 2lbs. weight, and is formed in a deep round vat.

The great Roman road, called Ermine-street, intersected this parish from N. to S. between the two stations of Godmanchester, called Darobridge, and at Calor, called Duraliporte. About one mile N. of Stilton is Norman-Cross, where very extensive barracks and a prison were erected during the late wars. The latter was appropriated to French prisoners, and several thousands were confined here at the time of ratifying peace.

South-west of Stilton, about one mile and a half, is Denton, the seat of the Cotton family, and the birth-place of the celebrated antiquary Sir Robert Cotton. (See Cotton.) This family, who retained large possessions in the north of Huntingdonshire, had formerly another estate, denominated Connington, at a short distance south-east of Denton, and many of the descendants of the Cottons are buried in Connington church. Some fragments of the old manor are remaining. It is now the seat of the family of Heathcote. — Beauties of England and Wales, vol. vii. Huntingdonshire, by E. W. Brayley.

STIMMERDORF, a town of Bohemia, in the circle of Leitmeritz; 5 miles W. N. W. of Kamnitz.

STIMULANT, in Medicine, any agent which has the property of increasing the mobility, or of exciting the motions, of the living body, or its moving parts.

It would be a waste of time to enter into any of the hypothetical speculations of physicians and physiologists respecting the mode of operation by which stimulants influence the living fibre; for the corpuscularian doctrines of the chemist, the chemical notions of combination, and the supposition of a nervous fluid, are all equally gratuitous, and equally inadequate to account for the phenomena. Our object is merely to observe the phenomena, and to mark the different effects of different agents, according to their nature, or to the parts of the body to which they are applied.

In the first place, the organs of sense are excited or stimulated by the impressions of certain matters only, light, noise, odours, &c. It must be observed, however, that every exercice of sensation is a stimulant power, by which the mobility of the living system is supported; and the stimulant effect is proportionate to the impression. Dr. Cullen remarks, that this impression, though it acts through the medium of the brain, as the common fenonour, yet it acts also on the adjoining parts, especially by exciting the action of the blood-veiles. Thus a strong light excites a stronger action in the numerous blood-veiles intermixed with the nerves of the retina; strong odours inflame the internal membrane of the nose; and strong and painful impressions upon the tongue inflame the surface of it. — The partial effects of these stimulants on the blood-veiles, independent of their agency on the fenonour, is proved by the operation of certain Substances applied to the skin. The first sensation which they produce, is that of heat in the part, with some degree of redness, from the greater fulness of the veiles, which at length proceeds to every circumstance of inflammation; to pain, tumour, blistering, suppuration, and gangrene.

Other stimulants, however, which are of more importance in a medical consideration, act principally upon the system at large, and chiefly through the medium of the stomach. It is not necessary to point out here the well-known facts, which prove the connatt and regular communication of all impressions made upon the stomach to other parts of the system, and particularly to the fenonour, through the medium of which perhaps the other organs are exclusively affected. The operation of many stimulants taken into the stomach, is too speedy to allow of the suspension of their being taken up by the absorptions, carried into the circulation, and thus transported to the brain in the blood-veiles. The impression is obviously communicated through the medium of the nerves. The energy of the vital powers is thus excited, as evinced by the activity of the mental and corporeal powers, under the influence of stimulants applied to the stomach; by the increase in the frequency and vigour of the pulse; by the general determination of blood to the surface of the body, producing at length, flushing, heat, and even sweating. Various substances have been contrived and manufactured in all ages, for the purpose of producing this pleasurable sensation in health, and have been also employed in the cure of certain diseases. The most powerful of these are the products of fermentation, in which may be included every thing containing spirit, all wines, and malt liquors, mead, cider, the koumis of the Tartars, and every species of alcohol distilled from these liquors. There are besides many other substances of a stimulant quality, though of much less power, taken from the vegetable and animal kingdoms;
ST I

kings; among which may be enumerated all the aromatic plants, with their seeds, bark, and roots, the bal- foms, gums, and essentinal oils, procured from them; am- moniac, etc.

However these stimulant substances may have contributed to the sensual gratifications of mankind, there cannot be a doubt that they, especially the vinous and spirituous matters, have contributed quite as largely to their pains, diseases, and vices. The derangements of the functions, and ultimately of the structure, of some of the most important organs of the body, which continued or excessive stimulation induces, are well known, as well as the disorder of intellect, and the dilatation of the moral principle, which so frequently result from it. But upon these topics it were useless to enlarge.

With respect to the medicinal employment of stimulants much might be said; for although the rational and observ- ing part of the profession make a very sparing use of them in practice, they experience much difficulty in counteracting the mischief which popular and vulgar medical prejudices are constantly inflicting by cordials, and nervous drugs, and by the use of heating and irritating diet. There are few morbid conditions in which the constitution is benefited by stimulants. In all diseases that are called nervous, some organ or other is deranged in its structure or functions, most commonly the stomach, bowels, liver, or uterus; and he who attempts to remove the lowness and languor by stimulants, while the function or structure continues disturbed, will only amuse the patient, while the symptoms remain unmitigated or increased. In respect to many febrile diseases, indeed, the general acknowledgment of the truth has at length prevailed, and since the sweating and stilting sphygm was abandoned, we now never see the military fevers, the lingering diseases after child-birth, the low nervous fevers, &c. which were once so prevalent and so fatal. But too much of this stimulant plan, too much of bark, and wine, and brandy, remains in the common treatment of all fevers, which, how- ever, the most intelligent of our contemporaries have nearly banished. The Brunonian sphygm, whose founder was pragmatically too fond of the diffusible stimulants to see clearly upon the subject, contributed to prolong the reign of stimulation in medicine, longer than unbiased reason and experi- ence would have maintained it.

Gentle stimulants, employed with proper caution and regulation, are chiefly valuable under those circumstances of debility, which succeed fevers, hemorrhages, and other vio- lent diseases, when the morbid action has ceased, and no organic disorder remains. The powers of the constitution often languish under such circumstances; the circulation is fecile, and the digestive function weak; and the muscles, therefore, very slowly recruit their vigour and subsistence. Under such a condition of tardy convalescence, these func- tions are materially assisted by a supply of gentle stimula- tion; and it is then principally that stimulants are useful and safe.

STINCHER, in Geography, a river of Scotland, which runs into the sea at Ballantrae, in the county of Ayr.

STING, Cinclus, an apparatus in the body of certain insects, in form of a little spear, serving them as a weapon of offence.

The sting of a bee, or wasp, is a curious piece of mecha- nism; it consists of a hollow tube, at the root of which is a bag full of sharp penetrating juice, which, in stingins, is injected into the flesh through the tube.

Within the tube, Dr. Derham has observed, there lie two small sharp bearded spears: in the sting of a wasp, he told eight beards on the side of each spear, somewhat like the beards of fish-hooks.

One of these spears in the ring, or sleet, lies with its point a little before the other, to be ready, as should seem, to be first darted into the flesh, which once fixed, by means of its forearm board, the other then strikes in too; and so they alternately pierce deeper and deeper, their beards tak- ing more and more hold in the flesh: after which the sleet or sting follows, to convey the poison into the wound, which, that it may pierce the better, is drawn into a point, with a small slit below that point, for the spears to come out at.

By means of these beards it is, that the animal is forced to leave its ring behind it, when disturbed, before it can have time to withdraw the spears into their scabbard. See Anatomy, &c. of Dee.

STING or STENCH, a disagreeable smell exhal- ing from a corrupted or other body, and which is prejudicial to the nose and brain.

A stinking breath is usually the result either of diseased lungs, or of scrobicular gums, &c.

A stinking nose, factor naris, is the result of a deep ulcer within the nose, whence arterial fces, &c. Its cause, according to Galen, is a sharp putrid humour falling from the brain, on the procefsus mammillares. This is reckoned, by the civilians, one of the legal causes of annulling mar- riage.

STING-HORN, in Botany. See PHALUS.

STINK-Pot, an earthen shell charged with powder, and other inflammable and suffocating materials, with a lighted fuse at the aperture, thrown on board an enemy’s ship in the action of boarding.

STINKING HOREHOUND, in Agriculture, a common weed in hedges and rubbishy places, of the more troublesome perennial kind. By the Swedes it is considered as an univer- sal remedy in the diseases of cattle. See BALLOTA NIGRA.

STINKING-ILL, a name sometimes provincially applied to a disease of the brazy kind, often met with among sheep in some situations. See STOMACH-ILL.

STINKING ISLANDS, in Geography, a cluster of islands near the E. coast of Newfoundland. N. lat. 40° 28’. W. long. 52° 50’.

STINOS, an island in the Grecian Archipelago, about six miles in circumference; 6 miles S. of Naxia. N. lat. 46° 52’. E. long. 25° 33’.

STINT, Tringa Cinclus of Linnaus, in Ornithology, the name of a small bird common about the sea-shores in many counties of England, and seeming to be the same with the Cinclus prior of Aldrovandus, and the scinthus, or junco of Bellonius, called by the French alouette de mer, the sea-lark; and by Pennant, parre.

It is somewhat smaller than the common lark, and in shape resembles the smaller pipit. Its beak is black, flen- der, and straight; its legs of a dusky green, the toes being divided to their origin; the head and hind part of the neck are ash-coloured, marked with dusky lines; a white froke divides the bill and eyes; the chin white; under side of the neck mottled with brown; the back is of a brownish ash- colour; the breast and belly white; the coverts of the wings and tail of dark brown, edged with light ash-colour or white; the greater covers dusky, tint with white; the upper part of the quill-feathers dusky, the lower white; the two middle feathers of the tail dusky, the rest of a pale ash-colour, edged with white.

These birds come in prodigious flocks to our coasts during the winter; in their flight they perform their evolu- tions with great regularity; appearing like a white or dusky cloud, as they turn their breasts or backs towards you,
you. They leave our shores in spring, and retire to some unknown place to breed. They were formerly a well-known dish at our tables, under the name of flints. Pennant.

STINTER, in Geography, a river of Switzerland, which runs into the Thur, near Büchel-Zell.

STIO, a town of Naples, in Principato Citra; 16 miles S.W. of Cangiano.

STIPA, in Ichthyology, a name given by the Dutch in the East Indies to a fish of the class of our European ones which have two back-fins, the anterior of which is prickly, the hinder not so. Its skin is spotted, and its flesh very delicate, and well tasted. It is generally caught by books. Ray.

Gen. Ch. Cal. Glume fingle-flowered, of two laxes, pointed valves. Cor. of two valves; the outermost terminated at the tip by a very long, twilled, erect awn, jointed at the base; inner valve the length of the outer, awl-feaves, linear. Neotyly of two linear-lanceolate, membranous scales, gibbous at their base. Stam. Filaments three, capillary; anthers linear. Pif. Germen oblong; styles two, hairy, united at the base; stigmas downy. Peric. none, except the glume adhering to the seed. Seed solitary, oblong, covered by the corolla. Ob! Linnaeus remarks that the genus is distinguished by the awn of the corolla being connected by a joint to the extremity of the glume.

Eff. Ch. Calyx of two valves, fingle-flowered. Outer valve of the corolla terminated by a very long awn, jointed at the base.

1. S. penata. Soft Feather-grafs. Linn. Sp. Pl. 115. Engl. Bot. t. 1356. Knapp. t. 88. — Awns feathery.—Native of many parts of Europe, and admitted into the British Flora on the authority of Dillenius, to whom specimens were sent from Westmoreland, fast to be gathered on lime-rove rocks. The plant has, however, never been detected since in this country. It flowers in June. Root perennial, fibrous, tufted. Stems a foot high, leafy, smooth, simple, jointed. Leaves upright, long, slender, acute, roughish, their flabels very long, dilated, embracing the stem, frillated, smooth, shining on the upper side. Stipula lanceolate, adhering to the leaf. Flowers in a simple panicule, burbling from the sheath. The valve of the corolla, being very sharp and barbed, works its way into the ground, and the awn then separates from it by means of the brittle joint.

"In curious gardens this elegant plant is cultivated for the sake of its plummy awns, which are sometimes worn by ladies as feathers, or used to decorate the chimney-piece in winter, the air of a room keeping them in continual motion."

5. S. poleacea. Chaffy Feather-grafs. Wild. n. 5. Vahl. Symb. v. 2. 24. Fl. Græc. t. 86. (S. tortilia; Desfont. Atlant. t. 31.) — Awns hairy at the base, twilled. Calyx longer than the seed. Leaves involute-awl-shaped, downy.—Native of Turkey, and also of the Peloponnæus. Root annual, fibrous, downy. Stems several, a foot high, erect, jointed, leafy, round, smooth. Leaves linear, pointed, involute when old, fringed, smooth and furrowed above, frillated beneath; their flabels furrowed, fringed, the uppermost generally elongated and ventricose, embracing the panicule. Stipula fringed. Flowers erect, in a branched, archèd panicle.

7. S. caprifolii. Cape Feather-grafs. Wild. n. 7. Thunb. Prodr. 19. — Awns hairy at the base. Panicle spikied. Leaves sword-spiked.—Native of the Cape of Good Hope. All that we know of this is from the specific character given in Thunberg's Prodromus.

8. S. ficata. Spiked Feather-grafs. Linn. Suppl. 111. Thunb. Prodr. 20. — Awns hairy at the base. Flowers in a spiked cluster, all inclining one way.—Native of the Cape of Good Hope. Root perennial, creeping, producing numerous smooth flabels, a foot and half high. Leaves grasy, smooth, the upper ones shorter. Flowers fiddle, scarcely downy, hairy at the base, in a narrow spike about three inches long.

branched, spreading panicle. Corolla rough at the top. Cavaniiles rightly determined the plant of Vahl.

11. S. membranacea. Membranaceous Feather-gras. Linn. Sp. Pl. 116. Wild. n. 11. (Flower-flals dilated, membranaceous.—Native of Spain. This species is also like an Avena in habit, and is scarcely a foot in height. Stem smooth, thread-like. Panicle simple, nearly oblong, looser, feble. Flowers-flats complished, blunted. Awn of the calyx the length of the glume of the corolla. Linnaeus in his Mantilla calls the panicle a racemus, and observes that the upper flower but one is sessile. This is mentioned in Fl. Brit. 119, as certainly a Festuca, very near to uniglumis, if not the very same.

16. S. fortes. Purple Silky Feather-gras. Michaux ibid. 54. (S. capillus ; Lamark n. 6.) —Leaves thread-spikes, very long. Panicle spreading, capillary. Calyx one-third the length of the corolla. Awns straight, naked.—In sandy fields, from New Jersey to Carolina, flowering from June to Augill. The silky purple panicles exceed in beauty every other grass. Pursh.

18. S. paniculata. Panic Feather-gras. Lamark n. 19. —Leaves laciniate, smooth. Panicle contracted, of few flowers. Awn naked, thrice as long as the calyx. Seed lenticular. —Gathered by Commerlon at Monte Video. This has the habit of a Panicum, with straight, smooth flsm, and long very slender leaves.

27. S. micrantha. Minute-flowered Feather-gras. Br. n. 8. Cavan. v. 5. 42. t. 467. f. 2.?—Stem branched, smooth as well as the sheaths. Leaves nearly flat, rough. Awn naked. Corolla smooth, nearly sessile. Calyx pointed.—Gathered near Port Jackson, by Mr. Brown, who has some doubt respecting Cavaillies's synonymy. The latter describes his as a New Holland plant likewise, flowering in April. The stem is slender, a foot and half high, erect, with three or four reddish-brown joints. Leaves rather short, with long sheaths. Panicle four inches long, divided into short branches like a spike. Flowers very small, smooth, each with a bent awn, not an inch in length.

downy. Calyx pointed. —Native of Mexico, near the town of Chalma, flowering in August. The flang, three feet or more in height, is nearly covered by the long flaccid leaves of the flill longer leaves. Panicle lax, compound, a foot in length. One half of the corolla were downy all over. Awn an inch and half long, bent towards the middle. 29. S. humilis. Dwarf Feather-gras. Cavan. Ic. v. 5. 41. t. 466. f. t. Lamarck n. 3. —Leaves convolute; the floral one with an inflated sheath, and taller than the panicule. Awn naked at the base; festherty below the joint. —Native of South America, near Port Defire, in a barren foil, flowering in December. Stems several, from four to fix inches high, slender, fmmooth, leafy. Lower leaves slender, involute, awl-shaped; the upper one with a long swelling flaccid, embracing the panicule, which does not rife so high as the leaf itself, and is fearcely branched, confilling of but eight or nine flowers, on short smooth flanks. Calyx white, very acute, more than twice as long as the corolla. Awn with a series of long white feathery hairs, below its joint. 30. S. ukrainensis. Tartarian Feather-gras. Lamarck n. 22. Ill. Gen. v. i. 157. (" Tifs; Guettard. Mem. v. i. 19. t. 1. 2." )—Leaves channelled, keeled. Awn naked, ftraight. Calyx coloured, longer than the corolla. —Native of the Ukraine. The radical leaves are copious, forming denfe tufts. Stem two feet high. Panicle eight inches long, a little drooping, with almost fetaeous branches. Calyx redifh, with pale taper points. Corolla downy at the base, with a ftraight, naked, capillary avon, four or five inches long. Hairs are laid to be very fond of the seeds. STIPEL, in Geography, a town of Prufia, in Oberland; 9 miles N.N.W. of Soldau. —Alfo, a town of Germany, in the county of Mbrk; 3 miles S. of Bockum. STIPEND, STIPENDIUM, among the Romans, signifled the fame with tribune; and hence stipendarius were the fame with tribunarius. STIPES, in Botany and Vegetable Physiology, an old Latin word for a flake, or the trunk of a tree, is technically used for the flake of a ftronc; fee that article. Thus the flake of a fern is a true Stiper. The fame term is alfo used in fango, for the flake of an agricic, &c.; but never for any thing except cryptogamous plants. STIPITE. Naum de Stipes. See NATIV. STIPILLING is a mode of engraving on copper by means of dops; and is contradiftinguifhed by this word flippin, from that mode of the art which consists of courses of continued lines. The dots in flippel engraving aie either round, that is to fay, each dot forms a fmall cone in the copper, whose apex is downward; or they are angular, each dot forming a peck, or fmall iffaceous triangle, on the furface of the plate; or, when the dot conflits of more than one of these peeks, (as is commonly the cafe in engraving in the chalk manner,) its form is of course multigular. The round dots in flippin are performed by means of a dry needle, or an etching-point; and the angular dots by means of that well-known itefil inlament which is termed a graver. Stippling with the graver is alfo much ufed in the art of engraving on wood. It has happened unfortunately for the public and for this branch of engraving, that some thirty or forty years ago, while it was imperfectly known and practifed, it was much fought after by the English traders in art, on account of its cheapnefs, and the novelty which then rendered it attractive; and that now,—to fkee is fale or fashionable, and fuch an unhappy influence on art; fo crafty are the majority of dealers, and fo heedles the majority of the public;—now chalk-engraving is improved, it is neeq-dift. In the hands of the older Schiaovetetii, Cardon, and Holf, it acquired a variety, a rich and harmonious copiousness, and an energy it had not before difclofed; of which "The Land of General Abercornphie's Army in Egypt," after De Loutherbourg, and " The Woman taken in Adultery," after Rubens, are felicitous examples. In the former of these, the water, fly, smoke, broken ground, and other passages of the landscape part of the performance (which had hitierio oppofed most difficulties to the progres of chalk-engraving), are fearcely less happily differentiated than they would probably have been, had Schiaovetetii employed the fine-engraver's art, in which he was fo great a proficient: but it is observable, that the clear- nefs of the water, the crumby criraphs of the ground, &c. are in a great degree owing to the flipping being wrought into lines, fuch as are ufually hitched in drawing with chalks. The belt line-engravers have always, from the very ini- fantasy of the art, intermingled with their word a large por- tion of flipping. The works of the celebrated portrait en- gravers of France more especially abound with it. And the belt chalk-engravers have either mixed positive lines with their flipped work, or brought their flipping into courses of chalky lines, as is exemplified in the work above-men- tioned by Schiaovetetii, and in the draperies of Cardon's print of " The Woman taken in Adultery." In our account of the English School of Engraving, we have afered that the modern improvements in chalk-engrav- ing have "been effected chiefly by living profeflors:" but Schiaovetetii and Cardon are now no more! STIPILLING is a term alfo ufed by miniature painters, to express the minute touches of colour laid on with the points of hair-pencils, with which their works on ivory for the most part conflit, and which give that mottled or granulated sur- face to miniature pictures which is more or less obvious, and in which the granulation is larger or smaller in the different works of this species; serving to discriminate the style of execution of one artist from that of another. STIPULA, in Botany and Vegetable Physiology, an ancient Latin word for stubule, as well as for the fheaths of the leaves remaining upon fraw or reeds. Linnaeus has adopted it for those appendages to the herbage of plants, which ac- company the leaves in a great many infances, though not premarked in all. See Pelcura. STIPULATION, in the Civil Law, the act of flipu- lating, that is, of treating, and concluding terms and con- ditions to be inferted in a contract. Stipulations were anciently performed at Rome with abundance of ceremonies, the first of which was, that one party should interrogate, and the other answer, to give his conient, and oblige himself. By the ancient Roman law, nobody could flipulate but for himself; but as the tabelliones were publice fervants, they were allowed to fhipulate for their mailers; and the notaries, succeeding the tabelliones, have inherited the fame privilege. The flipulation had its origin in the law Aquilina, and another law of the emperor Arcadius. See SATISDATIO. The word is formed from the Latin fipula, a fraw, becaufe in making a fale, a fraw was given to the purchaser, in fign of a real delivery; which custom is flill retained in some parts of France, particularly at Verdun. The custom always has been on this occasion, for the two parties to break a fraw between them, and each take his moiety, which they afterwards joined again, to recognize their promife. STIPULICIDA, in Botany, from fipula, the appendix-
ages of the leaves, and *cedo*, to cut, because the flippulae are divided into many fine segments, a supposed genus of Michaux, *Pl. Boreal-Am. v.* 1836, t. 6, of which he then describes a delicately divided species, *S. fuscans*. This is *Polycarpus flippuliferus*. Pursh, 1800, after Persoon. It occurs in barren gravelly soil of Lower Carolina, flowering in May and June. The root is annual. Stem erect, very slender, a fawn hue, repeatedly subdivided in a forked manner, with a pair of small feathery *flippulae* under each joint. Leaves all radical, small, ovate, falcate. Flowers minute, three or five together in each little terminal tuft.

**STIRI, in Geography, a town of European Turkey, in the province of Livadia; 9 miles S. of Livadia.**

**STIRIA, in Ancient Geography, a small island near the isle of Cyprus, on the northern coast, towards the west, in a small gulf, between the promontory of Acanthos to the N.W., and the town of Arfinne to the S.E.**

**STIRIA, or Styria, in Geography, a duchy in the empire of Austria, bounded on the north by the archduchy of Austria, on the east by Hungary, on the south by Carinola, and on the west by Carinthia. It is divided into Upper and Lower. Upper Styria is bounded on the north by Austria, on the east by Hungary, on the south by Lower Styria and Carinthia, and on the west by the archbishopric of Salzburg; and is about 110 miles in length from east to west, and from 25 to 45 in breadth from north to south. Lower Styria is bounded on the north by Upper Styria, on the east by Hungary and Carolia, on the south by Carinola, and on the west by Carinthia: its extent from north to south is about 80 miles, and about 48 from east to west. Upper Styria contains many lofty mountains, but, by the industry of the inhabitants, the whole country is pretty well cultivated: isomuch that, in many places, the very highest tops of the mountains are inhabited. The people who dwell in these parts in winter, when large quantities of snow fall, are for several months kept as it were prisoners; and even in general seldom come down from their heights. By continual cullom too they are habituated to the cold. It is very astonishing, that amidst these mountains and steep heights they are able to succeed with the plough, and that the enmities themselves are likewise fertile. They cultivate a fine sort of wheat, which is sufficient not only for the supplies of their own necessities, but in some measure also for sale. They have, in particular, large breeds of cattle, wild fowl, game, and chamois: the brooks and lakes, of which there are many situated between the high rocks, are rich in fish. In some places too are small vales; and the inhabitants endeavour to avail themselves of every spot of earth. The mountains contain silver, lead, copper, and, in particular, iron. The iron-mines have been already worked above one thousand years, and still continue rich. The Styrian fleec is highly valued. The forests with which the ridges of the mountains here are covered, yield in sufficient quantity the wood necessary for the smelting-huts. Silver was formerly dug; but ever since the year 1658, the mines have been filled with water. In the mountains, likewise, are hot-baths and medicinal springs. At Aulnitz are some good salt-works. The principal rivers which run through this country are the Much or Mura and Ena. Judenburg is the capital. Lower Styria contains fewer mountains, and more champaign: the soil is generally fertile, and on the hills is produced some good wine. In it are hot-baths and medicinal springs. This part of the country is watered not only by the Muehr, but also by the Drave and Save. Graz is the capital. In the whole duchy are nearly 1120 towns, and 500 citadels; many of the last stand on the highest summits of the rocks. The highways are good, notwithstanding the country is mountainous. The language is very rough. The inhabitants of the quarter of Ciliccy are Winds or Wends, and speak the Wendish language, which is in use even among the common people, for some miles from Gratz. Those who are but a small degree removed from the common rank speak Wendish, German, and Italian, and the principal inhabitants also French. No other doctrine, or worship, was till lately permitted in all this country, excepting that of the Roman Catholic. At Seekau is a bishop, who bears the title of a prince of the holy Roman empire; he is subject to the archbishop of Salzburg, whose general vicar he also is through the greatest part of Styria. The most important manufactures in the country are the iron and steel works, the produce of which is exported in great quantities. Styria was formerly a part of Carinthia, but in the eleventh century was separated from it, and made a peculiar mark. The number of inhabitants, as stated by M. Marcel-de-Serrès, (Voyage en Autrich, &c. published at Paris in 1814,) was 86,000.

**STIRIA, in Ancient Geography, a town of the Phociade, situated in the environs of the frontiers of Eucaria. Here was a temple dedicated to Ceres Stiritis: the statue of the goddess was of fine marble, holding a flambeau in each hand. Ceres was highly honoured in this place. Paufanias.**

**STIRK, or STIRK, a term used among country people for a young ox or heifer.**

**STIRLING, formerly STRYVELING, in Geography, an ancient town, and capital of the county of Stirling, Scotland, is noted, in the annals of Scotish history and topography, for many important events connected with its castle, and for the peculiar situation of that and its other buildings. Like the castle of Edinburgh, that of Stirling is erected on the summit of a craggy precipice; and the town is built and disposed along the ridge of a hill, which slopes to the north and south, and is very abruptly terminated at the west. The origin of this fortress is not recorded, but it is evidently of remote date. Border wars generally occupied its inhabitants till the accession of the Stuart family to the throne of Scotland; whence the ancient name of Stryveling arose, it is thought, from the frequency of skirmishes in its vicinity. The ready communications between the northern and southern parts of Scotland, by means of the bridges and fords in this neighbourhood, rendered the possession of Stirling castle always an object of great importance. From its hill may be viewed two of the most celebrated scenes of Scotish triumph, the fields of Falkirk and of Bannockburn.**

The history with respect to the incorporation of the town is wholly unknown: the earliest charter which is extant bears the name of Alexander I.; but as this only conferred some additional privileges, it is supposed that the town existed at a much earlier period. About the middle of the twelfth century, Stirling was honoured as a royal residence, for David I. kept his court here, to be near the abbey of Cambuskenneth, which he founded in 1147. Some marks of royal magnificence yet remain about the castle.

James III. afterwards raised Stirling higher into notice, by making it the principal place of his habitation. He adorned it with a magnificent hall for parliamentary meetings, of which the walls alone remain. Pope Alexander VI. when it became a kingly residence, added a royal chapel adjoining the fort building. Within the towers of Stirling, several of the Scotish monarchs were either born, or underwent the ceremonials of coronation; and it became a place of retirement for the unhappy Mary, and for the minority of James VI. under his tutor Buchanan. In the north-west part of this edifice, James II., about the middle of the 15th
Stirling

5th century, flayed William, earl of Douglas; and the cloot is still designated by the name of the Douglas room.

Near the castle is a flat piece of inclosed ground, once appropriated for tournaments, and a rock, whence the female spectators used to behold the valor of the knightly champions, now called "The Ladies Rock." On the south side of this fortress, surrounded by a stone wall, is the park; at the exit end of which, vestiges of the royal garden, and a mount of earth, the frequent scene of the amusements of James IV., are yet visible. This park, with several other neighbouring pieces of land, form the contiguity of the castle. Since the reign of Queen Anne, when this building was enlarged, and a battery erected, and called by her name, no material alterations have taken place; it is now commonly commanded by the usual routine of military officers, and garnished by 100 men.

The houses and public buildings which constitute the town are chiefly of an ancient style; particularly that began by the earl of Marr, while regent of Scotland, in 1570, yet unfinished, and entitled Marr's work; and one known by the name of Argyle's lodging, some time polluted by that family, but originally erected by Alexander, vicount of Stirling. Two churches, denominated from their situations, the east and west kirk, have also a claim to antiquity; they constituted, it is fuppofed, at the period in which they were built, but one edifice, and were connected with the monastery of the Franciscans. They are thought to have been erected by James IV. in 1494: and from the circumstance of the eastern end having received some additions from cardinal Beaton, in the reign of Mary, they are sometimes described as having been built by different founders, and at different times. At the reformation, a partition wall was added, which now forms them into two extensive and convenient churches. James VI. was crowned here in 1567, and general Monk raised his batteries in this church-yard in 1651, when the castle was besieged. The fleete and roof yet retain the marks of having been violently battered by the shot from the garrison.

The town-houfe is a large building, with apartments for the town and county courts: in the council chamber is kept the jagg, appointed by law as the standard for dry measure in Scotland. Stirling contains three hospitals, viz. one, endow'd by Robert Spittal in 1530, for poor tradesmen; a second, founded by John Cowan in 1659, for decayed brethren of the guild; and a third, instituted by John Allen in 1735, for the education and maintenance of the children of poor tradesmen. Befide these charitable institutions, the merchant company, the kirk feoff, the kirk feoffion of the burgh feoffed, the town funds, and those of each particular incorporation, in addition to large voluntary contributions, are all employed to relieve the wants of the poorer inhabitants.

In this town is the only prison in the county. Here are a weekly market on Friday, and six annual fairs. The population of Stirling, till the manufactures caused the erection of many new buildings, has undergone but very little alteration for the last 600 years; but of late, as the comparative reports of 1800 and 1811 prove, it has considerably increased; in the former year it amounted to 3251 inhabitants, with 620 houses; and at the latter period, to 3820 inhabitants, and 749 houses. The manufactures which are carried on here are those of carpets and cotton, which have been introduced from Glasgow; formerly, hallows were made in Stirling to a considerable extent; but though in some degree still carried on, the manufacture has greatly declined from its first commercial greatness. There is a valuable salmon fishery on the Forth, which forms a part of the corporate revenue. (See Forth.) In this borough, the municipal government is vested in a provost, four bailies, a dean of guild, a treasurer, seven merchant-counsellors, and seven deacons of trade; it has also the privilege, in conjunction with some other places, of returning one member to parliament.

To the north-east of Stirling, a small village, called the abbey, marks where that of Camuludun, formerly stood. The abbey of this place was originally denominated abbey of Stirling. This was founded, as already noticed, by David I., in 1147, and supplied with inhabitants from Arloch, near Arras, in France. For about 200 years after its erection, it rapidly increased in ecclesiastical power and splendour. In the reign of David Bruce it was defpoiled of its most costly furniture, and in consequence of this, the vicarage of Clackmannan was presented to it by the bishop of St. Andrews. In 1559 the monastery was again depoiled, and the reformed religion received by many of its former inmates. In the commotions attending the reformation, its benefits were seized, its revenues forcibly dispofed of, and its very stones were carried by the earl of Marr for the construction of the building entitled Marr's work. The extent of the whole parifh does not exceed 200 acres.—

STIRLINGSHERE, one of the counties of Scotland, situated nearly in the centre of the southern portion of that country, and occupying a narrow tract of land; bounded on the east and part of the north by the Frith of Forth, on the west by loch Lomond, on the north-west by Perthshire, and on the south by Dumbartonshire. This area of land measures about 49 miles from east to west, and on an average nearly 16 miles from north to south. The boundary line is however very irregular, and is formed in a great measure by the natural demarcation of rivers and lakes; on its southern side was a famous Roman wall. From the peculiar natural features and situation of this district, it appears to have been a repeated scene of hostilities in former ages, when political jealousies and animosities impelled the Scots, Picts, Britifh and Roman colonists of these islands, to wage continual wars with each other. Hence this county is particularly noted in the historic annals of Scotland.

The Romans erected one of their celebrated fortresses on the edge of this district; and the most famous of the Scottish battles have taken place at Falkirk and Bannockburn, within this county. The lawless Highland chief, Rob-Roy, at one time held the lands along the eastern shore of Loch Lomond, and levied black mail, or money for protection, to the north-east of this district. Several of his caverns are yet remaining. The parish of Kilcarn is noted for the birthplace of the poet and historian George Buchanan, and Kilkenny for the greatest victor James, marquis of Montrose, gained in behalf of Charles I. The toponographical antiquities of the county are, the northern front of the Roman wall; two large cairns, wherein human bones and funeral urns have been discovered; a singular druidic monument of three large stones, denominated "the auld wife's lift," and remains of early fortifications along the course of the Forth. The embalmed bodies of lady Kilkenny, with her son, may be also regarded as a singular though not a remote piece of antiquity, they having been preserved in a most surprizing manner after death, for many years. A rude circular building was formerly standing on the banks of the Carron, and entitled by the neighbouring inhabitants "Arthur's oven." It was suppos'd to have been a temple to the god Terminus, the protector of land-marks, erected by Agricolus, when he fixed the boundaries of the Roman empire. The parish of Dunkipace is also suppos'd to have derived its name from...
two artificial mounts near the church, thought to have been reared at the conclusion of some important treaty. The remains of a religious house, founded by king Malcolm IV., about the year 1156, for nuns of the Bernardine order, called Emanuel nunnery, are situated on the west bank of the water of Avon.

Mountains.—The most hilly parts of this county are in the neighbourhood of loch Lomond to the north; and those of the southern division are in the parishes of Kilpatrick, Baldernock, Campsie, Kilflyth, and Denny. The northern ranges of the latter are denominated the Lennox hills. The more southern branches receive the names of the parishes in which they are, and are called Campsie falls, Kilflyth or Kilpatrick hills.

The principal northern mountain is Ben Lomond, which rises from loch Lomond. (See Ben Lomond.) The highest in the southern division of those denominated the Campsie falls, is about 1500 feet above the level of the sea; and nearly 1200 from the base of the ridge. Although the activity of the hills is generally very rapid, they present more of the character of the Lowland than of the Highland mountains, for their surfaces are either verdant, or covered with moly pasture, and they do not present terrific and precipitous naked peaks. In the parih of Kilflyth, these mountains never exceed in their elevation 1200 feet from the valley, or 1368 from the level of the sea: the view from the highest of these is one of the most extensive, beautiful, and variegated in all Scotland, and commands nearly one half of that delightful kingdom, the prospect being supposfed, at a moderate computation, to embrace an area of 12,000 square miles.

Mineralogy and Mineral Products.—The minerals of Stirlingshire consist chiefly of coal, iron-stone, and lime-stone. The vicinity of the Grampian hills appears to cut off all secondary strata to the north-west; and towards loch Lomond the country is destitute of any valuable mineral. Ben Lomond is composed of granite, intersected with quartz, which is found near the top in such masses as to weigh several tons. The shores of the loch beneath are covered with rounded pebbles, composed of quartz, granite, and micaceous schistus, with coarse red jasper, similar to the composition of the adjoining hills, from which they have been washed by rivulets, and polished by the waves of the lake. Upon the Enrick, and the upper part of the Forth towards the centre of the county, peat is the ordinary fuel; but in Campsie, Kilflyth, and towards the exit, large strata of coal run within the bowels of the mountains. In various parts of the hills, passing from Dumbarton to Stirling, are lumpy masses of bafaltic rocks; and a grand colomnade of basaltic columns rises in a hill called Dun or Down, in the parish of Fintry. This consists of seventy pillars in front, of a gigantic stature, some appearing to be separated in loose blocks, and the shafts of others seeming entire through the whole extent; they stand perpendicular to the horizon, and rise to the height of fifty feet. They consist of various shapes, being square, pentagonal, and hexagonal. On the eastern side of this range the pillars are parted the distance of three or four inches. This gradually lefens towards the west side, till nothing more than a mark is to be dected, and which soon disappears in one solid mass of rock, very much honeycombed, and which has the appearance of having been ignited. The mountain on which they stand consists of extensive beds of red ochre. The front of a precipice in the parish of Strathtbaine, for the space of a furlong, is lined with lattely columns of the fame kind. They consist of four, five, and six fides; are from two to three feet in diameter, and thirty feet high. They rise from the horizon with a little inclination from the perpendicular, and some of them are apparently bent in the fegment of a curved line. In the latter mentioned parish, at the water-fall called the Spout of Ballagan, a very remarkable fection of the hill is prefented. The fide of it, being perpendicularly cut by the water, diflopes 192 alternate strata of earth and lime-stone; but towards the bottom of the fection are fiemal strata of the pureft alabaker. Near the fame place, in a late inundation of the river, fome fragments of antiquity were thrown up, which on trial were found to be of the finift quality. The vein, however, from which they were torn, has not been discovered. In what are fided the fconadary hills, coal is very abundant. The strata of these mountains, immediately succeeding the vein of coal, consist of lime-stone mixed with clay, here denominated cam- stone, and which burns into a heavy lime, but requires to be flaked while hot. Above this mixture of lime and clay are several strata of excellent iron-stone, of different degrees of thickness, with a soft flate, which interpose between the layers. The summit of the mountains is formed of layers of rock, called moor-stone. In the inferior hills, about the Glauffart, is a large field of coal on both fides of the fream, at the depth, on the north fide, from two to fifteen fathoms, and on the fouth of nearly twenty-two fathom. The coal is, in the latter part, immediately below the pebbles, and in the former part, immediately above them. The ftrata of the latter part are all folid and ftraight, and the thickest, in a circle about the breadth of the town, are about one foot in thicknefs. The neighbouring parish of Baldernock, upon the Kelvin, contains likewife abundance of coal and lime-stone. The coal refembles that of Newcastle, caking together, and giving out a strong heat when allowed to reek for hours undisturbed.

The parish of Kilflyth contains also very valuable minerals in great abundance; and iron-stone, which was wrought by the Carron company upwards of thirty years since, still continues to be worked to a great extent. (See Carron and Iron.) In the western part of the above parish are found great quantities of ball iron-stone, and confiderable beds of lime-stone. In the Garrel Glen is a large quarry of freeclose; loft and easily wrought when fill drawn from the quarry. The bed whence it is taken is generally from ten to fifteen feet, and is placed upon a beam of coal about as many inches thick. There is a variety ofiftals arifing, from thin leaves like trees, from the surface of the earth. Some of them are fix, ten, or twenty feet long, in proportion to the depth of the free-stone; and they differ as much in diameter as in length, being all fizes, from an inch to two feet. Thfe are esteemed as confiderable curiosities, and have furnished much matter for fpeculation. They exceedingly resembfe a petrifaction, and yet the fubfance is not calcareous earth, but folid fress-stone, of a fimilar texture with the circumjacent rock. One of the largeft of them is defcribed as being nearly sixteen inches in diameter, and about fix feet nine inches in length.

Rivers.—Of the rivers in this county, the Forth is the chief, and though not the largest, has always been considered the most distinguished of the Scottifh rivers. (See Forth.) The Carron river rises in the centre of the county, and running eafward, enters the Frith of Forth about three miles from Falkirk. (See Carron.) Bannockburn is more celebrated for the historical events that are connected with it, than for any importance it poftifles as a river, being only a small fream. (See Bannockburn.) The leffer rivers in this county are the Avon, which rises in the south-eastern parts; the Enrick; the Kelvin, which descends from the west and fows to the south-east; and the Blane, which gives its name to the parish of Strathtbaine, fprings from a high hill called the Earl's feat, amidit the Lennox hills. In a fhort courfe this river forms feveral water-falls, one of which, called
called the Spout of Ballagan, forms a cascade 70 feet in height, confined to a narrow channel, with lofty mountains on each side. This stream is sometimes increased to a torrent by violent flurms of rain, which occasionally pour down like water spouts. At such times, very considerable injury is done by the rapidity of the torrents, in overwhelming the low ground.

Lakes.—This county contains no lakes of importance, unless Loch Lomond be considered as partially belonging to it. In the parish of Buchanan, near Loch Lomond, there are three small lakes, Dulochan, Lochardie, and Lochamancairn. In the parish of Strathblane are six lakes; the largest of them, however, does not exceed half a mile in length, and a quarter of a mile in breadth; but they serve to bellow a degree of huskiness upon a defolate region. In the parish of Killyth, the great reservoir for the canal between the Forth and Clyde, though artificially formed, may be considered as a lake. See Forth and Clyde Canal.

Soil, Climate, and Agriculture.—The soil of this county is extremely various, as may be expected in a territory so much diversified by hills and dales. In the western parishes, it generally contains a considerable portion of clay, that renders it cold, retentive of water, and productive of moles and coarse grasses. The subsoil is mostly a hard till, impenetrable by water, or else an argillaceous kind of grit, of a reddish colour, blotched and veined with white, grey, and yellow. The surface lands comprise one of the most remarkable soils in the county. They lie in a low situation on the banks of the Forth, and extend from the river Avon on the east, to Kelly-water on the west; at an averaged space of about 30 miles in length and 2 in breadth. They are elevated from 10 to 20 feet above high-water mark, and a small portion of them is in some places overflowed at times by the river. The soil is universally allowed to be the alluvial deposited by the Forth and its tributary streams, and consequently to be the spoils of the higher grounds through which the river takes its course. It chiefly consists of a high-coloured clay, a small quantity of sand, and a pretty large mixture of once organized matter. In some places, are patches of till of various colours; but not a stone so large as to obstruct the plough is to be found. The soil of the belt quality, when dug first from the natural bed, is of a bright-blue colour, and of a substance resembling the richest loam, and sometimes evenoverride as a substitute for fuller's-earth. In many places, the clay is excellently fitted for making bricks, tiles, and a coarse kind of stone-ware. The depths are from five to sixty feet: the subsoils are stiff clay, hard till, and tea-hills in a natural state. The beds of shells are from a few inches to four yards in thickness; they are chiefly large oysters, with a mixture of cockles, whisks, and some other shells at present found in the Frith. Patches of rich and fertile loamy soils are intermixed in different parts of the shore. Light gravelly soils are chiefly on the banks of the Enrick, Carron, Blane, and other rivers in the western and midland parts of the county.

The high moors of Stirlingshire, as in other parts of Scotland, consist of a moily foot, extremely loose when dry, but when wet, retentive of moisture. Of the many peat-moors in this county, some have been formed upon the kerf or low grounds adjoining the principal river, by the Romans having cut down the trees, which formerly grew here, and which formed the most formidable retreats of the natives. Where the moor is removed, these trees are found lying in all directions beside their roots, which still continue firm in the ground in their natural position; and from impreissions still visible, it is evident that they have been cut with an axe, or some similar instrument. That they were cut down by the Romans, is not only probable from the accounts which the historians of that people have given of their operations, but is confirmed by a circumstance that occurred in May 1768, when a large round vessel of thin brass, and of curious workmanship, 25 inches in diameter and 16 inches in height, was discovered upon the surface of the clay, buried under the mosses. It was denominated by the Edinburgh Society of Antiquaries, a Roman camp-keilee.

The agriculture of this county is very varied. In the parish of Gargunnock, and elsewhere upon the Carle or Kerf, all elevates consist of moor, dry field, and kerf farms. The dry fields occupy the space between the hills or moor and kerf grounds; and upon these, great improvements have of late been effected. The kerf lands, which are all arable, are subdivided into farms from about 15 to 100 acres each; but those of 30 and 40 are most common. Farms in the higher part of the county are from 20 to 1000 acres, of which there is commonly a mixture of rough wet land, that is pattered only. Almost universally the farms are occupied by the persons who rent them. Small possessions, from 2 to 20 acres, are to be met with in several parts, and in the old language of the country are still designated parcles. The occupiers of them are generally day-labourers, who gain their livelihood by working on the high roads, or for the neighbouring farmers. Many of them are also in the possession of manufacturers or mechanics, for the accommodation of their families. Around the villages there are some considerable numbers of small properties held in feu.

In the Kerf, wheat is usually preceded by summer-fallow; and much barley is reared. The cultivation of turnip-grasses is become very general. Peas and beans are little cultivated in the high parts of the county, but very generally in the Kerf as a mixed crop. The turnip-handy is extensively carried on towards the eastern part of the county. It appears from a memoir presented to the Board of Agriculture by William Wright, M.D. F.R.S. that potatoes were not planted in the open fields in this county, or any where else in Scotland, till about the year 1728, when Thomas Prentice, a day-labourer, first cultivated them in this mode in the parish of Killyth. About 12 or 16 years after this introduction, a Mr. Graham of that place cultivated them in great quantities for sale. He was one of the first who supplied the market of Glasgow with potatoes. Being very successful, his example in raising the large, round, reddish-coloured potatoe in the open field for the market was soon followed by many farmers; and the practice is now so universal, that they are even planted in strong clay land.

On some elevates, the farm-buildings are substanital and well arranged, and a good situation is generally chosen. Dwelling-houses on many elevates are two stories high, and are usually covered with slate or tile. About two-thirds of this county, exclusive of the moors, are supposed to be inclosed; and every description of fences, from high walls of stone and lime to neglected quickset hedges, are to be seen. One proprietor in the neighbourhood of Falkirk, has inclosed within eight years no less than 7000 Southfield acres. The fences are mostly of white-thorn, with double ditches, between which a mound or dyke of earth is placed. The ditch next the hedge is commonly five feet wide at the top, and three feet deep; the other is three feet wide. The dyke or bank between them is four or five feet broad at the base, and as much in height above the surface. The lines of the inclosures are all straight, at right angles with one
one another, and many of them run in the same direction for several miles. The ridges follow the same course as the fences, for which the situation and the ground correspond remarkably well. Wet ditches alone are in some parts of the carse supposed to be sufficient fences; several of them are ten feet wide, and of considerable depth. It is believed, that the extraordinary dimension of these excavations has been owing to the long continued practice of procuring from them clay for various purposes.

The cattle of Stirlingshire are few; the inhabitants being supplied by the Highland dealers. A considerable part of the moors is paddled with sheep, which are almost universally of the black-faced kind, and are called here the Linton breed, from the name of the village in Tweeddale whence they originally came. It appears, from the valuation of lands in the middle of the 17th century, that Bea Lamond, with the whole of the upper part of the parish of Buchanan, was almost entirely stocked with goats. A considerable portion of the rents, in those days, consisted of kid's and goat's milk cheese. Very few of that species of stock are now kept in the county.

Woods and Plantations. — Stirlingshire contains many coppices, that have been used as such from time immemorial. Torwood, in the parish of Dunipace, and the woods of Callander, in the parish of Falkirk, are generally believed to be the remains of the Caledonian Forest, with which the greatest part of this county, when the Romans invaded Scotland, seems to have been covered. The trees are principally oak, beech, hazel, and birch. Some of the oaks, when allowed to remain, grow to a great size. Of this, the county affords several examples. The most noted tree in the whole district was Wallace's oak, in the midst of the famous Torwood. This tree, which, when entire, measured 12 feet in diameter, afforded in its trunk, hollowed by age, a shelter in the hour of danger to that bold colony whose name it bears, and a party of his followers. The oak, the ash, and the beech, are the most valuable trees in this county. Great attention has been paid, especially during the last 35 years, to rearing timber of all kinds. Plantations for shelter, ornament, and profit, form a considerable part of the improvement of the many estates which have been inclosed and improved since that period. The ground on which these plantations occupy, amounts, exclusive of hedge-rows, to between 2000 and 3000 acres. The trees generally planted are those before named, with various pines, especially the larch, which at seven years old raises its head nearly double the height of any other tree of the pine genus.—Beauties of Scotland, vol. III. Chalmers's Caledonia, vol. 1.

STIRPFING, a town of Aulafia; 4 miles N.E. of Weikendorf.

STIRRUP, or Stirrup, in the Mange, a reft or support for the horfeman's foot, ferving to keep him firm in his feat, and to enable him to mount. The great art of a cavalier in the ancient tournaments was to make his antagonist lofe his stirrup. For combating, it is a rule to have the right-foot stirrup somewhat shorter than the other. Stirrups are allowed to be a modern invention; no mention being made of them in any ancient Latin or Greek author; no figure of them to be feen in any statue or monument; nor any word expressive of them to be met with in classical antiquity.

Menage observes, that St. Jerom is the first author who mentions them. This paffage, however, is not to be found in his epiftles; and if it were there, it would prove nothing, becaufe St. Jerom lived at a time when stirrups are fuppofed to have been invented, and after the use of faddles. Montfaucon denies the authenticity of this paffage; and, in order to account for the ignorance of the ancients with regard to an instrument fo ufeful and fo caufy of invention, he obferves, that while cloths and houfings only were laid upon the horfes' backs, on which the riders were to fit, stirrups could not have been ufed, becaufe they could not have been fanned with the fame fecurity as upon a faddle. But it is more probable, that in this inftance, as in many others, the progress of human genius and invention is uncertain and flow, depending frequently upon accidental caufes. Berenger's Hist. and Art of Horfemanship, vol. i. p. 65, &c.

To foil one's stirrups, is to fuffer them to flip from the foot.

Stirrup-foot is the near or left foot before.

Stirrup-leather is a thong of leather defending from the faddle down by the horfe's ribs, upon which the stirrups hang.

Stirrup-bearer, called in French porte evrier, is an end of leather made flat to the end of the faddle, to trufp up the stirrup when the rider is aughted, and the horfe fent to the flable.

Stirrup, in Ship-Building, an iron or copper flrap or plate, that turns towards on each fide of a fhip's keel and dead-wood, clofe forward or abait, and bolts through all. Stirrups are only ufed to British fhips, when the after-piece of the keel is carried away by accident, and is replaced without the dead-wood bolts being driven through. See Horse.

STISSIC MOUNTAIN, in Geography, a mountain of America, that lies between Connecticut and Hudson river, near which the Mahikandi Indians formerly refted.

STITCH, in Agriculture, a term which in foine districts signifies a ridge or butt in a field which is under the plough. The forms and breadth of fitches are liable to vary according to the nature and ufe of the land in different districts and places. In the county of Exef, their variation is laid not to be confiderable. In the greatest part of the western portion of it, the more wet land is laid out on two-bout ridges, or four-furrow work; and a fattering of thefe is everywhere, it is laid, to be seen; but on the strong land in the tea-diftricts, eight, as they are termed, or fitches of eight furrows, are more common. And towards the south of the county, ten-furrow work is rather more general. Thefe form the chief variatics in refpect to this matter. But there is a melancholy manner of forming the fitches in foine inftances, where they are laid by the plough in an admirable way. In particular cafes, not one furface furrow can be seen, nor any fort of tendency to any thing of the hog-troach kind, upon the whole extent of fitches on the farms: the form of the lands is perfectly correct, and fo regularly and gently rounded, that not a drop of water can any where lodge upon them. It is difficult, it is thought, to plough lands of fo flift a quality to thoroughly well. They are all ten-furrow lands or fitches, and the harrows and other tools for them are made for the breadth in a fuitable manner.

Some farmers are particularly cautious in ploughing down old fitches or ridges, efcpecially where the land is of the cold clayey kind, though others bring them down, without much hesitation or caution, in a gradual manner. Some have ploughed down high old fitches for the purpofe of forming granf-land, but have repented it ever afterwards; confidering that the incapable of cultivation; and if it should be buried, and the under foil be brought up by fuch levelling, is injurnt for an age, or
for ever afterwards. They are consequently decided of opinion, that high lands or fitches should on no account whatever be ploughed down. They have often seen them laid to grass in their old form with great success, but rarely ever when ploughed down. In such cases, if brought to good pasturage, it has been, it is thought, by force of manuring or top-dressing.

There can, however, be no fort of doubt, but that high and badly formed lands or fitches in grounds may be brought down and reduced, in many cases, with considerable advantages in different respects, though it should always be done with a good deal of care and caution, as well as molly, perhaps, in a regular and gradual manner.

STITCHEL, in Rural Economy, a term applied to a kind of hairy wool met with on some sorts of sheep. See Sheep and Wool.

STITCHING, in Agriculture, a term applied to the forming of ridges in land, the same as ridging.

STITCHWORT, a name sometimes given to the alfme, or bellaria of botanists, otherwise called chickweed. See Bellaria.

STITHY, or STUTY, is used either for a smith's anvil, or a diface in oxen, causing their feet to stick so close to the ribs, that they cannot fir.

STIVA. See THIBIS.

STIVER, in Commerce, a money of account and copper coin in Holland and Flanders. The older gilders or forms of account contain 20 flivers, each of which is divided into 16 pennings. A fliver contains 2 groats Florins, and 8 duits; and a duit, 2 pennings: a gold fliver, with which accounts are kept in the coin-trade, is worth 28, and the wolfe, 26 flivers. In fliver, there are pieces of a fliver; and in copper, duits which are the 8th part of a fliver. At Antwerp, and the whole of the Brabant and Flanders, accounts are kept mostly in florins and gilders of 20 flivers, or flivers, formerly called patars, which were formerly subdivided into 16 pennings, but for a long time have been divided into 12 parts or deniers. The smaller fliver coins are the new pieces of 5 and 2½ fl Ch. flivers, and plaquettes of 3½ flivers current. A piece of 5 flivers is valued at 44¼, and a plaquette at 36. See COIN.

STIVING, in Sea Language. See STEEVING.

STIXXYS, in Geography, a town of Austria; 3 miles N.W. of Brugg.

STIXIS, in Botany, a species of dicot or prickling, because of the dotted rind of the fruit.—Loureir. Cochinch. 295.

Loureiro supposes the Avisus, Rumpl. Ambossi. v. 1771. t. 66, to belong to the same genus. But that is an upright tree, with ployandra or icofandrous flowers. If, indeed, there be no mistake in the author's account of the flower in his Stixis, it cannot belong to the natural order we have guealed, nor are we able to form any further conjecture on the subject.

ST. LAWRENCE COUNTY, in Geography, a county of New York, erected in March 1802; bounded on the N.W. by the river St. Lawrence, and the British possessions in Canada; E. by Franklin county; S. by Montgomery and Herkimer counties; S.W. by a small corner of Herkimer county, and by Lewis and Jefferson counties. Its extent on the St. Lawrence is 65½ miles, in a right line; the E. line is 61 miles, the S. line 26, and the S.W. 43 miles; so that it has an area of about 2000 square miles. It is situated between 44° 38' and 45° N. lat., and 79° and 80° W. long. from New York. Its number of towns is 12, the capital being Osgoodville, 212 miles from Albany; its population consists of 7894 persons. The soil is principally sand or loam, thickly wooded with maple, beech, ash, tilia or bass wood, butternut, elm, and groves of white and yellow pines: it is not mountainous nor even hilly; it is well watered by springs and streams, washed on the N.W. for an extent of 75 miles by the St. Lawrence, and penetrated by many navigable rivers. In the southern part are small lakes. This county sends one member to the house of assembly.

STOE, see, in Antiquity, the porticoes at Athens. There were full of exedras, 125 ep, and side buildings, furnished with seats for study or discourse. Here it is probable philosophers and their scholars used to meet. See EXEKI.

STOA KED, in a Stoa. When the water in the bottom cannot come to the well of the pump, they saw, the top is afford, or floated: to say that they also, the timber holes are floated, when the water cannot pass through them; and that the pump is floated, when something is got into it which choke it up, so that it will not work.

STOA, in Zoology, the name used by many for the animal whose skin is the erin: see Erinus

This genus consists of nine species, all natives of the Cape of Good Hope, only one of which had previously been described by Linnaeus. With this original species, Carlina atratylodes of the Amaranthaceae, v. 6. 96, the younger Linnaeus confounded two other very distinct plants, which are perhaps the S. glabrat and rigula of Thunberg. The specific characters of this writer are too short and incomplete to determine the point; and we must content ourselves with giving all the information he has afforded.

1. S. glabrat. Thum. Prod. 141. Wild. n. 1.—Leaves heart-shaped, clasping the stem, oblong, smooth. —We should rather have said "leaves oblong, smooth, clasping the stem with their heart-shaped base," which is the case with both the uncertain species allied to above.

2. S. carinoides. Thum. ib. Wild. n. 2.—Leaves heart-shaped oblong, smooth, with runcinate spinous teeth.

STOBjEUS, in Ancient Geography, a town of India, which belonged to the people called Ichthyophagi.
STOBI, a town of Macedonia Salutaris, which succeeded that of Pelagonia, as the metropolis of this province. It was colonized by the Romans. Play.
STON, in Geography, a town of European Turkey, in Macedonia; 42 miles N. of Edessa.
STOBORRHUM, or Stoborum Promontorium, (Mers-el-Berber) in Ancient Geography, a promontory of Africa Propria, upon the coaft of the gulf of Numidia, between the promontory Hippus and the town of Aphrodifium.
STOBREZ, in Geography, a small sea-part of Dalmatia, near the coaft of the Adriatic, on the fitcfe of the ancient Epetum, a colony of the Illi; the ruins are full vi fi ble; 4 miles E. of Spalatro.
STOC and Stovel, in our Old Writers, a forfeiture where any one is taken carrying fliples and pubulum out of the woods; for flec signifies flecks, and flovel, pubulum.
STOCK, in Commerce, a fund raised by a commercial company; or a principal item of property employed in trade.
Stock, in Book-keeping, denotes the owner or owners of the books.
STocks, or Public Funds, are the loans advanced to government, for which interest is regularly paid, from revenues fett apart for the purpose. This mode of raising supplies by levying taxes for the payment of interest, is called the "fund ing system," and the loans thus raised constitute the "national debt." (See Public Funds and National Debt.) The debts of government differ from other contracts in this, that the public creditor can claim only his interest; he may, however, sell his flock, that is, he may transfer his claim, and thus obtain his capital, more or less, according to the price of flock, which fluctuates from various caufes. The different funds or flocks are variously denominated, according to the terms on which they were established. Thus, fome are called the 3 per cent., fome the 4 per cent., others the 5 per cent., &c. And the manner of buying flock is to give a fpecific sum for a nominal hundred: e.g., if the price of the 3 per cent. be 60l., this sum is paid for 100l. flock, which yields a dividend of 3l. a year, that is 5 per cent. per annum; for at the fame rate 3l. for 60l., 100l. would yield 5l. If flocks are low, the interest is high; and vice versa. In fome funds there is a higher interefl than in others, and this is chiefly owing to the preference given to that flock which is most marketable, or the least likely to be redeemed; for government has an option to pay off or redeem certain loans, when an advantage may be made by such redemption. New loans are paid by infallments of 10 or 15 per cent., at flated periods, and they generally comprehend different kinds of flocks, which together are called "omnium." If they be disposed of separately, before all the infallments are paid, the different articles are called "scrip," an abbreviation for subscription. In raising loans, a douceur is fometimes given by government of an annuity for a limited time: fuch are called "terminable annuities," and "irredeemable;" but the regular flocks, on which the common interefl is paid, are called "perpetual annuities," and are redeemable. Loans are called a "funded debt," when taxes are appropriated for paying the interefl; but fums raised for which no fuch provision is yet made, are called the "unfunded debt." Of this latter defcription are exchequer, navy, victualling, and ordinance bills, which are iffued by thefe different offices, and bear an interefl until they
they are paid off. The interest is mostly 3d. or 2½d. per day for every 100l.

Stock, Capital. See Capital, and Stock supra.

Stock Brokers. See Brokers.

Stock-Exchange Fund, an institution formed in the year 1801, for the relief of the decayed members of the Stock-exchange and their unprotected families. The annual subscription is one guinea, and that for life is two guineas. The annual relief does not exceed 40l. to any applicant; donations are restricted to 20l. Persons receiving any annual allowance are ineligible; and the allowance may be withdrawn if the party is no longer deserving, or if his circumstances have improved so that he ceases to be an object of charity.

Stock-Jobbing denotes the practice of trafficking in the public funds, or of buying and selling stock with a view to its rise and fall. The term is commonly applied to the illegal practice of buying and selling stock for time, or of accounting for the differences in the rise or fall of any particular stock for a stipulated time, whether the buyer or seller be possessed of any such real stock or not. This is that gambolling at the Stock-exchange, which runs numbers of people every year, and which is injurious, in a variety of respects, to individuals and the public. Transactions of this kind are declared to be illegal by an act of parliament "to prevent the iniquitous practice of stock-jobbing," and no debt accruing from stock-jobbing accounts is recoverable at law. (7 Geo. I. A.D. 1734.) The broker who is unable or unwilling at the settling day to pay for himself or his principal the difference, becomes, in the cast language of the Stock-exchange, a "lame duck," so that he can no longer frequent the house, nor do any more businesfs on credit, with his brethren. A stock-jobber, who has bought stock for time, which he never intended to take, is called at the Stock-exchange a "bull" laden with a burden which he wishes to shake off. On the contrary, he who has sold, upon speculation, what he does not possess, and consequently cannot transfer, is called a "bear," eager and hungry, and trying to devour the property of others. The first of these parties wants the fund he has bought to rise, that he may sell the fame fund at an advanced price, and receive a profit, which he has called the "difference." It is this man's interest to propagate false intelligence in time of war, of victories, negociations for peace, &c. The bear, on the contrary, will endeavour to obtain false news of defeats by sea and land, in order to lower the price of the fund he has sold on speculation, that he may have an opportunity of buying the same fund at a lower price, and thereby receiving a profit. Thus, by the various arts of the stock-jobbers, real property is affected, and the rise or fall of the funds is regulated by the jobbing accounts at the Stock-exchange. The greatest part of the national debt, consisting of 3 per cent. consol. annuities, in which most business is daily transacted, the greatest jobbing, and the most frequent variations, happen in that fund. All ranks of people, and persons of both sexes, engage more or less in stock-jobbing, often through the persuasion of their brokers; especially if they are known by transferring, or by purchasing, to have considerable property in the funds. But foreigners involved with public characters, and persons connected with them, have the best opportunities of playing a pure game, by means of early intelligence; and so they generally carry their gains out of the country: this is a great evil. Commerce likewiseuffers considerably by stock-jobbing, for tradesmen are tempted, by the hope of more rapid profits, to sell any cheap market, in the name of businesfs, to frequent the Stock-exchange; and not being in the secret of obtaining true in-

intelligence respecting public affairs, they lose instead of gaining, and too often become fraudulent bankrupts. See Stock-Broker.

Stock, in Agriculture, a term signifying any fort of crop, or other kind of farm property. All kinds of flocks of this nature should constantly be well tended and adapted to the size, quality, and nature of the farms, so far especially as relates to tools, machinery, crops, and the different forts of animals which are to be kept and employed upon them, whatever this fort may be; as, upon this being nicely and properly adjusted, a great deal in their economy and utility depends. It has now been long well known that very great advantages result to the farmer, from his thus accuratelyattiug his crops and live-stock of different kinds, as well as other things, to the lather, qualities, and circumstances of his lands; as they are found to be greatly influenced by them, and of course to be much benefited, where such a correct attention is had to the matter.

This has sometimes the terms of farm and farming flock applied to it, by different writers on husbandry.

Stock, Livestock, that kind which comprehends all forts of domestic animals. See Live-Stock.

Stock, Live-Stock, Choice of Food for, the particular selection or choice of that fort to which they are attached, as being the most agreeable to them. The attachment or dislike to a particular kind of food, as shewn by animals, however, is said, affords no fort of proof of its nutritive properties or powers; as different sorts of neat cattle, sheep, and other animals, at first refuse linseed cake, which is well known to be one of the most nourishing and fattening substances on which they can be fed; and the fame is probably the case with some other matters used as food of animals.

The writer of the late work on "Agricultural Chemistry" has given the following remarks on the selection or choice of different kinds of common food, by sheep and cattle, on the authority of Mr. G. Sinclair, the gardener to his grace the duke of Bedford, at Woburn Abbey. With respect to ryegrass (lolum perenne), sheep, it is said, eat this grass, when it is in the early stage of its growth, in preference to most others; but after the feed approaches towards perfection, they leave it for almost any other kind, its place at the above place was laid down in two equal parts, one part with the above grass and white clover, and the other with cocks'foot and red clover. From the spring till midsummer, the sheep kept almost constantly on the ryegrass part; but after that time they left it, and adhered with equal constancy to the cock's-foot part, during the remainder of the season. In regard to the cock's-foot grass (dactylis glomerata), oxen, horses, and sheep, are stated to eat this grass readily. The oxen continue to eat the flowers and fruits, from the time of flowering until the time of perfecting the seed. This was exemplified in a remarkable and striking manner, in the field just alluded to. The oxen generally kept to the cock's-foot and red clover, and the sheep to the ryegrass and white clover. In the experiments published in the "Amenitates Academicae," by the pupils of Linnaeus, it is asserted, it is said, that this grass is rejected by oxen. The above facts, however, is in contradiction of it. As to the grass which is usually known by the title of meadow fox-tail grass (alopecurus pratensis), sheep and horses feed it, is said, to have a greater relish for it than oxen. It delights in a soil of intermediate quality as to moisture and dryness, and is very productive. In the water-meadow at Prielle, near Oxford, every year, water is being pumped for the purpose of producing this excellent produce. It there, it is said, invariably keeps pollietion of the top of the...
the ridges, extending generally about six feet from each side of the water-course; the space below that, to where the ridge ends, is flanked with cock's-foot, the rough-flaked meadow-grass, the meadow fescue, the hard fescue, the agrostis flabinfera and palustris, with the sweet-fcented vernal gras, and a small admixture of some other kinds. In speaking of the nature of the meadow cat's-tail gras (phleum pratensf), it is said that it is a gras which is eaten without science by oxen, sheep, and horses. It is noticed, that it has been said by doctor Pulteney, that it is disflked by sheep; but that in pastures where it abounds, it does not appear to be rejected by these animals, but to be eaten by them in common with other animals as are growing with it. In respect to the fiorin gras (agrostis flabinfera), in the experiments detailed in the Accomplishments Academic, it is said that horses, sheep, and oxen, eat it greedily. On the Duke of Bedford's farm at Maulden, fiorin hay was placed in the racks before horses, in small distinct quantities, alternately with common hay; but no decided preference for either was, it is said, manifested by the horses in this trial. But that cows and horses prefer it to hay, when in a green state, seems rurally proved, it is thought, by Dr. Richardson, in his several publications on fiorin; and of its productive power in England, which has been doubted by some, there are satisfactory proofs. Lady Hardwicke has given an account of a trial of this gras, it is observed, whereas twenty-three milch-cows, and one young horse, besides a number of pigs, were kept a fortnight on the produce of one acre of ground. In regard to the rough-flaked meadow-gras (poa trivialis), oxen, horses, and sheep, eat it, it is said, with avidity. Hares also eat it; but they give a recided preference to the smooth-flaked kind, to which it is, in many respects, nearly allied. Respecting the smooth-flaked meadow-gras (poa pratensis), oxen and horses are, it is said, oberved to eat it in common with others; but sheep rather prefer the hard fescue, and the sheep's fescue, which affect a similar foil. This, it is noticed, is a species of gras that exhausts the foil in a greater degree than almost any other; the roots being numerous, and powerfully creeping, become, in two or three years, completely matted together: the produce diminishes, as this takes place. It grows common in some meadows, on dry banks, and even on walls. With respect to the crefted dog's-tail gras (cynoferus criffatus), the South-Down fheep, and deer appear, it is said, to be remarkably fond of it. In some parts of Woburn park, it forms the principal part of the herbage on which these animals chiefly browse, while another part of the same park, that contains the agrostis capillaris and pumilis, fheeta ovina, durifcula, and cambrica, is seldom touched by them. But the Welsh breed of fheep almost constantly browse upon these, and neglect the crefted dog's-tail, the rye-gras, and the rough-flaked meadow-gras. The fine, or common bent gras, (agrostis vulgaris or capillaris,) is noticed to be a very common gras on all poor, dry, sandy soils. It is not palatable to cattle, as they never eat it readily, if any other kinds be within their reach. The Welsh fheep, however, prefer it, as has been just observed; and it is singular that thole fheep, being bred in the park, where some of the best gras are equally within their reach, should still prefer those grasales which naturally grow on the Welsh mountains; it would seem to argue, it is thought, that such a preference is the effect of some other cause than that of habitat. As to the fheep's fescue gras (fheeta ovina), all kinds of cattle are faid to relish, and perhaps to have a fort of preference for it; but it is thought that it appears, from the trial which has been made with it on clayey soils, that it continues but a short time in polfession of such kinds, being soon over-powered by the most luxuriant forts. It is suggested, that on dry shallow soils, which are incapable of producing the larger kinds, this should form the principal crop, or rather the whole; for it is seldom or ever, in its natural state, found intimately mixed with others, but by itself. Regarding the hard fescue gras (fheeta durifcula), it is noticed, that it is certainly one of the best of the dwarf sorts of grasales. It is grateful to all kinds of cattle: hares, too, are very fond of it; they cropped it close to the roots, and neglected the fheep's fescue, and the fheeta rubra, which were contiguous to it. It is preuent in most good meadows and pastures, it is laid. The meadow fescue gras (fheeta pratensis), is a gras, it is faid, which is seldom abfent from rich meadow and palure lands, and which is observed to be highly grateful to oxen, sheep, and horses, particularly the former. It may possibly be preferred to some other grasales by thole. It is noticed as appearing to grow moff luxuriantly, when combined with the hard fescue, and the rough-flaked meadow-gras. The tall oat-gras (avena elatiolis) is also noticed to be a very productive gras, which is frequent in meadows and pastures, but which is disflked by cattle, particularly by horses. This perfectly agrees, it is thought, with the small part of nutritive matter which it affords. It is said that it seems to thrive belt on a frong tenacious clay. The yellow oat-gras (avena fla-feefens) is likewise a gras which, it is said, feems partial to dry foils and meadows, and which appears to be eaten by fheep and oxen equally with meadow barley, crefted dog's-tail, and sweet-fcented vernal grasales, which naturally grow in company with it. It is noticed, that it nearly doubles the quantity of its produce, by the application of calcareous manure to the land on which it grows. The meadow foft gras (holcus lanatus) is a very common gras, it is said, and grows on all foils, from the richest to the poorest. It is noticed to afford an abundance of feed, which is light, and easily difpersed by the wind. It appears to be generally disflked by all forts of cattle. The produce of it is not fo great, it is faid, as a view of it in the fields would indicate; but being left almost entirely untouched by cattle, it appears as the most productive part of the herbage. The hay which is made of it, from the number of downy hairs which cover the surface of the leaves, is loft and fpong, and difflked by cattle in general. And the half, or the sweet-fcented vernal grasales (anchoferus and cymoferus), which seem to be fair to be eaten by hares, oxen, and fheep, though in festivals, where it is combined with the meadow fox-tail and white clover, the cock's-foot, and the rough-flaked meadow grasales, it is left untouched, from which it would foom unpalatable to cattle. It is noticed, that Mr. Grant of Leighton, in the fame district as the above place, laid down one half of a field of confiderable extent with this gras, combined with white clover; the other half of the field with fox-tail and red clover. The fheep would not touch the sweet-fcented vernal, but kept constantly upon the fox-tail. The writer raw the field, when the grasales were in the highest flate of perfection, and hardly any thing could be more fatisfactory. Equal quantities of the foeds of white clover were fown with each of the grasales; but from the dwarf nature of the sweet-fcented vernal grasales, the clover mixed with it had attained to greater luxuriance than that mixed with the meadow fox-tail. This is perhaps nearly the whole of what has yet been done on this interefting subject, which is important in several respects; as, though it may not lead exactly to the knowledge of the difference in the nutritive properties or qualities of different substantes as the food of live-flock of the farm kind,
kind, it may serve to direct the proper and most useful means of preparing and laying down lands, for the purpose of pasturing and feeding such flock in the belt and most beneficial manner and succession as to the use and consumption of the food, as well as probably be of utility and advantage in some other ways.

For the nature, qualities, and properties, of the different forts of domestic animals which constitute the living flock of the farmer, see Live-Stock.

Stock Account, that fort of account which is kept of the flock of a farm. It is of much utility and advantage to the farmer, in many different ways, that a correct account of the different forts of flock on the farm be kept in a perfectly accurate and proper manner; as it not only shews how he stands in respect to profit and loss, but, in some measure, directs the management which is the belt and most proper, as well as the most beneficial to be followed in different cases.

In order to accomplish the business in the most proper manner, a general flock-book should be kept; in which, at the close of every year, or at any other more suitable period, should be entered the result of a full and careful examination and estimate of the state, condition, and worth of the whole of the flock and property of every kind, as well as of the debts and credits which are existing. Such a book will at all times, and on all occasions, be of great value and utility for the purpose of referring to, and for affording the necessary satisfaction how every thing on the farm is going on, whether properly or improperly. In this intention, in the first place, all the different tradesmen's accounts and charges are to be got in, and the state and worth of the household property taken, but without any very great degree of minutenes in this particular; then more particularly exact accounts made out for the hores, the neat cattle, the sheep, and other forts of live-flock, with those for grain in the straw and threshed out, for hay and fodder of other kinds, for manure, for growing crops, for fallows, for timber-wood and woods, for ploughs, harrows, carts, wagons, harness, traces, sacks, and small implements of all forts; concluding with the situation and state of the fences of all kinds, the gates, the drains, and water-courses, &c.; with estimates of the necessary repairs which they may stand in need of, on the side of the proprietor, as well as the tenant. Such memorandum being at first made out upon a blank paper, the particulars of them may afterwards be copied and entered into the flock-book, in such a manner as may be considered necessary in regard to minutene.

After the whole of this fort of work has been completely and properly adjusted, a debtor and creditor account may be made out in the manner of Stock Dr., and Contra Cr., the balance of which will shew, in an exact and certain manner, the present state and worth of the farmer's estate and property.

On the debtor side of this account is to be entered or put down all the farmer owes, beginning with rent, tythe, and taxes, and proceeding with other items; and on the contra, or contrary side, all he possesses of every kind, and all which is owing to him. Every thing is to be rated at what is thought to be the fair and just worth or value of it at the time; manure, and tillage-work which has been performed, are to be valued at what is the common rate of the particular district; and the corn which is not threshed out, and other similar articles, are to be taken by estimation at the fair rate which is then to be had for them. All other things are to be valued in the same manner.

There are several different modes and forms provided for keeping accounts of the farm kind; but for common farmers, the ordinary method is probably the most suitable, and may most be made fully sufficient for the purpose. Instead of the puzzling, though beautiful and correct, philosophical Italian mode, a fort of half that method has been advised, as both useful and unattended with either intricacy or trouble. It is merely that of creating or entering what are called flock accounts, in a ledger, without any of the usual connections by reference, common in that method. Thus, it is said, if a farmer wishes to be very correct in his accounts of the profit or loss, upon a lot of rolled oxen, for instance, or on the crop of any particular field, his belt and method is to make out an account, either for the one or the other, in his ledger, debtor and creditor. On the debtor side let him place the colt or expense, including every minute particular; on the creditor, the returns: in course, on the sale of the articles, the account is closed, and the balance demonstrates the profit or loss.

The keeping of both a day-book and ledger is necessary for the farmer: the first, in order to serve the purpose of affording necessary memoranda, as guides in the conducting of his business; and the latter, for shewing the general state of his affairs. But he need not be over nice or fiddulous of forms, but enter down in the former whatever he may think needful, with the date; as besides other things, the times when the mares were put to the females of different forts of domestic animals, as accidents are liable to frequently happen, for want of timely notice and care about the period of their bringing forth. It is also of vast use to keep correct accounts of the dates of different sowings, as well as of the various transfections of the tillage and other kinds on the farm.

In fact, the regular taking of the flock of farms annually, at some certain period of the year, and of keeping fair and exact accounts, is, on the whole, when well and perfectly considered, attended with far less trouble and inconvenience, than the everlasting puzzle, confusion, uncertainty, and loss, of heedless negligence in this respect, but which is a great deal too common among farmers. Regular accounts and annual valuation will, it is said, not only afford the farmer an exact knowledge of his real situation, but wonderfully sharpen and improve his judgment on the real worth and value of all those articles in which he deals, or has any concern; and in the necessary contemplation of the final event, he will have the satisfaction of reflecting that all stands fair for the benefit of his family, and as little liable as possible to loss or dispute in any way.

In a situation like that of a farm, where the whole home-stead or residence is necessarily surrounded with different forts of combustible matter, the insurance against accidents by fire should never, on any account, be neglected, or put off for even the shortest space of time. The accidents and deaths of different forts of live-flock may likewise be probably injured against, both of which should, of course, form accounts in the flock-book.

Stock, in Gardening. See Stocks.

Stock, in Block-making, a wooden instrument used for boring holes, by fixing a bit in the lower end, and a pin with a round head in the other end; the pin and the bit serving as an axis upon which to turn it.

Stock of an Anchor, is composed of two long pieces of oak, tapering from the middle, fastened together with iron hoops and tree-nails, and fixed on the shank transversely to the arms. Some anchors have iron locks.

Stock-Shave, in Block-making, a large sharp-edged cutting-knife, with a handle at one end, and a hook at the other, by which it hooks in an iron-flap, that is driven

E. c. 2 into
into an elm-block: it is used to pare off the rough wood from the shells of blocks, &c.

Stock-Fish, in the Fish-Trade, a name given to the common cod-fish, when cured in a particular manner, which makes it necessary to beat it with fists before it is fit for dressing.

The commerce for stock-fish is very considerable in Holland, both from the great consumption of it in the country, and from their victualling their vessels with it. See Cod-Fishery.

Stock-Gilly-Flower, in Botany. See Cheiranthus.

Stock Rock, in Geography, a rock on the W. coast of South Wales, in St. Bride's bay.

Stockach, a town of Germany, in the landgraviate of Nellenburg, of which it was the capital; 15 miles N.W. of Constance. N. lat. 47° 52'. E. long. 9° 1'.—Alto, a river of Germany, which rises in the landgraviate of Nellenburg, and runs into the lake of Constance, 5 miles S.E. of Stockach.

Stockau, a town of Germany, in the principality of Culmbach; 5 miles S.E. of Bareuth.

Stockbridge, locally situated in the upper half of King's Sombourne, and division of Andover, Hampshire, England, is a small market-town on the eastern side of the Test, and on the road from Winchester to Salisbury. The population, according to the report of 1811, amounted to 663 inhabitants, occupying 149 houses. A new bridge was erected here over the river Test a few years since; about two miles to the westward, on Houghton-down, is a good race-course. Stockbridge is a borough by prescription, and its government is vested in a bailiff, who is the returning officer, a constable, and a sergeant at mace. This place sends two members to parliament, which privilege was first policed at the commencement of the reign of queen Elizabeth; since which time, the members and voters have frequently been cited before the house of commons for corruption and bribery. This, indeed, is one of those boroughs which has brought the English representative system into frequent and severe reproach. The ingenious and learned sir Richard Steele was elected one of the members for this borough in the time of queen Anne; and obtained his election by flicking a large apple full of guineas, and declaring it should be the prize of that man whose wife should first be brought to bed after that day nine months. The two members are now elected by 57 voters, who receive, according to Oldfield, 6d. a man. (See a particular account in the Repertamen. Hist. vol. i. part ii. p. 507.) The right of election is in the inhabitants paying the church and poor rates. A weekly market is held here on Thursday; and here are three annual fairs. It is 66 miles W.S.W. from London, and 15 E. from Salisbury. The parish of Stockbridge contains the borough, and Stockbridge-parish, alias White-parish.—Beauties of England and Wales, vol. iv. by J. Britton and E.W. Brayley. Oldfield's Representative History, vol. i. part ii.

Stockbridge, a township of America, in Windsor county, and county of Vermont, situated on White river, and containing 700 inhabitants.—Alto, a post-town in the rate of Massachusetts, and county of Berkshire, 44 miles W. by N. from Springfield. This is the chief township of the county, incorporated in 1739, and containing 1372 inhabitants.

Stockbridge, West, a town of Massachusetts, in Berkshire county, containing 1049 inhabitants.

Stockbridge, New, a tract of land, six miles square, in the S.E. part of Orenda Reservation, in the rate of New York, inhabited by about 300 Indians, who some years ago removed from Stockbridge, in Massachusetts, and from this circumstance are called the "Stockbridge Indians." They are an industrious people; and are employed in agriculture, and in breeding of cattle and swine.

Stockdale's Harbour, a bay of the North Pacific ocean, in Prince William's Sound, on the W. coast of America. N. lat. 60° 50'. W. long. 148°

Stockdorf, a town of Sweden, in the province of Smaland; 54 miles N.W. of Calmar.

Stockem, a town of France, in the department of the Lower Meuse, situated on the W. side of the Meuse; 12 miles N. of Maestricht. N. lat. 51° 10'. E. long. 5° 45'.

Stockler, in Ichthyology, a name given by the Germans to the sarrus of the ancients, the trachurus of the later writers. It is a species of the family, known among us under the name of horse-mackerel.

Stockerau, in Geography, a town of Austria, on the left bank of the Danube; 12 miles S. of Sommenberg.

Stockery, a town of Sweden, in the province of Smaland; 28 miles N.N.W. of Wexio.

Stockheim, a town of the duchy of Wurzburg; 2 miles N. of Neufadt.

Stockheim, Froben, a town of the duchy of Wurzburg; 4 miles E. of Kitzingen.

Stockheim, Main, a town of the duchy of Wurzburg; 2 miles N. of Gerolzhofen.

Stockheim, Tiefen, a town of the duchy of Wurzburg; 6 miles E.S.E. of Kitzingen.

Stockholm, the capital of Sweden, is said to have been founded by Birger Jarl, regent of the kingdom, about the middle of the 13th century, during the minority of his son Waldemar, who had been raised to the throne by the flates of the kingdom; but the count and royal residence were not removed hitherto from Upsal before the 17th century. The situation of this city is singularly distinguished by its romantic scenery. This capital, which is long and irregular, occupies, besides two peninsulas, seven small rocky islands, scattered in the Maler, in the streams which issue from that lake, and in a bay of the Baltic. The harbour is an inlet of the Baltic; the water of which is so deep, that ships of the largest burthen can approach the quay, which is of considerable breadth, and lined with spacious buildings and warehouses. At the extremity of the harbour, several streets rise one above another, in the form of an amphitheatre; and the palace, which is a magnificent building, crowns the summit. Towards the sea, about two or three miles from the town, the harbour is contracted into a narrow strait, and winding among high rocks, disappears from the sight; the prospect is terminated by distant hills, overspread with forests. The central island, from which the town derives its name, and the Niddarholm, are the handomest parts of the town. Excepting the suburbs, where several houses are constructed of wood, painted red, the buildings are generally of stone, or brick stained white, mostly erected on piles. The palace, situated in the centre of Stockholm, and on the highest point of ground, was begun by Charles XI., and is a large quadrangular stone edifice, the style of architecture being both elegant and magnificent. From an eminence in the fourth suburbs, called the "Mount of Moles," the spectator commands a bird's-eye view, almost unparalleled in its kind, of the city and various islands, of the harbour, the channel, and the lake Maler, forming an affluence of rocks, houses, wood, ships, and water, in all the variety of rugged, beautiful, and romantic scenery. The several parts of Stockholm communicate with one another by 12 bridges.
bridges. The arsenal of Stockholm contains an immense number of standards and trophies, chiefly taken from the Imperialists, Poles, Russians, and Danes. The manufactures of this city are of glafs, china, wood, silk, linen, &c.; and the number of its inhabitants is estimated, by the latest accounts, at about 80,000. For an account of its academies, see Academy; and of its bank, see Bank. For other particulars, see Sweden. N. lat. 59° 20'. E. long. 17° 40'.

STOCKHORN, a mountain of Switzerland, in the canton of Berne, the height of which is estimated at 7218 English feet.

STOCKING, in Rural Economy, an improper practice with cow-jobbers, or dealers, confilling in obliging the cows to suffer the pans of retention twenty four, or sometimes forty-eight hours previous to sale, in order that they may have a great flow of milk in the udder. Such buyers, however, as know anything of cattle, are fully aware of the custom, and consequently avoid the deception. The idea of any knowledge of the animal being more favourable for the purpose of milking, when obtained in this state, is highly ridiculous; as there are other better rules of judging, and which are familiar to every experienced flock-farmer. Many cows get inflamed and even indurated udders by such means. This unnatural practice ought of course to be generally reprobated and put an end to, as being productive of much mischief to these animals.

STOCKING OF FARMS, &c. in Agriculture, the means of first supplying and providing them with all the different forts of appropriate flock, according to their several natures and kinds, both of the living and dead forts, and of afterwards keeping them properly up, so as that all the necessary operations and management of the whole may be carried on in the most full, proper, suitable, and advantageous manner. It comprehends the providing of all the various descriptions of domestic animals for carrying on the work, as well as for keeping, fellowing, or feeding off in the view of profit; and of the numerous tools, implements, machinery and carriages, as well as all other contrivances and things, which are requisite and proper in the husbandry. It is a matter which the farmer should neatly attend to and adjust, as much depends upon these several different kinds of flock being well fitted, suited, and adapted to the nature, size, rate, situation, kind, and quality of the farms, whatever they may be, otherwise great inconvenience, loss, and disappointment, may be experienced.

In addition to what has been laid on hiring and flocking of farms, under the proper head Farm, in speaking of and considering their general nature and management in these and different other respects, it will only be necessary to observe, that the farmer should seldom or never, on any account whatever, engage for more land as a farm, than what he has capital fully at command for flocking, managing, and carrying on with proper spirit, and in the belt, most proper, and most beneficial manner; that he should, as seldom as possible, divert any of such capital from these its proper objects, to speculations of other kinds; and that he should never, in any material way, neglect the supplying of the different necessary forts of flock, as they may become wanted on the farm, in the most suitable and appropriate kinds and quantities, as to their nature and extent, as well as the time of providing them. The improved methods of cultivation and farming in general, and the increased expenses of it, as well as the higher prices of tools, labour, and wages, and the vastly augmented rate of taxation, render the charge of flocking in different kinds of farms, with all the different kinds of flock, moily double, often treble, and in some cases nearly quadruple as much as it was twenty-five or thirty years ago. This should, of course, be constantly well considered and attended to by the farmer, before hiring and flocking any farm which he may be about to enter upon. See Farm.

In regard to flocking different forts and qualities of land with different kinds of live-flock, in the view of keeping them merely, or those of feeding and fattening the animals, in any other intention, it may just be noticed, that, for the most part, probably the best method is to run them neither too thickly nor too thinly upon the lands, but so as to have them constantly, without being either too full or too delitute of keep, no food being wasted or flock injured in either case, as there may be impropriety and loss in having the grounds too closely, heavily, or hard flockcd, as well as in having them too thinly or lightly supplied with animals; though hard or heavy flocking may be necessary and useful in particular cases, circumstances, and situations, and with some particular kinds of flock. The difference, however, between these two modes of flocking, has not yet been well decided upon; for though some farmers are of opinion, and strongly contend, that light flocking is less hurtful to the land than clofe feeding, which renders it not so productive, by its not having such a length, or so much herbage upon it in the hot season, during the summer months; that a full bite of palfline is preferable, especially for some forts of flock, which do well where there is a good portion of keep upon the land; that allowing the land to be well covered with herbage in the spring season, it is useful in promoting its growth in the summer, and by keeping it from the effects of the heat at that dry hot period; that it admits of the feeding of the gristles on thin poor lands, which renders them more strong, and the land more productive of herbage; and that the animals, where there is a full bite on the land, more quickly fill themselves, chew their cud more frequently, and, of course, feed or fatten more expeditiously; others, on the contrary, equally contend, that it is well known there are two modes of flocking which flave the animals, especially some forts, as those of sheep, which are those of flocking too hard, and too lightly; that in close flocking or feeding, times and seasons are to be confulted and fixed upon; continual hard flocking at some periods may be injurious to the increase of the herbage of the land, as well as encourage the growth of plants of the mofs kind, while occasionally hard or clofe flocking, and not flocking at all, at short intervals, will prove more beneficial; that there is not so much waste of food in clofe flocking, as by under-flockling, and the lands are more regularly fed down; that the young sprouts or shoots of gristles are more nutrient, and more powerful in fattening flock, especially of some forts, while short than when long; that where lands are suffered, from light flocking, to become too luxuriant in their herbage in the spring season, feed-items are thrown up, to the injury and mischief of the fertility of them; but where clofe-flockling, and feed-items are prevented from rising, there will be a greater retention of vegetable matter in the soil for the production of new sprouts and shoots; and that flock, especially of some forts, are not found to lie down and rest themselves more often in lands which have much keep, from being lightly flockcd, than in those which are hard flockcd, and closely fed down; while they constantly prefer those parts which are in a clofe state of herbage, and become fat more quickly on it than where there is a great length of coarse rank herbage. In fact, the examination of the lands of those who are the most frequents for light flocking, does not
not prove that their flock is in any way superior, or carried on better, or fattened more quickly, than those in the same vicinity, which flock clover, or in a heavier manner.

In the busines of stocking lands with live-flock, it consequently seems, that their nature, quality, present state, and different proportions of different sorts, as well as the readiness of markets, and means of procuring and providing different sorts of flock, should be well and fully considered. — also, the expenses of carrying the business on, and management with respect to them in all ways, the loaves that are attending the lands, and the advantages and disadvantages of different seafons in regard to them. The plans and methods of stocking for different purposes and seafons may thus be properly determined upon and adjusted, especially where the nature of flock, and the land on which it is to be fed, are sufficiently understood.

Stocking-up, in Rural Economy, a term signifying to grab up or eradicate any thing, as trees, hedges, woods, and other lich similar matters. The work is mostly performed by means of the spade and mattock in different ways, according to its nature.

Stocking Island, in Geography, one of the Bahamas, about 15 miles long and 3 broad. N. lat. 23° 30'. W. long. 76° 20'.

Stockings, the clothing of the leg and foot, which immediately cover and screen them from the rigour of the cold.

Anciently, the only stockings in use were made of cloth, or of milled fluffs sewed together; but since the invention of knitting and weaving stockings of silk, wool, cotton, thread, &c. the use of cloth stockings is quite discontinued.

Mozesfays that Henry II. of France was the first who wore silk stockings at his sister's wedding to the duke of Savoy, in 1559.

Dr. Howell, in his History of the World (vol. ii. p. 322.) relates, that queen Elizabeth, in 1561, was presented with a pair of black silk silk stockings, by her silk-woman, Mrs. Montague, and thenceforth she never wore cloth ones any more. The fame author adds, that king Henry VIII. ordinarily wore cloth hose, except there came from Spain, by great chance, a pair of silk stockings. His son, king Edward VI., was presented with a pair of long Spanish silk stockings by sir Thomas Grefham, and the present was then much taken notice of. Hence it should seem, that the invention of knit stocking originally came from Spain.

How early the invention of knitting was taken up in Spain does not appear; but though it existed there in the time of Henry VIII., who died in 1547, yet it was not practised in England till the third year of queen Elizabeth, vis. 1561.

Others relate, that one William Rider, an apprentice on London bridge, seeing at the house of an Italian merchant a pair of knit worlled stockings, from Mantua, took the hint, and made a pair exactly like them, which he presented to William, earl of Pembroke, and that they were the first of that kind wore in England, anno 1564. Anderdon's Hist. Com. vol. i. p. 40c.

The modern stockings, whether woven or knit, are a kind of plexus formed of an infinite number of little knots, called stitches, loops, or meshes, intermingling in one another.

Stockings, Knit, are wrought with needles made of polished iron, or brass-wire, which interweave the threads, and form the meshes of which the stocking consists.

This operation is called knitting, the invention of which...
the number of workmen so much increased, that they petitioned the Protector to constitute them a body corporate, but their request was refused. King Charles II. in 1663, granted them a charter, extending their jurisdiction to ten miles round London. See Company.

Such is the account given of this invention by Dr. Deerling in his Hist. of Nottingham, p. 100, who has also described the stocking-frame, and exhibited several figures of this machine, and of the numerous parts of which it consists.

The frame-work knitters or stocking-weavers hall is situated in Red-Cross street. They were incorporated 19th August, 1663.

In this hall is the portrait of the author of this ingenious art, pointing to one of the iron frames, and disengorging with a woman who is knitting with needles and her fingers. These words are on the picture: "In the year 1589, the ingenious William Lee, A.M. of St. John's college, Cambridge, devised this profitable art for stockings, (but being defiled went to France,) yet of iron to himself, but to us and to others of gold, in memory of whom this is here painted." Hatton's View of London, vol. ii. 605.

Yet Dr. Howell in his History of the World (vol. ii. p. 222.), makes this invention eleven years later, viz. anno 1600; and adds, that Mr. Lee not only taught this art in England and France, but his servants did the same in Spain, Venice, and in Ireland.

Mr. Lee's invention was made about twenty-eight years after we had first learned from Spain the method of knitting stockings by wires and needles; it has proved a very considerable benefit to the stocking manufacture, by enabling England to export vast quantities of silk stockings to Italy, &c. where, it seems, says Anderson (Hist. Com. vol. i. p. 435.) by Sir Joshua Child's excellent Difcours on Trade, first published in 1670, they had not then got the use of the stocking-frame, though not much less than one hundred years after its invention.

A late writer in the Bibliotheca Topographica Britannica, N. 7, says that Mr. Lee, after some years' residence in France, received an invitation to return to England, which he accepted, and that thus the art of frame-work knitting became famous in this country. This account of the invention, he adds, is most generally received, though it has also been attributed to a Mr. Robinson, curate of Thurcaston, in Leicestershire. The first frame, we are told, was brought into Hinckley, in Leicestershire, before the year 1640, by William Iliffe; and now the manufacture of this town is so extensive, that a larger quantity of hose, of low price, in cotton, thread, and worsted, is supposed to be made there, than in any town in England. The manufacture has since employed about two thousand five hundred and eighty-five working people; the number of frames has been computed at about one thousand, and there have been also about two hundred in the neighbouring villages. The towns of Leicester, Longborough, Nottingham, and Derby, with the villages in their dependencies, are the principal seats of the stocking manufacture in England.

About the year 1756, Messrs. Jedidiah Strut and William Woollatt, of Derby, invented a machine, by which, when annexed to the stocking-frame, the turned ribbed stockings are made the fame with those made upon the common knitting-pins: this is known by the name of the Derby rib. These, together with the manner of making the open-work mills, in imitation of the French mills, a curious sort of lace for caps, aprons, and handkerchiefs, as well as a great variety of figured goods for waistcoats, &c. have sprung from the same machine, and form a considerable additional branch of the stocking-trade.

Stocking-frame, a most ingenious machine for weaving or knitting of stockings. To comprehend the action of this machine, which is extremely complicated, it is first necessary to have a perfect idea of the nature of the fabric which is produced by it: this is totally difficult from cloth woven by a loom, as the flighthel inspection will shew; for instead of having two distinct systems of threads, like the warp and the weft, which are woven together, by crossing each other at right angles, the whole piece is composed of a single thread, united or looped together in a peculiar manner, which is called stocking-fitch, and sometimes chain-work.

This is best explained by the view in fig. 1. Plate Stocking-frame. A single thread is formed into a number of loops or waves, by arranging it over a number of parallel needles, as shown at R; these are retained or kept in the form of loops or waves, by being drawn or looped through similar loops or waves formed by the thread of the preceding course of the work, S. The fabric thus formed by the union of a number of loops is easily unravelled, because the stability of the whole piece depends upon the ultimate falling off the first end of the thread; and if this is undone, the loops formed by that end will open, and release the subfluent loops one at a time, until the whole is unravelled, and drawn out into the single thread from which it was made. In the same manner, if the thread in a stocking piece falls or breaks at any part, or drops a fitch, as it is called, it immediately produces a hole, and the extension of the hole can only be prevented by falling off the end. It should be observed, that there are many different fabrics of stocking-fitch for various kinds of ornamental hosiery, and each requires a different kind of frame or machine to produce it; we should greatly exceed our limits to enter into a detailed description of them all. That species which we have represented in fig. 1. is the common stocking-fitch used for plain hosiery, and is formed by the machine called the common stocking-frame, which is the ground-work of all the others.

Fig. 2. is a perspective view of a common stocking-frame, exhibiting as many of its parts as can be seen in a general view. The bafs is a wooden frame, consisting of four pillars N, and various cross-pieces, called rafters; the two uppermost, M, are called caps; upon the top of these the small parts of the machine are situated, being fastened in a frame of wrought iron. The pieces which compose the iron frame are two fol-e-bars a, which are ferewed down upon the wooden caps M, and at the ends have joints, g, to support the prefser-bows G, G, of which we shall soon have occasion to speak. At the back are two vertical standards, V, called the back standards, which support the axis T. These standards are united by back cross-bars, which are clearly seen in the figure near V. There are likewise two front standards W, erected from the fol-e-bars a, a.

To give motion to this machine, the workman leats himself before it, upon a board or seat A, and puts the different parts of the machine in motion by his hands and feet: he applies his feet upon two treads B, C, which have cords, b, c, ascending from them, and falling in opposite directions round a barrel or wheel, upon the axis of which is a large wheel, D, called the flart-wheel. By alternately pressing down one treadle, and allowing the other to rise, he can turn this wheel round in either direction at pleasure. The object of this movement will be described hereafter. There is likewise a third treadle, E, upon which he presses his foot, when he wishes to bring down what is called the prefser-bar, marked F, the use of which will be afterwards explained. This bar is attached to two small rods G, which the fabric able round the fixed centre pins or joints g. The ends of the levers are of a curved form; hence the pieces G are called
STOCKING-FRAME.

The connection with the treadle \( E \) is by a 
fling or wire \( r \), which works behind the machine, and is 
attached to the cross-bar \( H \), which is extended from one of 
the presser-bars to the other, and is cranked down, to avoid 
such parts of the machine as it would otherwise interfere 
in its motion. The return of the presser and middle treadle, \( E \), 
is produced by the re-action of the wooden spring \( I \), which 
draws it up with two flings; but in some frames a counter-
weight is used instead of the spring.

The weaver produces all the other movements by his 
hand; for this purpose, he applies them to the ends 
\( K, K \), of the hand-bar, and he can then very conveniently 
use his thumbs upon the thumb-plates \( L, L \). By drawing 
forward or lifting up the hand-bar \( K \), and at the same time 
pressing upon the thumb-plates \( L \), or relieving them, he gives 
the requisite motions to what is called the frame of finkers, 
or simply the frame, because it contains the principal works 
of the machine. The thread of which the flocking is to be 
made is kept upon a bobbin \( M \), stuck upon a pin in 
the front upright, \( N \), of the frame, and the thread from this 
is carried upon the needles; and when it is woven into the 
flocking piece by the action of the needles and finkers, the 
piece hangs down at \( S \), and is received upon a small roller 
fixed in an iron frame \( p \), called the web, which is made suf-
ficiently heavy to stretch the piece to a moderate tension.

As an introduction to a description of the whole machine, 
it will be proper to give the reader an idea of those parts which 
operate upon the thread, and of the motions which are 
given to them to produce the loops or meshes. These parts 
are the needles, the frame of finkers, and the presser-bar: 
the needles are stationary, the rest moveable.

Fig. 1. represents what are called the needles: these 
are made of iron-wire, of the shape represented, and are hooked 
or barbed at the ends, the returned points of the hooks or 
barbs being made very delicate. There is a small cavity or 
groove punched or fink in the stem of the needle, imme-
diately beneath the barb, of sufficient depth to receive 
the point, when an adequate preasure is applied upon the 
hook to bend the barb down. The barb then becomes a 
closed eye; and if a thread is looped over the wire or stem 
of the needle, and drawn forwards while the barb is thus 
closed, it will draw over the barb of the needle, and come 
off at the end of it: but if the thread is drawn forwards 
whilst the barb is open, it will be caught under the hook, 
and be thus detained, as shown at \( R \). This circumstance 
must be particularly attended to, as the principal action 
of the machine depends upon it. The deprefion of the 
barbs of the needles is produced by the edge of the 
presser-bar \( F \), which is extended horizontally over the whole 
length of the needles, and actuated by prefling the foot on 
the middle treadle, as before explained.

Between every two adjacent needles, 1, 1, a thin plate of 
fluel, 2, 3, is placed: these plates are called finkers; they 
are formed to a particular shape (as shown in fig. 4.), 
and are capable of being elevated or deprefed, and also of 
being drawn backwards or forwards between the needles. 
These motions are given by the hands of the weaver, as the 
hand-bar \( K \), which he holds, is part of the frame containing 
the jacks and finkers. The finker-frame consists of the 
hand-bar \( K \) (fig. 2 and 4.), extending across it at the bottom; 
the hanging cheeks \( O, O \), which form the upright sides of 
the frame; and the upper bar \( P \), which is called the finker-
bar, because the finkers are fixed to it, being united for-
ward, and not far from each other, being united fore-
ward, and not far from each other, which are 
cast round the ends of the finkers, and fastened by screws 
to the bar \( P \).

To allow the frame of finkers to have the motions of 
which we have spoken, it is suspended by joints at the top 
of the hanging-cheeks, called the top joints: these joints 
are formed at the ends of the two arms \( Y, Y \), which are 
two horizontal levers fixed to an axis \( T \), called the spindle-
bar: the extremities of this turn on pivots, supported by the 
upper end: of iron uprights \( V \), called the back standards. 
By the motion of the spindle-bar upon its centres, the 
frame of finkers can rise and fall, and the quantity of this 
motion is limited by stop-fersews applied to the vertical 
standards \( W \). To draw the finkers forward between the 
needles, the finker-frame can be inclined upon the top 
joints of the hanging-cheeks, by drawing forwards the hand-
bar \( K \). From the middle of the spindle-bar, \( T \), a short 
lever projects, which is borne upwards by a spring, \( Y \), 
called the main-spring: this is supported by a piece which 
projects from the fixed cross-bar of the frame, and is of 
sufficient force to bear the frame of finkers upward, and 
give the top arms, \( Q, Q \), a tendency to rest always against 
the upper stop-fersews, \( X \), of the standards \( W \).

The hooked part or nips \( f \) (fig. 4.) of the finkers, are 
for the purpose of forming loops in the thread between the 
needles. To effect this, the nips \( f \), of the jacks and finkers 
are raised above the level of the needles, as in fig. 4., and 
the thread is extended across all the needles, immediately 
below the nips. If then the jacks and finkers are all deprefed 
down between the needles, it is evident that the nips of 
the finkers must carry the thread down before them, and form 
the circles into loops hanging down between each needle, as shown 
at \( X \). This, then, is the principal office of the finkers: but 
to perform the operation of spinning in the manner now de-
scribed, by depreffing the whole number at once, would not 
be practicable; because, as a greater length of thread is 
required when it is deprefded into loops, than when it lies 
straight across the needles, it would require to draw the 
thread all at once from the bobbin \( M \) (fig. 2.), in sufficient 
quantity to make up the difference; to do which, the thread 
must slide or draw beneath the nips and the needles, 
which it could not do, on account of the friction.

The contrivance to render this depreffion or looping down 
of the thread between each needle practicable is very in-
agenious. The row of finkers shown in fig. 4., is composed 
of two kinds, called jack-finkers and lead-finkers, which 
are very different in their movements, although we have hi-
therto spoken of them as one. The lead-finkers are all 
those of which we have spoken as being fastened to one bar 
\( P \), called the finker-bar, which is part of the finker-frame, 
and which the workman moves by his hands: on this account, 
the lead-finkers all move together; they are one half of 
the whole number, and are disfipèd between every other needle, 
so that the space between each lead-finker has two needles 
in it. The back-finkers are made of the same form as the 
lead-finkers, one being placed between each of the two 
needles contained between each lead-finker; therefore the 
lead-finkers and jack-finkers are disfipèd alternately to form 
a row, and a needle is placed in every space in the whole 
row.

Each jack-finker is supported by a small lever, \( b \), 
(fig. 3.) called a jack, freely movable on a centre-pin: 
the opposite end \( i \), or tail of each jack, is preflèd by a 
spring \( k \), which has a notch or indentation at a particular 
place; and when the jack-finker is elevated, so that its nip, 
\( f \), is above the level of the needles \( t \), ready to receive the 
thread, the end of the tail, \( i \), is received in the notch of the 
spring \( k \), which retains it in that position; but at the same time a flight 
force applied beneath the tail, \( i \), or for jack to lift, it up will 
dercape the nip, \( f \), of the jack-finker, \( V \), between the needles.

It is to be understood, that all the jacks, \( b \), are arranged in a 
row, and move upon one wire, which is a common centre of 
motion;
STOCKING-FRAME.

The operation of finking or forming the loops between the needles is thus conducted: the nips of all the finkers are raised above the needles, as in fig. 4; the thread is then extended lightly across the flur-wheel, between the nips. By precribing on one of the treadsles, B or C, the flur-wheel is made to turn round, and this, by the flur-line, draws the flur, m, from one end of the flur-bar, l, to the other. In its passage it encounters the tails, i, of the jack, and lifts them up one by one, which at the same time depresses the corresponding jack-finker 3; and its nip, j, links the thread between the needles, and forms a loop. As these loops are formed successively, the thread draws easily beneath the nip to produce each single loop, and the workman allows the threads to draw off from the bobbin, M, through his fingers, as fast as it is required. When all the jack-finkers are depressed, a loop of the thread will be formed between every other pair of needles. The workman then depresses the lead-finkers, 4, by pulling down the hand-bar K, and their nips carry down the thread between the remaining needles in loops, in the intermediate spaces between the former loops: in doing this, he causes the jack-finkers, 4, to rise up, as much as he depresses the lead-finkers 3; because it should have been mentioned before, that the first loops formed by the jack-finkers were double the depth intended, although only half the number: by this means they contained the proper quantity of thread to form the whole number of loops; viz. one between every two adjacent needles.

The lead-finkers are caused to rise up by means of the locker-bar, p, extending over all the treadsles. Each end of this bar is screwed to a lever, g, called a locker, which moves upon the same centre as the jacks, and the front ends of these levers are made with inclined ends, so as to be lifted up by wedges fixed at the back of the thumb-plates, L, which move on joints fixed to the finker-bar, and hang down in a convenient situation to be acted upon by the thumbs of each hand, when holding the ends of the hand-bar K. The weaver, therefore, preffes back the two thumb-plates L, at the same time that he depresses the hand-bar, K, of the frame containing the lead-finkers; by which means he produces the ascent of the jack-finkers, in an equal degree to the descent of the lead-finkers, until the nips of the two arrange exactly in one line, which position is determined by proper loops attached to the finker-frame. By this means, a complete row of loops is formed, one loop between each needle.

These loops are now to be carried backwards upon the needles, into the position of S, fig. 1, so as to occupy the arch or opening, z, of the finkers, which open part is made purposely to admit the loops last made to remain upon the items of the needles, quite detached from the action of the finkers, which are at liberty to form a new course of loops by the nips, f, of their points, t.

If we suppose the frame has been before at work, the loops last formed, which hang upon the items of the needles, will not be a single thread, but the loops at the upper part of the work S, fig. 2: it is only when the frame first begins to work that the loops will be a detached thread, as we have just described.

But it remains to shew how the loops are put back upon the needles: this is done by merely lifting up the hand-bar K, till the points, t, of the finkers rise above the needles: the hand-bar is then drawn forwards a little, to advance the finkers so much, that the points t, which were behind the loops of thread upon the needles, will now come before them, and then the hands are depressed, to infert the points, t, between the needles again before the threads; and by pulling back the hand-bar, the points, t, carry back the work upon the items of the needles, so that it will be situated in the arch, or opening, z, of the finkers.

When the finkers advance or recede, they must all move together both the lead-finkers and jack-finkers, as if they were one. It is clear that there is no impediment to the moving forwards of the lead-finkers, because they are at liberty to incline or swing forwards upon the joints at the tops of the hanging-checks, O, O, which suspend the frame containing them: but for the jack-finkers to advance at the same time, it is necessary to bring forward the jacks, and their centre of motion, together with the springs and flur-bar. To admit of this motion, all these parts are framed upon a strong bar called the camel; and upon this is placed four wheels, which run upon the sole-bars, as to become a carriage. To communicate motion to this carriage, a link is jointed to a piece at each end, marked r, fig. 2 or 4, which is screwed to the finker-bar P, just within the thumb-plates L. These links are jointed at the other ends to the common centre of motion of the jacks. The joints of the pieces, r, are so adjusted, that they will exactly line with the joints which unite the jacks and jack-finkers together; and the links are the same length between the centres of the jacks, for which reason they are called half-jacks.

By means of this connection, the carriage, with all its appendages, viz. the jacks, with their springs and the flur-bar, are drawn forwards at the same time that the finker-frame is drawn forwards, by pulling the hand-bar K; or, by a contrary movement, the loops of threads which were last formed upon the needles, will be carried back from the hooks or beards of the needles upon their items, as shewn at S, fig. 1, so as to be in the arch, z, of the finkers, as before described.

The first row of loops being thus difposed of, the frame of finkers is restored to its former position, and a second row is formed upon the items of the needles by a repetition of the same process, viz. extending the thread across the needles beneath the nips, f, of the finkers; moving the flur by the two outside treadsles B, C, which depresses all the jack-finkers, and makes a loop of double depth between every other pair of needles; this is called drawing the jack: next precribing on the thumb-plates L, and depressing the hand-bar, K, at the same time, which elevates the jack-finkers, and depressing the lead-finkers by one movement, and produces a loop of thread between every two adjacent needles. Another complete row of loops is now formed upon the items of the needles; and this row is to be brought forwards, so as to be under the beards or hooks of the needles, in the manner shewn by R, fig. 1. This is produced by simply drawing forwards the hand-bar K, which

Vol. XXXIV.
which advances all the finkers together, and their points, \( t \), pull forwards the thread till it comes into the beards, and these prevent it from coming off the needles.

The next operation is lifting up the hand-bar and frame of finkers as much as will raise their points, \( t \), quite clear up above the needles between which they were situated, and applying the foot to the upper treads, \( E \), to bring down the pruffling-bar, \( F \), upon the beards of the needles, to close them up, and while so closed, they hold the loops of thread at \( R \), as if they were looped through the eyes of as many needles.

The upper loops of the works which are at \( S \), fig. 1, upon the items of the needles, in the arch, \( s \), of the finkers, are next brought forward upon the needles, by drawing forwards the frame of finkers; but in advancing these loops, draw over the closed beards of the needles, and consequently over the lof;formed loops, which remain under the beards, in the position shown at \( R \), fig. 1; or, in other words, the loops last formed, and rising under the beards at \( R \), fig. 1, are drawn through the loops of the upper or half course of the finished work which remained upon the items of the needles, as represented at \( S \). By this means, the loops of what was the upper or last course of the finished work, become secured from opening or unravelling, and the loops under the beards now become the last or upper course of the work, and are preferred from unravelling by the needles, one of which palls through each loop; and these loops will not be drawn off from the needles until there is another row of loops prepared, and rized under the beards of the needles, ready to be drawn through them.

When the piece of work is finished, and taken off from the frame, the last row of loops must be secured by running a thread through them, or other means, or they would draw through the preceding loops, and release them, which in like manner would release their predecessors, and so the whole piece would unravel.

The motion of the frame of finkers, which produces the advance of the finkers towards the points of the needles, or their recession towards the item, takes place upon the centres, called the top joints \( a \), and the wheels of the carriage, as before mentioned. The quantity of motion is limited by a piece, fig. 7, called the arch, which is fixed fast against the inside of the wood-frame \( N \), fig. 2: a part of the hanging-checks \( O \), of the frame of finkers descends with a projecting part to act round this arch, which, at the same time that it limits the quantity of motion, prevents the motion being made, except in a proper succession, to produce the effects before described.

Thus, when the hook is beneath the arch, the points, \( s \), of the finkers will be beneath the level of the needles, and then the frame of finkers cannot be raised up without first moving the lower part of the frame either forwards or backwards.

In the same manner, when the hook is above the arch, the finkers cannot be depressed till they are moved. When the thread is first extended across the needles, in order to be funk into loops, the frame is said to be over the arch, that is, the hook is at the back, or on the farther side of the arch, and by applying thereto, the finkers are guided in their sinking, that is, when they descend, they depress the thread to form the loop. When this sinking has taken place, the finkers-frame will be at its lowest position, and the top arms, \( Q \), will rest upon the lower flop-screw of the standards \( W \). When the finkers are brought forwards, to draw the loops from the items of the needles into their beards or points, the hook of the frame moves along the under side of the arch, and this prevents the points lifting up, while the lower flop prevents them from sinking down; but when the finkers are brought sufficiently forwards, the frame is lifted or thrown up by the main-spring, the hook following the curvature of the arch, until the points are completely above the needles, or the frame has reached the upper flop. The finkers are then brought forwards upon their centre of motion, while the prefler is drawn down to close the beards of the needles and draw the loops over them; in doing which, the hook quits the arch, and the frame comes forwards without any guide, the same being unnecessary, because the elevation of the finkers is determined by the upper flop, again which the frame rises by the action of its main-spring; and the proper degree for the advance of the finkers is determined by the drawing forwards of the frame with sufficient force to draw the loops of the work tight: this force the workman must regulate by habit, so as make his work close.

In returning the frame of finkers, in order to put back the work upon the items of the needles, so as to be out of the way while a new row of loops is made, the hook, \( s \), must be carried back beneath the arch, which will keep down the points of the finkers, so as to prevent them from rising above the needles, as they would then quit the work they are intended to drive back upon the needles.

By the operation which we have described, one course of the work is formed; but, to render it more clear, we will continue the description, in a few words, of the working of another course. Preparatory to working it, the loops of the last course of the work, and by which the work is suspended from the needles, must be pushed back upon the items of the needles to the position \( S \), fig. 1, so as to come into the arched or open part \( s \), fig. 4, of the finkers: this is done by depressing the finkers low enough for their point, \( s \), to enter between the needles, and then pushing back the hand-bar and frame of the finkers to carry back the work upon the items of the needles. This is the situation in which we suppose the frame, when the operation commences; and the frame is over the arch.

The first movement is the gathering of thread. The thread laid over is lightly extended across the needles, beneath the nips, \( f \), of the finkers; and by depressing the slant-treadle \( j \), the jack-finkers are depressed one by one, so as to form double loops. This is called drawing the jacks.

The second movement is sinking. This is done by drawing down the hand-bar \( K \), and bearing upon the thumb-plates, \( L \), at the same time; the whole row of lead-finkers is thus depressed, whilst the jack-finkers rise, and the thread is carried down into a loop between every two needles.

The third movement is to bring the frame forwards under the arch. This is done by drawing the hand-bar forwards, and the row of loops just made is brought under the beards of the needles.

The fourth movement is to bring the work forwards from the items of the needles. To do this, the finkers-frame is lifted up, by elevating the hand-bar \( K \), so that the point, \( s \), of the finkers will be quite drawn out above the needles; and in this situation, the hand-bar and finkers-frame being brought forwards, the breast or curved part of the arch, \( s \), of the finker will bring forwards the piece of work which hangs upon the items of the needles, by its loops laid made.

The fifth movement is closing the work, or drawing the loops laid made, through the finished loops of the work. The slant-treadle \( E \), being borne upon at the same moment, will bring down the prefler, and it will bear upon the beards, and close them, while the loops are drawn forwards; consequently the loops of the old work will be drawn over the beards, and quite off from the needles; this draws the loops thereof over the loops laid made, which remain...
main in the beards of the needles. To draw the work tight, the hand-bar, \( K \), is drawn forwards two or three times with a slight jerk, so as to extend all the loops to their fullest quantity, and make the loops of the work unite closely.

The course is now finished; but as a preparation for making another course, the work must be carried back upon the frogs of the needles into the situation of \( S \), fig. 1. This is the sixth and last movement. To put back work, the frame is pulled down to bring the points of the finkers below the level of the needles; and in this position, by pressing back the hand-bar, and all the finkers together, the points, \( r \), will enter between the ends of the needles, and carry back the loops of the work upon the frogs of the needles, where it will remain in the arches of the finkers, so as to be detached from them, and out of the way, while a new set of loops is formed by the nips of the points of the finkers; and then the loops of the old work are to be drawn over those last made.

The movements are then repeated: 1st, gathering the thread upon the needles, and detaching it into large loops between every two needles, by the motion of the feet; 2d, finking, to make the loops between all the needles; 3d, bringing the thread under the beards of the needles; 4th, bringing the work forwards from the frogs of the needles towards the beards; 5th, closing the beards by the pressure of the prelfer-bar, and drawing the work over the beards; and, 6th, putting the work back on the needles, ready for working another course.

The operation of the machine proceeds in the manner deferred; and as fast as the courses are completed, the work descends lower, and hangs down in a web from the needles. When the piece is of a considerable length, it is rolled upon a roller, in an iron frame, called the web, and the weight of the frame is sufficient to keep the piece to a proper tension. The roller in the web can be turned round occasionally to wind up the piece, and it is retained by a ratchet-wheel and click.

Having given an idea of the manner of the operation of this curious machine, it only remains to explain the adjustments with which it is provided, in order to make it work correctly.

The fineness of the work depends on the number of loops which the thread will make in any given length, and this will be equal to the number of needles and finkers in the same space. The number of needles in an inch is called the gauge of the frame, and they vary from 15 to 40, which latter are used for the finest firkings. The gauge of a frame cannot be altered when it is once made, and the work which it will produce must always be of the same degree of fineness, although it may be made a little more dense or more loose by drawing the loops very close, or by allowing a greater quantity of thread, and making the loops longer. This circumstance will evidently depend upon the depth to which the nips of the finkers descend beneath the needles, when they carry down the thread into loops. To regulate this depth, the needle-bar, or that piece which sustains the heads containing the row of needles, is made to rise or fall a flight quantity, by means of two long adjusting screws, the heads of which are made with notches, and springs fall into them to keep the screws from turning back; these heads are called the firs, and the notches nicks: one is marked \( g \), in fig. 2 and 3.

The motion allowed to the frame of finkers is limited, as before-mentioned, by stops projecting from the two upper right standards, \( W \); and through these stops, firk-screws, \( y \), are fitted, to regulate the degree of ascent and descent. The main-spring, \( y \), is made of sufficient strength to lift the weight of the frame of finkers, and make them always rise up as high as the upper firk-screws will permit.

The manner of making different parts of the flocking-frame is worthy of notice. The needles are made of iron-wire, of a proper degree of fineness: it must be of good quality, as that is liable to split or splinter, either in filing, punching, or bending, is totally unfit for the purpose. The wire is cut to lengths, and annealed or softened in a box of charcoal, in which they are heated to redness, and suffered to cool gradually. The needles are next punched with the small cavity which is necessary to receive the point of the firs: this is done by a simple screw-press. The point of the needle is next formed by the file and burnisher, and the hooks are then bent to form the bars: next the needles are flattened, each with a blow of the hammer. To fallen these needles together, and fix them in the machine, they are placed parallel to each other in a mould or frame, and tin or pewter poured into the mould, round the flattened ends of the needles. The piece of lead or pewter is just an inch in width, and the number of needles which it will contain, gives the denomination to the gauge of the frame. These leads of needles are fastened to the needle-bar by a loop through each. The leads of finkers are made of steel-plates, which are put together by calling lead round them at the upper ends, in the same manner as the needles. The rack or piece, which contains the centre of the jacks, is called the comb, because it is composed of a number of small plates, fixed into a bar by casting them with lead or tin.

The flocking-frame has undergone very few alterations since its first invention, a circumstance highly creditable to the genius of the inventor. A flocking-frame for weaving the tartan plaid hose which is worn in Scotland, is described in the Society of Arts Transactions, vol. xxix. p. 84: it contains some additions invented by Mr. John Robertson.

STOCKPORT, in Geography, a town of Saxony, in the Vogtland; 3 miles S.E. of Plauen. — Alto, a town of the duchy of Wurzburg; 3 miles S. of Königshofen in der Grabfeld.

STOCKPORT, anciently written Stockeport and Stocport, a town in the hundred and deanery of Macclesfield, is feated 175 miles from London, on the banks of the river Mersey, partly in Cheshire and partly in Lancashire. The part of the town in the latter county is called Heaston-Norris, and is united to the Cheshire part by a bridge. In 1811 it contained 859 houses, and 5232 inhabitants: whilst the remaining portion of Stockport contained 3326 houses, and 17,545 inhabitants. The population of the town and its neighbourhood is chiefly employed in various branches of the cotton manufacture. According to Melish, Lysons's Statement in 1810, there were then 25 factories for cotton goods, one silk-mill, and several establishments for the making of muslins. The parish of Stockport contains fourteen townships, viz. Stockport, Bramhall, Bredbury, Bresford, Didsbury, Withington, Eccles or Stockport-Eccles, Hyde, Marple, Norbury, Offerton, Romiley, Torkington, and Withington. These are all populous, and appear chiefly to have been parts of baronies and manors; and there yet remains in some of them, armorial or architectural relics of their antiquity.

In the time of Edward I., Robert de Stockepour, Earl of Chester, made Stockport a free borough. In 1260 he also obtained a grant of a market, and an annual fair: at present there are four of the latter, and the former continues Friday and Saturday. Although there he no charter extant, yet a mayor is annually elected, or rather nominated, at the lord of the manor's court. Soon after the Norman conquest, the manor of Stockport belonged to the De La Speencers.
it is now the property of lord Viscount Balkeley, in right of his lady. In the year 1773, the castle of this place was held by Geoffrey de Calvente against king Henry II. It afterwards belonged to the Stockports, and subsequently to the earls of Warren; but the whole has been long since demolished. During the civil wars in Charles I.'s reign, Stockport was garrisoned by the parliament's army, and was considered an important post. In May, 1644, Prince Rupert appeared before it with his army; the garrison, to the number of 3000, drew out to oppose him, but were repulsed, and the town taken. In 1745, Stockport bridge was blown up, to prevent the retreat of the rebels after their advance to Derby.

The places of religious worship at Stockport are, the parish church of St. Mary, which, from the style of its architecture, appears to have been erected about the 14th century; the chapel of St. Peter, built and endowed, in 1568, by William Wright, esq.; a meeting-house for Presbyterians; another for Quakers; and several for Methodists. Near the town is a chapel for Roman Catholics, many persons of that persuasion, emigrated from Ireland, being resident here. The chief public institutions are, a free-school, founded, in 1487, by Sir Edmund Shaw; an almshouse, endowed, in 1659, by Edward Warren, esq.; a dispensary, on a very enlarged plan, established in 1792; and several Sunday schools, instituted in 1714; one of which, conducted chiefly by the Methodists, is supported on such an extensive scale, that three thousand children are now educated in it wholly by gratuitous teachers; a large school-house was erected by subscription in 1805. — Lysons's Magna Britannia, Cheshire, 4to. 1810. Beauties of England and Wales, vol. ii. 8vo. by J. Britton and E. Bracey.

Stockport, a town, or rather village, of America, in the state of Pennsylvania, and county of Northampton, on the W. side of the Popanunk branch of Delaware river; from which is a portage of about 18 miles to Harmony, on the E. branch of the Susquehannah river.

Stocks, in Gardening, such young trees as are raised from seed, suckers, layers, or cuttings, and designed for the reception of grafts and buds of other trees, to continue them the same and become trees in every respect like the parent trees from which they were taken. Stocks for general use are proper, when from the size of a good large goose-quill to half an inch, or not more than an inch thick in the part where the graft, &c. is to be inserted; but they are sometimes used when two or three inches in diameter: these are made of in mottled kind of fruit-trees, and occasionally for some varieties of forest and ornamental trees, and many of the shrub kind: they should in general be specie, or varieties of the same genus as the trees with which they are to be engrafted.

They are usually divided into three kinds: as crab stocks, free stocks, and dwarf stocks, each comprehending various sorts, both of the same and different genera, species, and varieties.

Crab Stocks.—These are all such as are raised from seeds, &c. of any natural or ungrafted trees, particularly of the fruit-tree kind; such as the crab-apple of the woods and hedges, any kind of wild thorny uncultivated pears, plums, wild red and black cherry, &c.; and also of such trees as have been grafted or budded: some sorts, being strong suckers and hardy, are preferred, on which to graft particular species, to improve the size and duration of the trees; for example, apples are very commonly worked upon the common wild crab stock, and cherries on the great wild black and red cherry stock, as tending to promote a large, hardy, and durable growth, proper for common standards and the larger kinds of dwarf trees. In using crab stocks to graft any sorts of fruit-trees, it is proper to reject such of them as assume a very wild crab-like growth, or of a flinty, thorny nature, preferring those that are the freest clean growers: sometimes, however, the appellation of crab stocks is given to all stocks indiscriminately, before being grafted, whether raised from the seed, &c. of wild or cultivated trees, until worked with grafts or buds, but with the distinctions of wild crabs and free crabs.

Free Stocks.—This is a term commonly applied to such sorts as are raised from the kernels of the fruit, layers, &c. of any of the cultivated garden and orchard fruit-trees, and others, which often prove more free clean suckers than the wild crabs, and are more proper than they for grafting choice apples, pears, peaches, nectarines, apricots, and plums upon, to improve the growth of the trees and quality of the fruit.

Dwarf Stocks.—These are such sorts as are raised from low growing trees, of a shrub-like nature, or but very moderate tree-growth, being used for the lower and middling sorts of standards and to form dwarfs, either for walls or espaliers, or for dwarf standards in small gardens, and others occasionally for varieties, as well as for planting in forcing-frames, or to pot for forcing, or curiosity, &c. as the paradise apple and codlin stock, for dwarfing apples; the quince stock, for pears; the bird-cherry, morello, and small May cherry stock, for cherries; the baluce and mulice stock for dwarfing apricots, peaches, and nectarines, and sometimes dwarf-almond stocks for the latter, when designed to have these trees of a very dwarfish growth, either to pot for curiosity, or for forcing in small forcing-frames.

But the most dwarfish kinds are: the paradise stock, bird-cherry, black baluce, and dwarf-almond; but they are not so proper in general culture as common dwarf trees, as they never attain a large growth, sufficient to produce any considerable quantity of fruit: the codlin dwarf stocks, quince stock, morello cherry, and mulice-plum stocks, are proper for the middling or larger kinds of dwarf trees, either for walls or espaliers, or dwarf and half standards: they are all raised from suckers, layers, or cuttings.

Sorts of Stocks adapted to each Kind.—For apples, in all the kinds, they are those of their own sort, raised from the kernels of any of the cultivated apples or crab for common standards, and the larger kinds of dwarfs; but the wild crab stock is often esteemed preferable to the free stock, for its hardy and durable nature, on which to graft common standards; and sometimes used for espaliers: and for lower dwarfs, the codlin, Siberian crab, and paradise stocks are sometimes used; the former for middling dwarfs, and the latter for the smallest dwarfs: they are all easily raised, the free stock and the crabs from the kernels of the fruit; and the codlin and paradise stocks, likewise from suckers, layers, and cuttings. See Pyrus Malus.

But for the pear, it is chiefly grafted and budded on pear stocks for general use, but on quince for dwarfs; the former chiefly raised from the kernels of any sorts of pears; and the latter freely by suckers, layers, and cuttings: but the pear stock is always to be preferred for the general supply of larger trees, for all common standards, and the larger dwarf pear-trees for extensive walls and espaliers: the quince stock is esteemable principally for its dwarfish property, or in being productive of moderate floaing trees for walls, espaliers, or middling standards, sooner arriving to a bearing growth. In order to form dwarf pears, white thorn stocks, raised from seed, were formerly sometimes in repute, but they are very improper, as the trees rarely
STOCKS.

prosper well; as the good sports of the pear is often improved or diminished by the nature of the stock on which it is grafted, it is of importance to use free stocks, raised from the kernels of the bell summer and autumn pears, as much as possible; and the prime sports should be worked always on the finest free-shooting stocks of the most cultivated-like growths; sometimes, to improve the quality of particular choice kinds of pears, it is the practice to double-work them, which is to graft the bell sports into free stocks in the spring, which shall the same year; then about midsummer, or soon after, to bud the young shoots of the graft with buds of the prime sorts of pears, suffering only the stocks from the second budding to run up to form the tree: the breaking kind of pears are often rendered less hard and flisty in this way, and the melting property of others is considerably improved. See Pyrus Communit.

And for quinces, two sorts of stocks are occasionally used, as that of its own kind, and the pear stock; the quince stock is raised from feed, suckers, layers, &c., and the pear kinds from the kernels of any sort of pears; but as all the varieties of quinces are so expeditiously raised with certainty the fame by layers and cuttings, it renders the raising of stocks for grafting or budding them on almost unnecessary. See Pyrus Cydnum.

Also for plums, the operation is performed only upon stocks of their own kind, raised from the flowers of any sort of cultivated plum, or by suckers and layers, as the most certain methods to obtain any particular variety of free plum stock, as the muske-plum stock, which many prefer as the bell stock of all on which to work the finer kinds of plums, as generally producing very thriving moderate growing fruitful trees; raising it, not from feed, which would vary exceedingly, but by suckers from the root of real muske-plum trees, or of those worked upon the true muske stock, or from layer stocks of the muske-plum tree; the plum will also grow upon the apricot and cherry stock, but not in a thriving late for any length of time. See Pyrus Doméstica.

For cherries, the proper sports are those of the cherry kind only; as the great wild cherry stock for large trees, the cultivated garden cherries for the more moderate growths, and the bird-cherry stock for small dwarfs: the two former are raised from the flowers of the fruit, and the latter also by feed, or by layers and cuttings: for general use, the wild black and red cherry stock, being strong free growers, are preferable for all common large standard cherries, also the larger dwarf trees for extensive walls and efpaliers; as these stocks, being of strong hardy growth, generally produce larger, more hardy and durable trees than the cultivated cherry stocks; sometimes stocks of the morello and May cherry, as being moderate growers, are used to raise the smaller cherry-trees upon, either in dwarfs for low walls and efpaliers, or for small standard standards; but the former, when raised from layers, is more certain of producing the real fruit in its naturally moderate growth: the common bird-cherry, as being a very moderate grower, is used to raise dwarf cherry-trees on, either to plant in borders, pots, forcing-frames, or to pot for forcing, &c.: they are raised plentifully from feed, cuttings, and layers; and have the effect of dwarfing trees exceedingly, so as to bear fruit when but one or two feet high; and shooting very little to wood, generally bear abundantly for their size: and cherries will also grow upon plum, apricot, and laurel stocks, as being of the same genus. See Pyrus Ceragulis.

For apricots, these prove the most durable on stocks of the plum kind, as common plum stocks of any variety for all common wall, efpalier and standard trees; and the buckeye stock for small dwarfs; the plum stocks are raised from the flowers of any kind of cultivated plum, or by suckers from the root; and the bollace from feed, suckers, and layers: though they succeed almost equally well upon stocks of any kind of plum, it is probable they may prove the most successful on the muske-plum stock, like peaches, &c., as being of a more moderate regular growth, and more prolific nature: the bollace stock is only used occasionally to raise moderate small dwarfs for low walls, or to plant in pots, or in forcing frames for forcing; the apricot will likewise grow on its own, and on peach and almond stocks raised from the flowers, but never in so prosperous or durable a manner. See Prunus Armeniaca.

For peaches, several sorts of stocks are occasionally used; as almond, peach, nektarine, apricot, and plum stocks: they are all raised from the flowers of the fruit, and the latter also by suckers and layers; but the plum stock, being the most hardy, is the most proper for general ufe; but the free plum stock is preferable for all the sorts of peaches and nectarines, as being productive of the most hardy, thriving, and durable trees; though it is remarkable, one foot of plum stock in particular is generally preferable on which to work peaches, which is that of the muske-plum, as producing the most prosperous trees, and a more moderate, regular, and fruitful growth, the fruit being of a superior quality, when the stocks are genuine; being raised from suckers or layers of the true muske-plum tree, or by suckers from the roots of such peach, nektarine, plum, &c., as are worked on muske-plum stocks, which generally send up plenty from the roots annually; planting them off at one year's growth into the nursery to train them for ufe: double stocks, or double working, is sometimes ufed for the more delicate peaches, to improve their bearing, and the flavour of the fruit.

For nectarines, the same stocks as in the peach are used: as almond, peach, nektarine, apricot, and plum; all raised as for the peach-tree; the plum stock should be preferred in general as for peaches.

For almond-trees, when raised for their fruit, the approved varieties may be budded into stocks of any sort of almond, peach, nektarine, apricot, or plum, raised from the flowers, and the latter also from suckers, &c.; but the trees are generally the most hardy and durable on plum stocks. See Amygdalus.

For medlars, three or four different stocks are occasionally used, to raise the approved varieties: as the medlar, white-thorn, pear, and quince stocks; the three former raised from feed, and the latter from suckers, layers, and cuttings: the medlar feeding-raised stocks are very proper to graft the approved varieties; and the white-thorn and quince stocks are only used occasionally: but free stocks, raised from the kernels, of medlars, or summer or autumn pears, are preferable to the two last for all the varieties of the common medlar, which, either on their own or pear stocks, generally assume a more free growth, and produce the fruit in greater perfection and abundance. See Mespilus.

For sweet service-trees, when defigned as fruit-trees, the approved varieties should be grafted or budded upon proper stocks; either principally their own raised from the seed, or occasionally on pear or quince stocks, raised as for the medlar and other trees; though any of the forbus, or the pear kind of stocks, are preferable to the quince to work this tree on to have it large and durable; but quince stocks may be used to have trees of smaller growth, for low standards, efpaliers, &c.

For the wild maple-leaved service berry-trees, the proper stocks are either their own kind, or those of the hawthorn,
thorn, raised from the seed; they also take upon pear
flocks, &c.,
For hazel-nuts, the filbert, &c., the flocks of the com-
mon nut-tree, raised either from the nuts, or by suckers
from the root, may be used; but this method is seldom em-
ployed. See Corylus Avellana.

For orange-trees; these are worked upon flocks of their
own kind only, as any kind of orange, lemon, or citron
flocks, raised from the kernels of the fruit; though the
Seville orange, as being a very free frangl fouture, is gen-
erally preferred for orange flocks; but the lemon and citron,
being also free growers, form very proper flocks to raise any
variety of oranges on. See Citrus Aurantium.

For lemon and citron trees; these varieties are also budded
or inarched upon lemon, citron, or orange flocks, raised
from the kernels of the fruit, as for oranges. It is evident,
that in this method, for curiosity, the same flock may be
made to support two, three, or more different varieties of
fruit, grafted or budded, either all into the flock, being
previously trained with branches, forsking off for the pur-
pone one for each graft, or by cleft or crown grafting
ingle large flocks, with two or more different buds by in-
oculation; likewise the flock being finely grafted or budded,
different flocks may be infected into the flocks arising from
the graft or buds; and thus two, three, or more flocks of
apples may be had on the same root; and by the same
method, different flocks of fruit may be had upon the same
flock, as plums, cherries, and apricots all on a plum flock
or peaches, nectarines, and apricots on the same, or on
flocks of their own kind; and pears, medlars, and quinces
upon the pear flock; also red and white currants, or cur-
rants and gooseberries, on a currant or gooseberry flock;
or white and red grapes on a vine flock; likewise red and
white roes, or other different flocks, upon a common roe
flock; as well as on numerous other trees and shrubs, which
are species or varieties of the same genus. See Citrus
Medica.

Method of Raising the Stocks.—All the different flocks may
be raised by seeds, suckers, layers, and cuttings. In the frill
or feed mode, various sorts of flocks may be raised from
the stones and fruits of different sorts of trees: as the ker-
nels of all the apple kinds, pears and quinces; and the
stones of plums, cherries, and apricots all on a plum flock
or peaches, nectarines, and apricots on the same, or on
flocks of their own kind; and pears, medlars, and quinces
upon the pear flock; also red and white currants, or cur-
rants and gooseberries, on a currant or gooseberry flock;
or white and red grapes on a vine flock; likewise red and
white roes, or other different flocks, upon a common roe
flock; as well as on numerous other trees and shrubs, which
are species or varieties of the same genus. See Citrus
Medica.

But before the appearance of the plants above ground,
where the surface of the bed is hard-bound or caked, it is
often beneficial to stir the surface lightly with a small iron
rake; also, if very dry weather prevails, to give frequent
moderate waterings, both before and after the plants are up,
repeating the waterings occasionally in very dry weather all
the spring and early part of summer, to encourage a free strong
growth; being likewise careful to keep the beds very clean
from weeds, by diligent hand-weedicings; and by thus giving
every encouragement, the feeding flocks will grow to
freely during the summer, as, by the autumn or the spring
following, to be mostly of a proper size to plant out into
nursery-lines in the open quarters, in rows two feet asunder,
to remain for grafting and budding upon; though, if they
have made but middling progress the first summer in the
feed-bed, and are rather small and weakly, the frangl flocks
should be planted out, leaving the red growing until the
next autumn, when they will be all of full size for plant-
ing out wholly into the open prepared nursery quarters,
forking the feeding plants up out of the beds, shortening
any perpendicular tap-root and long ftragglers, but leaving
all their tops entire, and then planting them in lines, either
by trench-planting, flat-planting, or dibble-planting, as the
sizes of the plants admit, in rows two feet or two feet and
a half asunder, setting the plants one foot or fifteen inches
apart in each row, in an upright position; and after having
planted one row, treading the earth gently all along close
to the roots of the plants, to fix them firmly in the earth
all evenly in a straight range; proceeding in the same manner,
row and row, till the whole is planted, levelling the surface
of the ground between all the rows with the spade or rake.

Their future culture, until grafted or budded, consists in
occasional waterings in the frill spring, hoeing over the
ground every summer, digging between the rows annually
in the winter or spring, and training the flocks each to one
stem; preferring their top always entire, but trimming off
the frangl laterals below, to encourage the strength of the
main stem, when they will be fit for grafting or budding
upon, in from one to two or three years. See Planting,
In Gardening.

It may be noticed, that they are proper for working
when from about the size of a large goose-quill, as already
obferred, to the thickness of a man's little finger, or a little
more; but the sooner they are worked upon, after they are
of a due size, the better they succeed, and the sooner they
form trees. See Grafting and Budding.

In some cafes, however, where the flocks have start freely
the first summer after planting out from the feed-bed, many
of them may probably be of a due size to graft the fol-
lowing spring and summer, at five or six inches height, to
form dwarfs for walls and eiplachers, &c.; or, even, in some
flocks, for full or half standards, provided the frill main
flock from the graft or bud is trained up finely, two or
three years, to form the stem, of from four or five to fix or
five feet stature; however, if they have grown but mo-
derately the frill and second fessions, and are not generally
in a condition for the operations of grafting or budding,
it is better to let them have another year's growth.

But in the second or sucker mode, the suckers of all the
trees which afford them should be planted off at one year's
growth, in autumn, winter, or spring, which is a very ex-
pedient method of raising several sorts of flocks; to that,
after being transplanted into the nursery, they often, in one
or two years' growth, afford proper flocks for the reception
of grafts and buds; and many of them are often fit for bud-
ging in the summer following, at the proper budding season,
or for grafting in the spring afterwards.

The suckers are generally fit to take up for the purpose
of flocks; when of one year's growth, and about the size of
a tobacco-pipe, or but little bigger, and should be collected
in autumn, or the early part of winter; taking them up as
well rooted as possible, cutting off all knots or knobbled
woody parts of the old roots that may adhere to their bot-
tom, trimming the frangl flings, and cutting off all fide-
flocks from the stem; then planting them in rows two feet
asunder, and one foot distant in the lines; treading the
mould gently to their roots, and infilling the work by level-
ing the surface baked out. This the colli gratings
afterwards, until grafted or budded, is nearly the same as that of the
feeding flocks, keeping them clean from weeds in summer
by hoeing; and probably some of the strongest shooters may
may be fit to bud in the July or August following, though the general greater part will require two years' growth, before they are proper for working; still continuing them all to one item, by timely displacing strong laterals, and preferring their top or leading shoot generally entire until grafted, &c.

The third or layer method is practised for some sorts of flocks of fruit and other trees, and when any particular variety of flock is required, such as the paradise flock for apples, mulch-plum for peaches, &c. that may be obtained of the real fort with certainty; but as this method of raising flocks would be attended with great trouble for general grafting or budding, it is only practised occasionally. In providing them in autumn or winter, some of the young shoots of such trees as have the branches naturally growing near the ground, or in which the items have been cut down low, while young, to force out branches near the bottom, to furnish shoots properly situated for laying, should be laid out in the common method, when they will mostly be rooted by the autumn following, and be fit to take off and plant into the nursery, being managed as directed for the feeding anducker flocks.

In the last or cutting method, cuttings of the last year's shoots should be chosen in autumn, planting them in the nursery, in a somewhat shady border, giving occasional waterings the following spring and beginning of summer, in dry weather, when they will be mostly well rooted by next autumn, and may then be planted out in nursery rows two feet asunder, managing them as the others. They should be kept with upright items, except any should assume a flunted or crooked growth; in which case, they should be headed down to the ground in the spring, when they will pull out strong from the bottom the ensuing summer, training them to one item, and with their leading top-shoot entire as above; and according as all the focks advance in growth, they should be divested of strong lateral fhoots below, repeating it particularly in the taller fstandard flocks, to encourage their upright direction more expeditiously to the proper grafting and budding heights. But the proper methods of grafting and budding, for the different focks, are shown more fully under the culture of the different kinds, as well as under the heades Budding and Graffing.

In regard to flocks in general, but little that is satisfactory has yet been done, in either determining the utility and advantages of such as are taken from different species of the same kind, or in any other way; but an ingenious inquirer on horticullural subjects, T. A. Knight, esq., has lately been engaged in some experimental trials for ascertaining the advantages or disadvantages of using flocks of different species in the culture of the peach, the nectarine, and the apricot, which may probably throw some additional light on this intricate and imperfectly elucidated practice.

It has been stated by this writer, on the authority of Sir Joseph Banks, in the "Transactions of the Horticultural Society of London," that in the practice of the French gardeners, they consider flocks of different species to be necessary to correct the defects of different focks and varieties of fruit; and that the peach-tree should, in some cases, be budded upon the plum-tree, in others upon the almond-tree, and in others again upon its natural flock, that of the apricot; while, on the contrary, our gardeners suppress the plum flock, under all circumstances, the best adapted to the peach; and still further, that Du Hamel, to whose opinions the greatest deference is confidently to be paid, pronounces the plum flock as never to be eligible, and affrets that he has seen the peach-tree thrive upon focks of the apricot, in soils where it would not succeed either upon the almond or plum flock. It is also stated by the ball writer, it is said, to be the opinion of the French gardeners, that the peach-tree, when grafted upon its natural flock, is more liable or subject to generate gum, than when it grows upon a flock of another species; and that, whenever the tree is confined to a small space, and consequently closely pruned, this opinion is believed by Mr. Knight to be, in some cases, well founded. But as he is not acquainted with any advantages that can be obtained or derived from selection of focks of a species different from that of the bud or graft inserted, except in cafes where it is necessary to render any tree more dwarf and governable in its manner of growing, and consequently more productive, in soils and situations where rapidity and exuberance of growth and health might prove injurious: it is indeed suspected, that the peach-tree might be budded upon its own flock, in many cafes, with considerable advantage. The growth of the peach-tree, it is said, is so rapid under those circumstances, that, with the aid of artificial heat, the flock which is raised from a seed in the spring may be budded and headed down in the same season, and afford a tree large enough to bear many peaches in the succeeding year; and for foreign-houses, where exuberance of growth may be effectively checked by a succession of heavy crops of fruit, the writer says, he should prefer such trees to any others. The fruit which they afford in the first season has, however, been found to be inferior in flavour to that which older or trees of longer growth produce.

The following interesting circumstances is stated by Mr. Knight, in respect to the Moor Park apricot. In his garden, this tree, as in many others, he says, becomes, in a very few years, diseased and debilitated, and generally exhibits, in spaces near the head of its flock, liches alburnum, beneath a rough and februous bark. About sixteen or seventeen years ago, a single plant of this variety was, it is said, obtained by grafting upon an apricot flock; and that the bark of this tree still retains a smooth and polished surface; and the whole tree presents a degree of health and vigour, so perfectly different to any other tree of the same kind in his garden, that he has found it difficult to convince gardeners, who have seen it, of its specific identity.

It is hoped that this statement may induce the possessors of public nurseries to try the effect of flocks of different species, and particularly those of the apricot; for though it may be their interest that the trees they sell should perish, as they now generally do within a very few years, it cannot be supposed that the more reputable nurserymen would be influenced by such a consideration: besides, an additional price, which will, it is said, to some extent be necessary, if such a method should be had recourse to, will afford a fair compensation, should the number of trees on sale be in any way diminished.

Such a mode of raising and providing fruit-trees of several different kinds is certainly well worth being put to the trial, as it is of great consequence, in many cafes, to have more lasting trees of such sorts than those which are at present employed in the ordinary practices of the garden.

STOCKS, Apple and Pear, for Field Fruit-grounds, in Rural Economy, the focks which are made use of in raising and providing them with trees of these sorts, in different districts. Several kinds of focks are employed in this in- tention, sometimes by way of having the branches or parts of suitable and proper trees of these kinds imparted into them, and at others as feeding-trees, without that being done; though the first mode is the most ready, and for the mult
The most part had recourse to, especially in some districts. The pear is, however, the most advantageously raised on blocks of its own species, and lasts longer than the apple-tree.

Raising the Stocks.—In performing this, the fresh pulp of the apples affords a sufficiency of pips or kernels for the supply of the seed-bed; which, after it has been well prepared by digging and other means, has them somewhat thickly sown, or the pulp spread evenly upon it, either in the autumn or spring season, and carefully raked or lightly harrowed in, so as to be well covered with the surface-mould: the latter of these actions is, however, supposed to be the best and most practised, as there is then less danger of their being destroys by mice and other vermin, which often greedily prey upon them during the winter months. All weeds are carefully prevented from rising during the ensuing summer-feast; and in the second or third autumn, the young blocks are most ready to be put out into the nursery-ground. This is to be dug with the same care as the seed-bed; and at the time of the removal of the blocks or plants, the roots of them are to be pruned and restrained, by taking off the tap or down-striking ones, and shortening the fibres of others. They are then to be planted out in rows at three feet distance, and about eighteen inches from each other. In this method of planting them in the nursery-ground, 9522 blocks may be raised on the acre, or thereabouts. They remain in these grounds from eight to ten years, when they will most likely have attained sizes proper for being finally put out into the field fruit-grounds. While in the nursery-ground, they are kept regularly pruned and trained: the side-shoots are cut off, and one neat upright stem preferred, with six or seven shoots regularly branching out each way at the head. In this state, the price for them was, some time ago, for the apple blocks 11 6d., and for those of the pear 21 6d. consequently the profit of an acre of ground thus employed is very consider- able: 9522 blocks, disposed of at the above prices, amount, it is laid, in the first case, to 714; in the latter, to 11626 5½: and that after the third year, the profit may be reckoned on as neat, since the occasional crops, raised in the void spaces and parts between the blocks, will pay the ex- pences of labour and rent.

In some districts, when the young block plants are come up from the seed, in the progress of their ensuing growth, care is taken to select all such as produce the largest and most luxuriant leaves, as it is from that character that the best expectations are formed for procuring the most valuable fruit in this view. The rejected plants or blocks are drawn out from time to time, and the preferred ones left, for the purpose of discovering their specific qualities. The, when approved of, which point is most commonly ascertained by the end of the sixth year from the time of sowing the pips, their heads being previously formed upon stalks of about five feet high, are removed to any eastern aspect, except that of the north-east; and on to the sloping sides of hills, where there is no stagnant moisture of any kind in the under soil, and are there, for the most part, planted finally out at the distances of from 25 to 30 feet apart, according to circumstances, as will be seen below.

In some districts, the blocks of these sorts of tree-plants are planted out finally sooner, or after they have had less growth, than in others; but they should never be put out in this way, until they are of sufficient strength and growth, as has been directed above.

Planting the Stocks out in the Fruit-Grounds.—As soon as the blocks have arrived at or attained the height and growth of six or seven feet, and are become about five inches in circumference, they are in a proper state for being planted out in these grounds. Where the land is in the state of grass, they are generally planted at the distance of from 8 or 10 to 12 or 15 yards from each other, suitable openings being prepared for them in a proper manner. In Devonshire, where smaller distances are allowed, holes are previously made, in which are deposited road-iciapings or way-foil in the proportion of about two feet or hor- loadst to each. Where the grounds are under the plough, the distances of planting are from 16 to 18 or more yards, with an interval of 30 and upwards, and opposite to each other in some places: the particular distance of the rows, however, depends greatly on the band of the ridge, as they are planted on the tops of such as most cafes: if the ridges be small, every other one is omitted, in some places; and where the contrary is the case, as where they are wide, always managing so as that the last distance may be nearly preferred. In wind land, the quincunx order of planting the blocks is sometimes practised, in order that space may be gained for spreading of the heads of the trees, as the distance allowed in such cafes is less.

When the planting is performed on tillage lands, advantage is supposed to arise not only from the manuring and keeping the mould loofe over the roots of the block plants, but from there being a considerable saving of expense in the articles of fencing and defending the plants. The young blocks or trees are to be protected and defended from external injuries of all kinds, until they have gained a con- siderable state of growth, and are become firm in the roots, and perfectly hard in the bark. There are different methods of effecting this, which will be noticed below.

Good blocks of these kinds are sometimes met with in the hedge-rows of fruit districts, and might, perhaps, be occasionally planted there with great utility and advantage. In respect to the most proper time for planting out the blocks, though something may most probably depend upon the season and the nature of the soil, February is the most usual and probably the best, as a long series of drought is inimical to late planting, while severe frosts are not left to that of the autumnal season. It is, however, much easier to protect the roots of the blocks during the winter, than to be continuously watering them during the summer-feason.

There is much less care also required in planting them out on light and loose soils, than on such as are of a heavy or of a clayey nature. In the former, it is sufficient to just dig out the holes deep enough to cover the roots perfectly, and to ensure the mould as it comes out of them; but in the latter, the digging of holes is complete ruin to the block plants, as the whole depth underneath the cultivated soil is so retentive as to form a port of irritable water or moisture: and where they are even filled with good mould, it is impossible for the roots to extend themselves into the surrounding clay or clayey matter. The bell prac- tise is, therefore, probably, to take off the surface-turf to some depth in a circle of about four feet diameter, and to lay the under soil in a light manner; on this to place some good earth, and then to plant the block, with another layer of good earthy mould, covering the whole with over with the sod or turf, generally laid upon flat. The tap-roots of the blocks are to be previously cut off or shortened, and the fibres also to be pruned at the ends, when they are to be placed out in regular order, having some new earth blended and shook down among them. But before the planting, the blocks are to be headed down; or at least the branches are to be shortened to fix or eight inches, to guard
STOCKS.

guard against the power of the wind, and throw the juices more into the limbs, by which the vigour of the flock is increased. The newly planted flocks are then to be well guarded from being in any way injured by live-flock, or in any other manner, in some of the modes which are directed below.

In the filling up old fruit-grounds, or the replanting new ones on the same ground, it is considered a bad practice, in some districts, to plant the flock on the exact spot where the old tree stood; but it is otherwise, if a pear be planted where an apple grew before, especially in cases where the surface and under foil has been well prepared by digging and properly manuring the ground.

Grafting the Stocks.—When the flocks have been three or four years planted out in the fruit-grounds, they are in a state ready for grafting, where that method is had recourse to in completing the trees. But though this mode, as being the most expeditious, may have been the most frequently had recourse to, it has been supersed by some, that no method of performing the operation that has yet been attempted, has been found fully adequate to the purpose. For the flocks that are inferted, in consequence of being taken from old trees, though they grow vigorously for a few years, on account of the strong growth of the flocks, they then often decay, decline, and degenerate, or run into all the infirmities of their parent trees. Of course, on this principle, the refining or renovation of the old fruits of these kinds would seem to be impracticable; as by the general laws of nature, each of the different beings endowed with life, lives to propagate its kind, and after a time relinquishes its place to a new. It has been observed, that the head and from which a twig is taken for this purpose, evidently partakes of the life of the tree to which it belongs; and that it is not less evident, that when part of a tree is detached, no new life is afforded to it, whether it be employed in this way, or placed in the ground to emit roots as a cutting; in this manner, a tree raised from a cutting, soon produces fruit in every respect similar to that of the tree from which it was taken. Alto, that the habits of feeding trees are very essentially different, that their leaves are small and thin, and that the general habit changes gradually, affording in a natural manner a more cultivated character; that if a flock for grafting with, be taken from a feeding tree of one or two years' growth, it will retain the character, and from which a twig is taken for this purpose, evidently partakes of the life of the tree to which it belongs; and that it is not less evident, that when part of a tree is detached, no new life is afforded to it, whether it be employed in this way, or placed in the ground to emit roots as a cutting; in this manner, a tree raised from a cutting, soon produces fruit in every respect similar to that of the tree from which it was taken. Alto, that the habits of feeding trees are very essentially different, that their leaves are small and thin, and that the general habit changes gradually, affording in an annual manner a more cultivated character; that if a flock for grafting with, be taken from a feeding tree of one or two years' growth, it will retain the character, and from which a twig is taken for this purpose, evidently partakes of the life of the tree to which it belongs; and that it is not less evident, that when part of a tree is detached, no new life is afforded to it, whether it be employed in this way, or placed in the ground to emit roots as a cutting; in this manner, a tree raised from a cutting, soon produces fruit in every respect similar to that of the tree from which it was taken. Alto, that the habits of feeding trees are very essentially different, that their leaves are small and thin, and that the general habit changes gradually, affording in an annual manner a more cultivated character; that if a flock for grafting with, be taken from a feeding tree of one or two years' growth, it will retain the character, and from which a twig is taken for this purpose, evidently partakes of the life of the tree to which it belongs; and that it is not less evident, that when part of a tree is detached, no new life is afforded to it, whether it be employed in this way, or placed in the ground to emit roots as a cutting; in this manner, a tree raised from a cutting, soon produces fruit in every respect similar to that of the tree from which it was taken.

Thrift taken off by means of a proper saw, and then rendered quite smooth by the use of a sharp strong knife; the height of doing which depends much upon the fancy of the planter, but is mostly performed at about seven feet high. The rest of the operation is done in the usual manner, according to some of the modes commonly practised in this fort of work, as either by the simple common method, that of the crown method, or the root and whip methods.

A new plan of the root kind, has, in some districts, been lately had recourse to. In this, when the flocks have reached a proper age or state of growth for planting out, the ground is opened about them, and they are separated from the largest roots; of which, such are chosen as are of a sufficient size for leaf-grafting, which method is to be preferred; and if the roots be inclining, they are raised to a perpendicular, without disturbing their extremities which are in the ground; the shoot or feion is then inserted in the usual way, and rendered perfectly secure. The earth is then returned to them all round, and one bud, or at most two, are left above the ground in order to guard against failure, which are mostly found to strike with extraordinary vigour. Where both succeed, the leaf promising is removed. The buds, which are covered with earth, shoot out into roots, so that when the trees are to be removed to their defined situations, they may be entirely separated from the original root on which they were grafted. Sufficient roots remain to the parent flock for the future support of it, and it may be planted elsewhere, for the purpose of either producing a fresh supply of roots for the same proceeds, or for grafting in the fruit-grounds. It is stated, that some trees, raised by grafts in this way, have become handsome ones eight feet high, and had fine fruit on them in the course of four years. That six of the flocks, which had been separated from the roots, and deemed useless, on being replanted, had kernel-fruit upon them in the same length of time. This method is said to be the discovery of Dr. Shelton of Gloucester.

In some places it is the practice, in performing this fort of work, to infect two shoots or feions, one in or on each side of the head of the flock; but one is mostly sufficient to form a head large enough. With some, where two are infected, it is the enrolm, however, to remove that which is the leaf promising, where both thrive, in the ensuing year, and with a knife, or chisel, to pace off the top of the flock in a flogging manner to the remaining graft, which prevents water from lodging, and the sap then becomes directed to and concentrated in a smaller compass. After this, the wounded part should be well guarded and protected, in order to promote the more speedy healing of it, and the whole graft be firmly and properly secured.

Where both the grafts are suffered to grow, the head of the tree, from becoming double, is not infrequently separated, and the trunk rendered by strong blowing winds, or even by the weight of the branches alone.

In case the grafts do not strike or take, it is considered dangerous, if not fatal to the flock, to infect new feions or shoots until the third or fourth year. Where they do strike, it is but seldom that any farther care is taken of them, until the trees begin to be productive of fruit.

This fort of negligence is, however, highly improper and disadvantageous, as they ought to be carefully watched in regard to the progress of the shoots, and the removing and cutting off the dragging, irregular, and useless branches, as by these and other means, the interior of the trees may be prevented from becoming loaded and incumbered with a red expanse of wood. See Grafting.

Defending the Stocks.—These are to be well guarded, protected.
S T O

tected, and defended, when newly planted, as well as in their growth afterwards; as they are very liable and much exposed to be rubbed, barked, and otherwise injured, in many cases, by different forts of live-flock, and in other ways. There are many different modes of accomplishing this; as by frames of wood differently formed and set up; by poles differently placed, and slips of strong board properly nailed upon them; by poles and rails differently contrived; and by various prickly and thorny substances and plants twisted and tied round the flocks in different ways. But the best method is probably that of having three poles put in a fort of triangular manner about the tree or flock, so as to come within a small distance of each other at the bottom or root part, and to diverge considerably in their upward direction, and formed into a fort of frame by proper short croak pieces being nailed against them at suitable distances apart. Though this requires more wood than some other modes, theearer forts may answer the purpose very effectually. There are objections to many of these methods from the flocks and trees, when they begin to frot freely, having their lateral branches rubbed greatly by them, and from the poles forming holes in the ground, by being agitated by the winds, into which the moisture is drawn from the roots of the flocks or trees, as well as from other circumstances. The thorny matters are cheap methods, but they are readily removed by live-flock, by which means the bottom parts of the flocks are liable to become naked and be rubbed by fleep, which is very hurtful to them.

The trees raised and formed from flocks in this way mostly come into bearing in from fix to seven years after the grafting has been performed, but the quantity of fruit is seldom large for some length of time afterwards, then, however, it becomes considerable for a great number of years. See Apple Tree.

Stocks, Ciprus, a wooden machine to put the legs of offenders in, for the securing of disorderly persons, and by the way of punishment in divers cafes ordained by statute, &c. And it is said that every vill within the precinct of a town, is indigible for not having a pair of stocks, and shall forfeit 5/.

Street, in Ship Carpenter, a frame erected on the shore of a river or harbour, on which to build shipping. It generally consists of a number of wooden blocks, ranged parallel to each other, at convenient distances, and with a gradual declivity towards the water. See Lauch.

Hence we say, a ship is on the flocks, when she is building.

Stocksee, in Geography, a town of the duchy of Holstein; 8 miles N. of Segeborg.

Stockstadt, a town of Germany, on the Main; 3 miles W. of Aichelau.

Stocksund, a town of Norway, in the province of Drammen; 60 miles N. of Drammen.

Stockton upon Tees, is a borough by prescription in the fourth division of Stockton ward, and parish of Stockton, in the county-palatine of Durham, England. The antiquity of this place may be readily inferred from giving its name to one of the county wards; but its origin is not ascertained. Stockton castle, on the south side of the town, was at one period inhabited by the bishops of Durham, who were appointed to govern the whole province committed to their care. This fortress was on the northern bank of the river Tees, and commanded an extensive prospect over the valley and country. In the time of Charles I. it was garrisoned in behalf of the King; but afterwards fell into the power of the parliamentarians, who ordered it to be demolished; which was so completely executed, that not a stone of the former edifice remains. The only vestiges are the most, which defended the cattle on three sides; and a barn, which appears to have stood within the area of the works. In the year 1325 Stockton was nearly destroyed by the Scots; but at the close of the civil wars it recovered its importance. The population, in 1725, amounted to 430 families; but in the reports of 1811, the inhabitants had increased to 4220, and the houses to 812.

Stockton consists of two parts; one, called the Borough, where all the land is freehold; and the other, designated the Town, where it is copy or leasehold; the latter held under the vicar and vestry-men, and is not within the borough jurisdiction: for this reason there are two constabularies, with peculiar officers, though both form one parish. The civil government is vested in a mayor, alderman, and recorder, (who is always aeward of the bishop's court-leet and baron,) besides inferior officers. The mayor is elected by a majority of the burgesses, yet it is not required that he should first have been an alderman. The situation of this town, on the northern banks of the Tees, at a convenient distance from the sea, renders it very favourable for commercial purposes; its maritime trade began to revive soon after the restoration, the officers of the customs removed hither from Hartlepool in 1680, and lawful quays were erected in 1683.

Below Stockton, the river flows in a very circuitous course; and as it approaches the German ocean expands into a large bay, upwards of three miles in width. Stockton is probably the most handsome town in the north of England, as well for the breadth of its principal street, as the general neatness of its buildings. This street is about half a mile in length, and upwards of sixty yards broad at the market-place, which is in the centre; and this renders the entrance to the town, either from north or south, particularly impressive. Several smaller streets branch off in different directions; and at the north-east side is a spacious square, which contains some good buildings. The townhall, near the middle of the principal street, is a large square building, partly occupied as a tavern, and containing various elegant apartments, devoted to civil and other public purposes. At a short distance is a handfome column, thirty-three feet high, of the Doric order, where the market is held; the site of which was formerly occupied by an open crofs.

Stockton was originally a chapelry to Norton, a pleasant village about two miles to the north, but was constituted a distinct parish in the year 1711. During the episcopacy of bishop Poore, who died in 1234, a chapel of ease was erected here, which, upon becoming both ruinous and too small, was taken down, and a new church opened in August 1712. The church is a handsome brick building, with the doors and windows cased with stone; its length, including the tower and chancel, is 150 feet; this tower is at the west end, and is 80 feet high. The vestry contains a collection of divinity, which is still increasing from donations and subscriptions. The various denominations of Presbyterians, Quakers, Methodists, and Roman Catholics, have each a meeting-house in this town; which also contains the public institutions of a grammar-school, charity-school, Sunday-school, and an almshouse, or hospital.

The manufactures of Stockton are sail-cloths and cordage, both of which are carried on to a great extent. The making of damasks, diapers, huckabacks, towelling, and checked linens, has likewise lately been executed in considerable perfection. Two docks for building ships are also situated on the banks of the Tees. An elegant bridge, with five arches, was erected over this river, towards the close of last century, at the expense of Eecol. The tolls on this bridge
bridge gradually augmenting, now let for 200l. annually, which is appropriated to discharge the principal and interest already incurred; and when these are liquidated, the bridge will be free, and the future incidental charges be defrayed by the county of Durham, and the North Riding of York- 
shire, jointly. The shock of an earthquake was felt at Stockton in December 1780: and in August 1783, a violent storm of thunder and lightning took place, with a shower of irregular pieces of ice, some of which measured from three to five inches in circumference.

Stockton is the birth-place of Joseph Reed, a dramatic author, who was born in 1722: of Bras Crosby, esq. born in 1726, who rose from a very humble station in life to be lord mayor of London: Joseph Ritson, an eminent literary critic, was also a native of Stockton. See Ritson.

Near this town, on the river Tees, is a considerable salmon fishery; and at the mouth of the river is a fishery for cockles. About four miles north of Stockton is Wynchard, the seat of Sir Harry Vane Temepl, bart. The house, a handsome, modern edifice, occupies the site of an old build-
ging, in a park which presents some interesting scenery. —
History, &c. of Stockton-upon-Tees, by the Rev. J. Brew-

STOCHUM, a town of Welfphalia, in the bishopric of Olmbruck; 5 miles E.S.E. of Olmbruck.

STODDARD, a township of America, in the state of New Hampshire, and county of Cheshire; about 15 or 18 miles N. of Walpole, on Connecticut river, containing 1,132 inhabitants.

STODE, a town of Sweden, in Medelpada; 18 miles W. of Sundfwall.

STODGED, in Rural Economy, a term provincially signi-
fying filled to the flretch, as the udder of a cow by milk.

STODHART Bay, in Geography, a bay on the N.W. coast of Jamaica.

STOEBE, in Botany, a name received by Pliny from the GREEKS, which he says is fynomynous with Pbleum. If the latter be, as many have believed, our Tarya, the ufe made of its downy feeds, for buffing cushions or beds, may account for the origin, or rather the application, of the name. The plant we have here referred to, appears to have designated a plant used for flrewing, or for making what was, doublets, the most ancient and simple sort of beds. The eros of Dios-
cordes however, merely mentioned by him as a well-known plant, useful for the afigrant properties of its feeds and leaves, is believed to be Petrium spinatum, whose qualities anfwer to this defcription, and which is called in modern Greek evous. How Linneus came to felect the name of Stoeb for the genus before us, in his Hortus Cliffortianus, where, without any explanation, it is for the firft time appears in his works, we are at a fofs to explain. The hard rigid African shrubs which compose it are, like the above Petrium, of all things moft unfit to make a bed, except for a rhinoceros or a hippopotamus. He seems to have taken up this name, for a new fynegenous genus, becaufe it had been variously applied by old botanifs to certain compound flowers, and was then vacant, nor did headvert, in any manner, to its fene or etymology.—Linn. Hort. Cliff. 390.

Gerrtn. t. 167.—Clafs and order, Syngenefa Polygona-freg-
gata. Nat. Ord. Compofta nudifemteae, Linn. Corymbi-
ferae, Jull.

Gen. Ch. Common Calyx roundifi, imbricatd; its scales awl-
shaped, permanent, invelving the common receptacle on all fides. Partial Parianthl folitary within each scale of the common calyx, fingle-flowered, of five linear, acute, equal, 

and fringed leaves. Proper Cor. of one petal, funnel-shaped; its limb in five spreading fegments. Stam. Filaments five, short, capillary; anthers united into a five-toothed cylinder. Fil-

Germa oblong; fyle thread-shaped, the length of the flaments; fligma acute, divided. Peric. none, except the unchanged calyx. Seeds solitary, oblong. Down fheathery, 

long. Proper Receopt. naked.

Obf. Garten considers the common calyx as nothing else than, either the upper leaves of the plant, or the outer scales of the receptacle, while the partial calyx consists of the inner scales of the receptacle. According to this view of the subject, Stocke should be removed to the third, or dicoid, fection of the order Polygonata eaudata, and we are much disposed to concur in that opinion.

The difcoveries of Thunberg have greatly enriched this, as well as other Cape genera, fo that Wildfaw reckons up twenty species, about half of which were known to Lin-

nus. But two or three of these really belong to Scatt-

trium, and are abfolutely fingular. Stem. Filaments five that article. Nin-

ten are natives of the fourth of Africa; one of the ifles of Mauritius and Bourbon. Scriphium, which has also a feathery feed-down, differs from Stoeb in having only one flower in each outer calyx.

Wildl. n. 1.—"Leaves sharp-pointed, thread-shaped, woolly."—Gathered by Thunberg at the Cape of Good Hope. We have seen no specimen.

Wildl. n. 2. Ait. n. 1. Lamarc Ililtr. t. 722.

f. 2.—Leaves awl-shaped, pointed, reflexed, keeled; po-
lifhed on the under side. Stem erect.—Specimens of this plant were brought very early from the Cape; and Lin-

eus feeing it in Clifford’s herbarium, though not alive in his garden, founded hereon the genus of Stoeb. Miller cultivated it in 1759, but no figure, except Lamarc’s and Garten’s, has ever appeared, Petiver’s tab. S. f. 1. being a different plant, as we shall mention hereafter. The stem is feburly, of humble growth, with round leafy branches. Leaves crowded, almof imbricated, scarcely half an inch long, twifted, recurved, entire, concave, with a fpinous point; fringed with long soft hairs towards the base. 

Flowers terminal, fesflie, hemifpherical, three-quarters of an inch in diameter. It is from this, the original fpecies of the Hortus Cliftonianus, that the character and idea of the genus are taken.

excluding the reference to Brenyus and Morifon. Wildl.

n. 3. Thub. Prodr. 169. Berg. Cap. 359 (Espatat-

roides capenis capitatus; Petiv. Gafoph. t. S. 1.)—Leaves minutely pointed, linear, revolute, oblique, reflexed. Stem er-
craft. Some ligulate florets.—Native of the Cape. The stem is a fpan high, determinately and repeatedly branched, 

twifted, leafy. Leaves about two lines long, spreading every 

way, obtufe, with a minute point, roughish, with a 

few little difperfed tubercles; hoary when young. 

Flowers round, fesflie, terminal, pale red or fesf-coloured. Each 

partial calyx usuallly contains, along with its proper tubular 

perfect flore, another short ligulate nueter one. The fede-
down is lloofly fheathy. Petiver’s figure undoubtedly re-

depresents this plant very charactetically. That of Brey-

G g 2
STOEBE.

m. erroneously quoted t. 9, instead of 69, by Linnaeus, is S. sylvestris, the leaves of which are much spreading.

4. S. prostrata. Prostrate Stoebe. Lindl. Mant. 291. Willd. n. 4. Thunb. Prodr. 169.—Leaves pointed, lanceolate, obtuse, with a concealed rib, beneath. Found at the Cape by Thunberg.—The stem is much branched, clothed with spreading, ovate-lanceolate, thyme-like leaves; green and smooth above; very white, with a concealed rib, beneath. Flowers the size of a large pea, tawny or reddish, with very white anthers. Scales of the common calyx exactly like the leaves, in this, as well as other species.

5. S. phylleoides. Phylleoid-leaved Stoebe. Thunb. Prodr. 169. Willd. n. 5.—Leaves pointed, lanceolate, obtuse. Stem erect. 1.—From the same country. Thunb. This description is insufficient to give any distint idea of the plant. We have seen no specimen.

6. S. gomphrenoides. Amanantie Stoebe. Lindl. Suppl. 391. Willd. n. 6. Berg. Cap. 336. Thunb. Prodr. 169.—Houttuya Linn. Fl. Syl. v. 4. 435. t. 34. f. 1. 1.—Leaves elliptic-oblong, concave, fringed; woolly on the upper side; the lower ones minutely pointed.—Gathered by Thunberg at the Cape. The stems are numerous, erect, leafy, a foot high, most branched at the bottom. Leaves half an inch or more in length, imbricated; conves, green and somewhat silky, at the back, with a flabby marginal fringe. They are mostly obsolete, without any minute sharp point, except on the lower ones. Flowers round, white, rather polished, resembling the heads of a Gomphrena. Each floret appears to have a double calyx; the outer one short, coloured, and somewhat woolly; so that this species should seem rather to belong to Seriphium, as Linnaeus has marked it in his copy of Bergius.

7. S. gomphrenoides. Cudweed Stoebe. Lindl. Syll. Veg. ed. 13. 664. Willd. n. 7. Thunb. Prodr. 169. (Seriphium corymbiferum; Linn. Mant. 119. Gomphaëon niveum; Linn. Sp. Pl. 1192. G. incanum, fohio lineai cauli acumbente; Burm. Afric. 215. t. 77. f. 1. and incomplete.)—Leaves sharp-pointed, ovato-lanceolate, concave; woolly on the upper side; polished at the back. Panicles cymoïde.—Gathered at the Cape by some of its earliest botanical visitors. The stem is shrubby, rigid; its upper branches leafy, woolly. Leaves erect, crowded, yellow-green, rather thin, slightly imbricated, half an inch long, pungent; smooth at the back and margin, curiously dotted, or reticulated. Flowers numerous, yellow, in dense, terminal, corymbose tufts; each flover cylindrical, with a squarrose, imbricated, tight, partly woolly, common calyx. Florets two or three. Seed-down club-shaped, very slightly feathered. We cannot but conceive the genus of this plant to be very doubtful, the inner calyx being fearfully distinctable.

8. S. joabah. Rough-leaved Stoebe. Lindl. Suppl. 391. Willd. n. 8. Thunb. Prodr. 167.—Leaves erect, linear, woolly above; imbricated at the back. Flowers racemose.—Found at the Cape by Thunberg. The minute ciliated leaves, and outer calyx, are rough with glandular prickles. Florets four or five. Their proper calyx is smooth, twice as long as the outer. Sometimes, but not always, the rough scales of the outer calyx surround and separate each particular floret, making the plant a true Seriphium; so nearly are these two genera related!

9. S. cinerea. Grey Heath-leaved Stoebe. Willd. n. 9. Thunb. Prodr. 169. Ait. n. 2. (Seriphium cinereum; Linn. Sp. Pl. 1136. Brachycaeris cinereaepilis; Petiv. Gazoph. t. 5. f. 9.)—Leaves spreading, linear; woolly above; smooth at the back. Flowers in dense whorled spikes. (See Seriphium, n. 1.) This appears however to be a true Stoebe. The common calyx his woolly obtuse scales, and contains many florets, whole partial calyx is smooth, with long bristle points, seeming to surround each floret distinctly.

10. S. jubata. Aul-leaved Stoebe. (Seriphium gnapalodes; Linn. MSS.)—Leaves somewhat spreading, involute, pointed, awl-shaped; woolly above; slightly imbricated at the back. Flowers faked. Outer calyx woolly. 1.—Native of the Cape of Good Hope.—The stem is erect, woolly, branched, leafy, round, slightly woolly. Leaves at first erect, then spreading or recurved, hardly an inch long at most, very tender, and apparently thread-shaped, but they are concave and woolly above; the under side is clothed in a decussate silky web, and armed here and there with prominent prickles. Spikes terminal, short, ovate or oblong, rather compound, somewhat leafy. Common calyx very distinct from the leaves, with short, obtuse, partially woolly scales, containing two or three, rarely four, florets, whose partial calyx is long, pointed, and membranous. Seed-down loosely feathered. We cannot find that this plant has ever been published before.

14. S. planifolia. Feather-leaved Stoebe. Willd. n. 13. Thunb. Prodr. 169. (Brevicynia capensis, capitus bonx spei; Bryna. Cent. 1. 69. Abrotanoides capensis, erica folio; Petiv. Gazoph. t. 5. f. 4.)—See Seriphium, n. 2, where this species will properly be placed. The stem is very commonly branched. Leaves very slender, half an inch long, embracing dense, grey, woody, axillary tufts of smaller ones. Flowers small, fidele. Common calyx many-flowered, fearfully distinguishable from the minute tufted leaves; partial one longer, with blunt, tawny, thinning scales. We cannot understand the observation in Linn. Mant. 481, "flores 5; flores 6; flores" unless each scale of the inner calyx was taken for a floret.

15. S. fulva. Brown Stoebe. Willd. n. 14. Thunb. Prodr. 170. (Eupatorium crinoides, capitis bonx spei; Bryna. Cent. 1. 69. Abrotanoides capensis, erica folio; Petiv. Gazoph. t. 5. f. 4.)—See Seriphium, n. 3, to which genus this species undoubtedly belongs, each floret having a distinct outer, as well as inner calyx; notwithstanding its great resemblance to Stoebe coccus, n. 3.

17. S. afra. Harsh Stoebe. Thunb. ibid. Willd. n. 16. —Leaves linear, pointless, smooth, reflexed. Flowers lateral. 1.—This and the last were found by Thunberg at the Cape, and do not appear to be known by any other author.

Gathered by Commerson in the isle of Bourbon. This is certainly a *Seriphium*, not a *Stoechades*. The *fem* is fix or eight feet high, with innumerable branches, resembling a *Tamarix* in habit. *Leaves minute, imbricated; smooth at the back. Inner leaves long and smooth, at length spreading widely. The *water* is cylindrical, of many roundish imbricated scales, woolly within, and contains a fugal flow, only. This should follow *Seriphium fuscum* in its proper place.

19. *S. rhinoceros*. Rhinoceros Thoebe. Linn. Suppl. 391. Wildh. n. 18. Thunb. Prodr. 170. — "Leaves triangular-awl-shaped, close-prelapped. Branches downy, drooping. Clusters proliferous." — Native of the Cape, and said to be the chief food of the rhinoceros. We have seen no specimen, but it is very possible, as Lamarck suspects, that this may not be different from the last species.

21. *S. nivea*. Snow-white Thoebe. Thunb. ibid. Wildh. n. 20. — "Leaves triangular, obtuse, close-prelapped. Flowe terminal." — In this view of the genus *Stoechades*, as it stands in Willdenow, we have been chiefly solicitous to ascertain species and their synonyms. The intelligent reader may range some of them under this genus, others under *Seriphium*; but the greater part must remain in uncertainty, either from the obscurity of Nature herself, in this very ambiguous cafe, or because we have not sufficient information from Thunberg, who alone has seen some of the species.

The genera appear to us too distinct to be resolved into one. They require to be carefully studied by an adept, who ought to be possessed of all the known species of both, and to examine the structure of all their flowers, before he attempts to draw any conclusion respecting their generic distinctions, or even their precise place in the Linnean system.

**STOECHADES**, in *Ancient Geography*, islands of the Mediterranean sea, upon the coast of Gallia Narbonensis. These islands are the same with the islands of Hieres. Strabo mentions five of them; and three of these deferve to be recorded, viz. Prote, Mefe, and Hypea.

**STOECHADES MINORES**, or the Lesser *Sto echades*, were two small islands of the five above-mentioned, situated opposite to Marielles, called Ratoneau and Poméque.

**STOECHADES**, in *Botany*, *Stoechades* is a genus, distinct from the above-mentioned, situated opposite to Marielles, called Ratoneau and Poméque.

**STOECHADES**, in *Botany*, *Stoechades* is a genus, distinct from the above-mentioned, situated opposite to Marielles, called Ratoneau and Poméque.

**STOEHADT, a town of Poland, in Volhynia; 44 miles S.W. of Luco.**

**STOICISM**, the doctrines and opinions of Zeno's followers, called *Stoics*.
of Zeno; thus called from the Greek τοίχος, portico, or the porch; because the place where Zeno chose for his school was the "Pocile," or painted porch, a public portico so denominated from the pictures of Polygnotus and other eminent painters, with which it was adorned. This porch, which was the most famous in Athens, was called τοίχος, the porch.

The author of this sect, Zeno, was a native of Cittium, a maritime town in Cyprus, originally peopled by a colony of Phenicians, whom he is sometimes called a Phenician, and is supposed to have borrowed many of his dogmata from Phenician philosophy, which many learned men maintain was, itself, borrowed from the Jews: though it must be allowed, there appear as many things in the Stoic philosophy, borrowed from Plato's and Socrates' school, as from that of Moses. The profession of his father was that of a merchant; but his son, manifesting an early propensity towards literature, he early devoted him to philosophy. The father, having frequent occasion, in his mercantile capacity, to visit Athens, purchased for his son several of the works of the most eminent Socratic philosophers. There he read with great avidity; and when he was about thirty years of age, he determined to take a voyage to a city, which was so celebrated as a mart both of trade and of science. What were his views in this voyage, whether mercantile or scientific, is not certain. Some writers report, that he made a trading voyage from Cittium to Athens, richly freighted with Tyrian purple, and was shipwrecked not far from port; upon which we are told, consulting the oracle how he should spend the rest of his life, he was answered, ἐξανθρωπίσον τὴν καλότην, by becoming of the same colour with the dead; upon which he applied himself to the study of the ancient philosophers, and became a hearer of Crates, the Cynic.

Others relate, that upon his first arrival in Athens, he went accidentally into the shop of a bookseller, and taking up a volume of the Commentaries of Xenophon, read a few paginations, and that, being highly gratified by the perusal, and forming a very favourable idea of the author, he asked the bookseller where he might meet with such men. Crates, the Cynic philosopher, palled by the shop at this moment, and the bookseller pointing to him, said to Zeno, "follow that man." Availing himself of an early opportunity of attending upon the instructions of Crates, he enlisted himself in the number of his disciples. But highly as he admired the general principles and spirit of the Cynic school, he could not reconcile himself to their peculiar manners; and, besides, his inquisitive disposition would not allow him to imitate that indifference to every scientific enquiry, which formed one of the distinguishing characteristics of that sect. Abandoning Crates, he repaired to the school of Stilpo, and when his former master attempted to drag him away from it by force, he said to him, "you may seize my body, but Stilpo has hold of my mind." Having for several years attended upon the lectures of Stilpo, he had recourse to other schools, particularly those of Xenocrates, Diogenes Cronus, by whom he was instructed in dialectics, and on whom he conferred a large pecuniary gratuity for the discovery of some of his ingenious subtleties, and various other matters; and at length he offered himself as a disciple of Polemo. Polemo, however, apprized that Zeno, by removing from one school to another, was merely collecting materials to form a new system of his own, when he came to his school, said to him, "I am no stranger, Zeno, to your Phenician arts: I perceive that it is your design to creep slyly into my garden, and to steal away my fruit." Polemo was not mistaken in his conjecture; for Zeno, after having made himself thoroughly acquainted with the tenets of others, determined to become the founder of a new sect, and established a school at Athens. Zeno was distinguished by that kind of subtle reasoning, which was at the period in which he flourished popular. He likewise exemplified the system of moral doctrine which he taught in his own life. We need not wonder, then, that he should attract a number of followers, and also enjoy the favour of the great. His lectures were attended by Antigonus Gonatas, king of Macedon, whilst he resided at Athens; and upon his return, Zeno was invited to his court. So highly was he esteemed among the Athenians, on account of his approved integrity, that they deposited the keys of their citadel in his hands. They also honoured him with a golden crown, and a statue of brags. Amongst his countrymen, the inhabitants of Cyprus, and among the Sidonians, from whom his family was derived, he was likewise highly esteemed.

In his person, Zeno was tall and slender; his aspect was severe, and his brow contracted. His constitution was flexible; but he preferred his health by great abstinence. The supplies of his table consisted of figs, bread, and honey; notwithstanding which, he was frequently honoured with the company of great men. It was a singular proof of his moderation, mixed, indeed, with that high spirit of independence which afterwards distinguished his sect, that when Demochares, Ion of Laches, offered to procure him some gratuity from Antigonus, he was so offended, that from that time he declined all intercourse with him. In public company, to avoid every appearance of an affuming temper, he commonly took the lowest place. Indeed, to great was his modesty, that he seldom chose to mingle with a crowd, or with the company of more than two or three friends at once. He paid more attention to neatness and decorum in external appearance, than the Cynic philosophers. In his dress indeed he was plain, and in all his expenses frugal; but this is not to be imputed to avarice, but a contempt of external magnificence. He shewed as much respect to the poor as to the rich; and conformed freely with persons of the meanest occupations. He had but one servant, or, according to Seneca, none.

Honoured and esteemed as Zeno was by a great number of perfons, and unaffuming and irreproachable as were his manners, he had his enemies. Philosophers of distinguished ability and eloquence employed their talents against him. Thales, the founder of the sceptic school, amongst the ancients held him in profound contempt. Zeno was the founder of the Middle and New Academy, towards the close of his life, Epicurus, whose temper and doctrines were alike inimical to the severe gravity and philosophical pride of the Stoical sect, was his powerful adversary. Zeno is said to have lived to the extreme age of 98 years, and at last, in consequence of an accident, voluntarily put an end to his life. In walking out of his school, he fell, and broke one of his fingers; upon which, he was so affected with a conficuousness of infirmity, that, striking the earth, he said, "Why am I thus imperturbed? I obey thy summons: and immediately going home, he strangled himself. He died in the first year of the 129th Olympiad, B.C. 264. The Athenians, at the request of Antigonus, erected a monument to his memory in the Ceramicum.

If we compare the doctrines of Zeno with the history of his life, his heterogeneous system will appear to have been compiled out of the various tenets of the schools which he frequented; and on the credit of these he assumed to himself the title of the founder of a new sect, which spread widely, and subsisted for many ages. Of Zeno, Cicero says, that he had little reason for defearing his masters, especially those of the Platonic school, and that he was not so much
STOICS.

much an inventor of new opinions as of new terms. A comic poet, quoted by Athenæus, thus ridicule the logomachics of Zeno and his followers:

"Ye fages of the Porch, loquacious tribe, Traders in trifles, arbiters of words, And confess! hear!"

Zeno transferred the dialectics of Diodorus Cronus, and the moral doctrine of the Cynic sect, into his own system; the principal difference between the Cynics and Stoics consisting in this particular, that the former disdained the cultivation of nature, and the latter affected to rise above it.

On the subject of physics, Zeno received his doctrine from Pythagoras and Heraclitus, through the channel of the Platonic school. Cicero censures the Stoics for encouraging in their schools a barren kind of disputation, and employing themselves in determining trifling questions, in which the disputants can have no interest, and which, at the close, leave them neither wiser nor better. And that this censure is not, as some modern advocates for Stricturn have maintained, a mere calumny, but grounded upon fact, sufficiently appears from what is said by the ancients, particularly by Sextus Empiricus, concerning the logic of the Stoics. Seneca, who was himself a Stoic, candidly acknowledges this.

The Stoics, whose ruling passion was vanity, were ambitious of that kind of reputation which was derived from skill in the arts of reasoning and sophistry. The moral part of their philosophy partook also of the defects of its origin. It may be as justly objected against the Stoics as the Cynics, that they assumed an artificialseverity of manners, and a tone of virtue above the condition of man. Their doctrine of moral wisdom was an offententious display of words, in which little regard was paid to nature and reason. It professed to raise human nature to a degree of perfection before unknown; but its real effect was, merely to amuse the ear, and captivate the fancy, with fictions which can never be realized. Laidly, the physical and theoretical system of the Stoics, like those from which it had been borrowed, had, in its principles, a strong bias towards enthusiasm.

The extravagancies and absurdities of the Stoical philosophy may in some measure be ascribed to the vehemence contained which suffused between Zeno and the Academicians on the one hand, and between him and Epicurus on the other. Whilist Epicurus taught his followers to seek happiness in tranquillity, or a freedom from labour and pain, Zeno imagined his wife man not only free from all sense of pleasure, but void of all passions and emotions, and capable of being happy in the midst of torture. That he might avoid the torpid indolence of the Epicureans, he had recourse to a moral institution, which bore indeed the lofty front of wisdom, but which was elevated far above the condition and powers of human nature.

The natural disposition of Zeno, and his manner of life, had no considerable influence in fixing the peculiar character of his philosophy. By nature severe and morose, and constitutionally inclined to reserve and melancholy, he cherished this habit at an early period, by submitting to the severe and rigid discipline of the Cynics. Qualities which he conceived to contribute to his own personal merit, he transferred to his imaginary character of a wife or perfect man. His followers, therefore, affected an appearance of gravity and dignity, which they supported more by external show than by the real practice of sublime or useful virtues. Hence many of them were philosophers in words, rather than in their actions; and thus it was that their adversaries found so much scope for satirical ridicule and invective against Stoical pride and hypocrisy. Indeed, a system of philosophy, which aims at raising men above their nature, must commonly produce, either wretched fanatics or artful hypocrites. It is no proof of the perfection which some have been willing to ascribe to the Stoic philosophy, that there were among its professors many persons highly distinguished by genuine wisdom and virtue. For their uncommon merit was rather the effect of a happy temperament, or of fortunate circumstances in concurrence with those moral principles which are common to all mankind, than to the peculiarities of the Stoical system, which, as we shall presently see, were not adapted to cherish the genuine sentiments either of virtue or piety.

In forming an accurate judgment of the Stoical philosophy, it is necessary to guard against two errors, into which those have been betrayed who have appreciated it too highly. We should not form our opinion of this philosophy from words and sentiments detached from the general system, but consider them in their connection both with the premises and conclusions: nor should we confound the genuine doctrines of Zeno, and other ancient fathers of this sect, with the glosses, or improvements, of the later Stoics; who, after the introduction of the Christian doctrine, artfully accommodated their language, and even their tenets, as far as possible, to the Chriftian model. (See FATE.) Brucker, in his "History of Philosophy," translated by Enfield, has given an abstract of the Stoic philosophy, deduced from the writings of Cicero, Plutarch, Laertius, Sextus Empiricus, Simplicius, and Stobæus, compared with those of Seneca, Antoninus, and Epictetus, under the different heads of philosophy in general, logic, physics, metaphysics, and morals. Our limits will only admit of a few extracts. The doctrine of the Stoics, with regard to "philosophy in general," was, that wisdom consists in the knowledge of things divine and human; that philosophy is such an exercise of the mind as produces wisdom, and that in this exercise consists the nature of virtue; and consequently, that virtue is a term of extensive meaning, comprehending the right employment of the mind in reasoning, in the study of nature, or in morals. With Socrates and the Cynics, Zeno represented virtue as the only true wisdom; but being disposed to extend the pursuits of his wife man into the regions of speculation and science, he gave, in his usual manner, a new figuration to an old term, and comprehended the exercise of the understanding in the search of truth, as well as the government of the appetites and passions, under the general term Virtue.

"Logic," according to the Stoics, is either rhetorical or dialectic; the former being the art of reasoning and discoursing on subjects which require diffuse declamation, and the latter being the art of close argumentation, in the form of disputation or dialogue. Rhetoric is of three kinds, deliberative, judicial, and demonstrative. The dialectic art is the instrument of knowledge, by enabling a man to distingiih truth from error, and certainty from bare probability; and it considers things as expressed by words, and words themselves. External things are perceived by a certain impression made either upon some parts of the brain, or upon the percipient faculty, which may be called an image, ζωγραφις, since it is impressed upon the mind, like the image of a real upon wax. This image is commonly accompanied with a belief of the reality of the thing perceived; but not necessarily, since it does not accompany every image, but those only which are not attended with any evidence of deception. Where only the image is perceived by itself, the thing
STOICS.

thing is apprehensible; where it is acknowledged and approved as the image of some real thing, the impression is called apprehension, ἀναγνώσθειν because the object is apprehended by the mind, as a body is grasped by the hand. Such apprehension, if it will bear the examination of reason, is known, else if it is not examined, it is mere opinion; if it will not bear this examination, it is misapprehension. The fancies, corrected by reason, give a faithful report; not by affording a perfect apprehension of the entire nature of things, but by leaving no room to doubt of their reality. Nature has furnished us with these apprehensions, as the elements of knowledge, whence further conceptions are railed in the mind; and a way is opened for the investigations of reason.

Some images are sensible, or received immediately through the fancies; others rational, which are perceived only in the mind. These latter are called innate, notions or ideas. Some images are probable, to which the mind affixes without hesitation; others improbable, to which it does not readily assent; and others doubtful, where it is not entirely perceived, whether they are true or false. True images are those which arise from things really existing, and agree with them. False images, or phantasms, are immediately derived from no real object. Images are apprehended by immediate perception, through the fancies, as when we see a man; consequentially, by likeness, as when from a portrait we apprehend the original; by composition, as when, by compounding a horse and man, we acquire the image of a Centaur; by augmentation, as in the image of a Cyclops; or by diminution, as in that of a pigmy.

Judgment is employed either in determining concerning particular things, or concerning general propositions, using in the latter case our preconceptions, or universal principles, as criteria or measures of judgment. The first impressions from the fancies produce in the mind an involuntary emotion; but a wise man deliberately examines them, and supposes his action or approbation (προταθέω) with regard to the report of the fancies, till he has investigated the nature of things, and fully estimated the weight of evidence. The mind of man is originally like a blank leaf, but capable of receiving any impressions. These impressions, made by the fancies, remain in the memory, after the objects that occasioned them are removed; a fusion of these continued impressions, made by similar objects, produces experience; and hence arise permanent notions, opinions, and knowledge. Even universal principles, πεποίημα, are originally formed, by experience, from sensible images. All men agree in their common notions or preconceptions; disputes only arise concerning the application of these to particular cases.

These three things are mutually related; the expression, the notion or image in the mind which is expressed, and the external object. Under the head of expression, dialectics consider vocal sounds, as expressed by letters; the formal parts of speech; the etymology, analogy, or anomaly of syntax; the significations of words, and other properties of language. The notion or image expressed is the προσερχόμενον, phantasm, already explained.

Dialectics consider things as capable of being clasped under species and genera. The most comprehensive genus is that which includes all things, both real and imaginary. Of things there are four subdivisions, viz. substances, qualities, modes, and relations. Things considered with respect to speech are called λόγια, capable of being expressed in words. Predicates are things predicated, or declared, concerning another. Hence arid axioms, syllogism and compound, and these admit of different characters. An argument (ἀργυρίον) commonly confits of a general truth admitted (ἀπόκομμα); a particular case supposed (προταθέω), and a conclusion (ἐπικόμμα). Argument its admit of different forms.

According to the Stoical doctrine concerning "nature," there existed from eternity a dark confused chaos, in which were contained the first principles of all future beings; which chaos, being at length arranged, and emerging into variable forms, became the world, as it now exists. The universe, though one whole, contains two principles, distinct from elements; one passive, which is pure matter, without qualities, and the other active, which is reason or God. Zeno, determining to innovate upon the doctrine of the Academy, and declining to adopt the Dualistic system, which held God and matter to be two principles, eternally opposite, not only differing in their essence, but having no common principle by which they can be united, and also the emulative system (see Emulation) embraced a third hypothesis, which is distinguished by the appellation of the "Stoical system." Unwilling to admit, on the one hand, two opposite principles, both primary and independent, and both absolute and infinite; or, on the other, to suppose matter, which is in its nature diametrically opposite to that of God, the active efficient cause, to have been derived by emanation from him; yet finding himself wholly unable to derive these two principles from any common source, he confounded their essence, and maintained that they were so essentially united, that their nature was one and the same.

The Stoical system teaches, that both the active and passive principles in nature are corporeal, since whatever acts or suffers must be so. The efficient cause, or God, is pure ether, or fire, inhabiting the exterior surface of the heavens, where every thing which is divine is placed. This ethereal fubstance, or divine fire, comprehends all the vital principles by which individual beings are necessarily produced, and contains the forms of things, which, from the highest regions of the universe, are diffused through every other part of nature.

Matter, or the passive principle, in the Stoical system, is delitute of all qualities, but ready to receive any form; inactive, and without motion, unless moved by some external cause. The contrary principle, or the ethereal operative fire, being active, and capable of producing all things from matter, with consummate skill, according to the forms which it contains, although in its nature corporeal, considered in opposition to gross and sluggish matter, or to the elements, is said to be immaterial and spiritual.

Some perils have been misfled in forming their notions of the Stoical system, by the bold innovations of its advocates in the use of terms; and accordingly they have inferred from the appellations sometimes applied by the Stoics to the Deity, that they conceived him to be strictly and properly incorporeal. Whereas the truth seems to be, that, as they sometimes spoke of the soul of man, a portion of the divinity, as an exceedingly rare and subtle body, so most omnipious και λοιπον, and sometimes as a warm or fiery spirit, πνεῦμα φύσεως, so they spoke of the Deity as corporeal, considered as distinct from the incorporeal vacuum, or infinite space, but as spiritual, considered in opposition to gross and inanimate matter. They taught, indeed, that God is uncreated, incorruptible, and eternal; possessed of intelligence, good and perfect; the efficient cause of all the peculiar qualities or forms of things; and the confiant preserver and governor of the world: and they deified the Deity under many noble images, and in the most elevated language. The hymn of Cleanthes, in particular, is justly admired for the grandeur of its sentiments, and the fulness of its diction. But if, in reading these descriptions, we fail to associate with them modern conceptions of Deity, and neglect to recur
cur to the leading principles of the sect, we shall be led into fundamental misapprehensions of the true doctrine of Stoicism.
For, according to this sect, God and matter are alike unde-
rived and eternal, and God is the former of the universe in
no other sense, than as he has been the necessary efficient
cause, by which motion and form have been impressed upon
matter. What unworthy notions the Stoics entertained of
God, sufficiently appears from the fable opinion of his
finite nature, an opinion which necessarily followed, from
the notion that he is only a part of a spherical, and therefore
a finite universe.

With respect to the doctrine of divine Providence, it ap-
ppears that, according to the Stoics, the agency of the
Deity is nothing more than the active motion of a celestial
ether, or fire, posseflled of intelligence, which at first gave
form to the shapeless mafs of gross matter, and being always
effectually united to the visible world, by the same necessary
agency, preserves its order and harmony.
The Stoic idea of Providence is, not that of an infinite wise and good being,
wholly independent of matter, freely directing and governing
all things, but that of a necessary chain of causés and effects," arising from the action of a power, which is itself a
part of the machine which it regulates, and which, equally
with that machine, is subject to the immutable law of neces-
fity. Providence, in the Stoic creed, is only another name
for absolute necessity, or fate, to which God and matter, or
the universe, which consists of both, is immutably subject.

The rational, efficient, and active prineiple in nature, the
Stoics called by various names; nature, fate, Jupiter, God.
"What is nature?" says Seneca, "but God; the divine
reason, inherent in the whole universe, and in all its parts;
or you may call him, if you please, the author of all things." And
again: "Whatever appellation imply celestial power and
energy, may be justly applied to God; his names may
properly be as numerous as his offices." The term nature,
when it is at all distinguished in the Stoic syinem from God,
denotes, not a separate agent, but that order of things
which is necessarily produced by his perpetual agency.

The universe, according to Zeno and his followers, is
actus naturalis or actus reipublicae, "a sentient and animated being."
But Zeno understood this doctrine in a sense different from
that in which it was conceived by many former philosophers.
Zeno, adopting the ideas of Pythagoras and Heracleitus, and
assuring that there is no real existence which is not corpo-
real, conceived nature to be one whole, confining of a subtle
ether and gross matter, the former the active, the latter the
passive principle, as effectually united as the soul and body of
man; and supposing God, with respect to nature, to be, not
a co-existing but an informing principle. Whilst the Stoics
allowed that the Deity is the efficient and intelligent cause of
all the effects which are produced in the world, their
notions of his nature and attributes were confused and de-
grading. Refuding primarily in the superior celestial region,
and being thence diffused, as a subtle fire through a finite
world, his universal presence is limited, and falls far short of
the attribute of immensity, as it belongs to the divine nature.
United to matter by the immutable chain of necessity, he
wants that freedom of action which appears to be one of the
most effential characters of the Supreme Being. The origi-
nal communication, and the perpetual preservation of forms
and qualities, by the necessary action of a subtle fire upon
matter, though this principle be fupposed to be posseflled of
reason and intelligence as well as energy, is certainly an idea
of Deity, which falls far short of that pure and sublime doc-
trine, which represents God as creating and governing the
world by voluntary agency, and with wise design. That

VOL. XXXIV.
the Deity is, according to the Stoic doctrine, subject to the
law of necessity no less than matter and all subordinate
beings, Seneca, and other writers of this sect, expressly
assert. "Both gods and men are bound," says he, "by the
same chain of necessity. Divine and human affairs are alike
borne along in an irresistible current; cause depends upon
cause; effects arise in a long succession; nothing happens by
accident, but every thing comes to pass in the established
order of nature."

Portions of the ethereal soul of the world being distrib-
uted throughout all the parts of the universe, and ani-
mating all bodies, hence arise, in the system of the Stoics,
inferior gods or demons, with which all nature is peopled.
All these divinities they considered as derived from the soul
of nature, and as limited in their duration. Demons were
divided by the Stoics into superior and inferior; the superior,
whose which inhabited the sun and stars, which they con-
considered as deuses maximi, animated substances; the inferior,
human souls separated from the body, or heroes. "Illuf-
trious men," says Cicero, "whole souls survive and enjoy
immortality, are justly esteemed to be gods, since they are
of an excellent immortal nature." Besides this, there
seems little reason to doubt, that the Stoics acknowledged
the existence of other inferior divinities, portions of the soul
of the world, and taught that they were endowed with human
passions, and therefore are proper objects of sacrifice and
worship.

As the Stoics held, that all the inferior divinities are por-
tions separated from the soul of the world; so they con-
ceived, that a period would arrive, when they would return
into the first celestial fire, and supposing that, at the same
time, the whole visible world would be consumed in one ge-
neral conflagration.

On the subject of the origin of evil, they had recourse to
fate, and taught that evil was the necessary consequnce of
that eternal necessity, to which the whole world comprehend-
ing both God and matter, is subject.

Concerning the second principle in the universe, matter,
and concerning the visible world, the doctrine of the Stoics
is briefly this: matter is the first essence of all things, defi-
tute of, but capable of receiving, qualities. Considered
universally, it is an eternal whole, which neither increas-
 nor decreases. Considered with respect to its parts, it is ca-
pable of increase and diminution, of collision and separation,
and is perpetually changing. Bodies are continually tending
towards dissolution; matter always remains the same. Mat-
ter is not infinite but finite, being circumfribed by the
limits of the world; but its parts are infinitely divisible.

The world is spherical in its form, and is surrounded by
an infinite vacuum. The action of the divine nature upon
matter, first produced the element of quidrature, and then the
other elements, fire, air, and earth, of which all bodies are
composed. Air and fire have effential levity, or tend to-
wards the exterior surface of the world; earth and water
have effential gravity, or tend towards the centre. All the
elements are capable of reciprocal conversion; air passing
into fire or into water; earth into air and water; but there
is this effential difference among the elements, that fire and
air have within themselves a principle of motion, while
water and earth are merely passive.

The sun is a sphere larger than the earth, constituting of
fire of the purest kind: it is therefore an animated being,
and the first of the derived divinities. The stars too are of
the same kind, fiery bodies endued with perception and in-
telligence, and therefore to be ranked among the gods.
They are nourished by exhalations from the seas and
rivers.
rivers. Because the heavenly bodies are animated, they are capable of foreseeing future events, and of declaring to mankind, by certain signs, the appointments of fate.

The celestial bodies move, in their orbits, in the following order: Saturn, Jupiter, Mars, Mercury, Venus, the Sun, the Moon. The moon, which occupies the lowest part of the ethereal region, is, like the rest, a fiery luminary poffefled of intelligence; but the fire is mixed with air; whence the spots upon its surface. Its form is spherical, and its motion spiral, and of two kinds: the one, from east to west, through the sign of the zodiac.

Below the sphere of the moon is the region of the air. The earth is the most dense part of the world, and is the main support of nature, like the bones of an animated body. The earth, with its waters, forms a globe, which is the centre of the world; it always remains immoveable.

The world, including the whole of nature, God, and matter, is filled from eternity, and will for ever subsist; but the present regular frame of nature had a beginning, and will have an end. The parts tend towards a dissolution, but the whole remains immutably the same. The world is liable to destruction from the prevalence of moisture, or of dryness; the former producing an universal inundation, the latter an universal conflagration. These succeed each other in nature as regularly as winter and summer. When the universal inundation takes place, the whole surface of the earth is covered with water, and all animal life is destroyed; after which, nature is renewed, and subsists as before, till the element of fire, becoming prevalent in its turn, dries up all the moisture, converts every substance into its own nature, and at last, by an universal conflagration, reduces the world to its prismatic state. At this period, all material forms are lost in one chaotic mass; all animated nature is re-united to the Deity, and nature again exists in its original form, as one whole, consisting of God and matter. From this chaotic state, however, it again emerges, by the energy of the efficient principle, and gods and men, and all the forms of regulated nature, are renewed, to be dissolved and renewed in endless succession.

As a necessary consequence of the doctrine of the conflagration, and subsequent reformation of all things, the Stoics maintained, that the human race will return to life. Hence it appears in what sense we are to understand the Stoic doctrine of reformation, upon which Seneca has written with so much elegance; and what meaning we are to annex to his words, when he says, "Death, of which we are so much afraid, and which we are so defirous to avoid, is only the interruption, not the destruction, of our existence; the day will come which will restore us to life." This tenet is not to be confounded with the Christian doctrine of the resurrection of the body; for, according to the Stoics, men return to life, not by the voluntary appointment of a wife and merciful God, but by the law of fate, and are not renewed for the enjoyment of a better and happier condition, but drawn back into their former state of imperfection and misery.

Man, according to the Stoics, is an image of the world; one whole, composed of body and mind. The mind of man is a spark of that divine fire which is the soul of the world. The human soul, being a portion of the Deity, is of the same nature; a subtle fiery substance, endowed with intelligence and reason; but the energy of this principle is confined and restrained, in the birth of man, by its union with grosser matter.

Concerning the duration of the soul of man, the Stoics entertained very different opinions. Cleanthes thought that all souls would remain till the final conflagration. Chrysippus was of opinion, that this would only be the lot of the wife and good; and Seneca seems to have entertained the same notion. Epicurus and Antoninus alleged, that as soon as the soul is released from the body, it returns to the soul of the world, or is lost in the universal principle of fire. Some were so absurd as to believe, that the human soul, consisting of a fiery spirit condensed by its union with air, is capable of being extinguished. While others, with equal absurdity, conceived that the human soul, shut up within the gross body, could not, at death, find a free passage, but remained with the body till it was entirely destroyed. The only idea of the immortality of the soul, which seems to have been entertained by the Stoics, was that of a renovation of being, in that fated circuit of things which we have seen to be one of their fundamental doctrines. In the universal restoration of nature, some imagined that each individual would return to its former body; while others conceived, that after a revolution of the great year, similar souls would be placed in similar bodies.

The soul, conceived by the Stoics to have been material, was represented by them as consisting of eight distinct parts, viz., the five senses, the productive faculty, the power of speech, and the ruling part, to which, or reason. Those who held the existence of the soul after death, supposed it to be removed into the celestial regions of the gods, where it remains, till, at the general conflagration, all souls, both human and divine, shall be lost in the Deity. But many supposed, that before they were admitted among the divinities, they must purge away their inherent vices and imperfections, by a temporary residence in the aerial region between the earth and the moon, or in the moon itself. With respect to depraved and ignoble souls, it was a common opinion, that after death they were agitated in the lower region of the air, till the fiery parts were separated from the grosser, and rofe by their natural levity to the orbit of the moon, where they were still further purified and refined: a kind of mechanical purgatory, which very well agreed with the mechanical principles of the Stoic philosophy. These fancies are treated with ridicule by Epicurus and Seneca, who frequently speak of the happiness of good men after death in terms which might have suited a better system.

Seneca, confounding Marcia under the loss of her son, says, "The sacred assembly of the Scipios and Catons, who have themselves defpised life, and obtained freedom by death, shall welcome the youth to the region of happy souls. Your father himself (for all are there known to all) shall embrace his grandson, and shall direct his eyes, now furnished with new light, along the courtes of the neighbouring fars, with delight explaining to him the mysteries of nature, not from conjecture, but from certain knowledge. Like a welcome guide in an unknown city, he will unfold to the inquiring stranger the caufes of the celestial appearances."

The Stoical doctrine of "Moralis" is founded on the principles of physics. Conceiving God to be the principal part of nature, by whose energy all bodies are formed, moved, and arranged, and human reason to be a portion of the divinity, it was their fundamental doctrine in ethics, that in human life one ultimate end ought for its own fake to be pursued; and that this end is, to live agreeably to nature, that is, to be conformed to the law of fate by which the world is governed, and to the reason of that divine and celestial fire which animates all things. Since man is himself a microcosm, composed, like the world, of matter and a rational principle, it becomes him to live as a part of the great...
great whole, and to accommodate all his desires and pursuits to the general arrangement of nature.

To live according to nature, as the Stoics teach, is virtue: and virtue is itself happiness: for the supreme good is, to live according to a just conception of the real nature of things, chiefly that which is in itself eligible, and rejecting the contrary. Every man having within himself a capacity of discerning and following the law of nature, hath his happiness in his own power, and is a divinity to himself. Horace seems to have adopted this notion, Ep. i. i. 18. ult.

" Sed fatea ort ara Jovem quae ponit et auro: "

Det vitam, det opes: sequam mi animam ipse parabo."

" For life and wealth to Jove I'll pray; 
The Jove can give or take away: But for a firm and equal mind, This blessing is myself I'll find." Francis.

Wisdom, say the Stoics, consists in distinguishing good from evil. Good is that which produces happiness, according to the nature of a rational being. As the order of the world consists in an invariable conformity to the law of fate, so the happiness of man is owing, that course of life which flows in an uninterrupted current, according to the law of nature. Since these things only are truly good which are becoming and virtuous, and virtue, which is feated in the mind, is alone sufficient for happiness, external things contribute nothing towards happiness, and therefore are not in themselves good. The wise man will only value riches, honour, beauty, and other external enjoyments, as means and instruments of virtue; for, in every condition, he is happy in the possession of a mind accommodated to nature. Pain, which does not belong to the mind, is no evil. The wise man will be happy in the midst of torture. All external things are indifferent, since they cannot affect the happiness of man; nevertheless, some of these are conductive, others unfavourable, to the life which is according to nature, and as such are proper objects of preference or rejection, προοπισ αν απορροιαμα. Every virtue being a conformity to nature, and every vice a deviation from it, all virtues and vices are equal. One act of beneficence, or justice, is not more truly so than another; one fraud is not more a fraud than another; therefore there is no other difference in the essential nature of moral actions, than that some are vicious, and others virtuous.

The Stoics advanced many extravagant affections concerning their wife man. For example, that he feels neither pain nor pleasure; that he exercises no pity; that he is free from faults; that he is divine; that he can neither deceive nor be deceived; that he does all things well; that he alone is great, noble, ingenious; that he is the only friend; that he alone is free; that he is a prophet, a prince, and a king; and the like. These paradoxical vauntings are humorously ridiculed by Horace. Serm. i. i. fat. iii. apud fin.

The Stoics, however, did not suppose that their wife man actually existed; but they formed in their imagination an image of perfection, towards which every man should continually aspire. The first object of pursuit, according to the Stoics, is, not pleasure, but conformity to nature; and every one who has a just discernment of what is good, will be principally folicitous, in all his actions and pursuits, to conform to nature. This, they teach, is the origin of moral obligation. Violent emotions and passions, arising from false conceptions of good, are contrary to right reason and nature; and these it is the office of reason to prevent or remedy. Of virtues, some are contemplative, others practical; some primary, others subordinate. The contemplative or scientific virtues are those which consist in just conceptions and principles; the practical, those which concern the conduct of life. The primary virtues are, prudence, temperance, fortitude, and justice. Prudence refers to the choice and pursuit of goods; temperance, the government of the appetites; fortitude, the endurance of that which is commonly esteemed evil; and justice, the offices of social life.

Duties were distributed by the Stoics into three classes, as they respect God, ourselves, and our neighbour. The duties of religion are, to think justly concerning God, and to worship him piously. He thinks justly of God, who believes him to be the supreme director of human affairs, and the author of all that is good and fitting in human life. He worships God piously, who reveres him above all beings; who perceives and acknowledges him in all events; who is in every thing resigned and obedient to his will; who patiently receives whatever befals him, from a persuasion, that whatever God appoints must be right; and in fine, who cheerfully follows wherever divine Providence leads him, even though it be to suffering and death.

The sum of a man's duty with respect to himself is, to subdue his passions of joy and sorrow, hope and fear, and every pity. He who is, in this respect, perfectly master of himself, is a wise man; and in proportion as we approach towards a state of apathy, we advance towards perfection.

The duty we owe towards others, is to love all men, even our enemies. A good man will love his neighbour from his heart, will refrain from injuring, and take pleasure in protecting and serving him. He will not think himself born for himself alone, but for the common good of mankind, and will do himself kind to all, according to his ability. He will think himself sufficiently rewarded by the consciousness of well doing, and will never cease to do good, although he has no witnesses of his good deeds, nor is ever likely to receive any applause or recompence for his beneficence. The wise man never remits the punishment due to a criminal through pity, which is a weakness not to be indulged: nevertheless, in cafes where reason suggests a sufficient ground for clemency, he will not treat a delinquent with rigour. He will relieve the sick, afflit the shipwrecked, afford protection to the exile, or supply the hungry with food, but with an undisturbed mind, and a cheerful countenance; disdaining all sorrow arising from sympathy, as well as from personal sufferings. No one is more ready than the wise man to exercise lenity and clemency, and to attend to the welfare of other individuals, and to the general interest of mankind.

Concerning the whole moral system of the Stoics, it must be remarked, that, although it is highly deserving of praise for the purity, extent, and variety of its doctrines, and although it must be confessed, that in many feebler passages of the Stoic writings it appears exceedingly brilliant, it is nevertheless founded on false notions of nature and of man, and is raised to a degree of refinement which is extravagant and impracticable. The piety which it teaches, is nothing more than a quiet submision to irresistible fate. The self-command which it enjoins, annihilates the vital affections of the human heart. The indulgence which it grants to suicide is inconsequent, not only with the genuine principles of piety, but even with that countenance which was the height of Stoic perfection. And even its moral doctrine of benevolence is tinged with the fanciful principle, which lay at the foundation of the whole Stoic system, that every being is a portion of one great whole, from which it would be unnatural and impious to attempt a separation.

We must then conclude, that the ethics of Zeno and his followers,
followers, however splendid, and in many particulars well-founded, devoted, as a system, from the true principles of nature, and had a tendency to produce artificial characters, and to encourage moral avarice and hypocrisy.

Zeno, the founder of the Stoical system, had many disciples and successors; such were Perperus, Aristo the Chian, Herillus, and Spheron. His immediate successor in his school was Cleanthes. (See his article.) After Zeno, no philosopher more truly exhibited the character, or more illustriously displayed the doctrine, of the Stoic sect, than Chrysippus. (See Chrysippus.) The immediate successor of Chrysippus in the Stoic school was Zeno of Tarsus, or, as some say, of Sidon. The chair was next assumed by Diodenes of Seleucia, called also the Babylonian. (See his article.) His disciple and successor was Antipater of Tarsus. The last of that series of Stoics which belongs to the history of the Greek philosophy was Posidonius. See Posidonius.

The Stoic school was patronized by many eminent men in the Roman republic; but the man who claims more special notice, as a Stoic in character as well as principle, was the younger Cato. See his article.

The Stoic philosophy, which under the republic found many patrons, particularly among the professors of the law, continued to flourish under the emperors till after the reigns of the Antonines. Its ethical doctrine became the permanent basis of the Roman jurisprudence; and the high tone of wisdom and virtue which it assumed, induced many persons of great distinction and eminent merit to declare themselves of the Stoic sect, or at least to prefer its moral system to that of any other school. The prevalence of Christianity contributed also, in no small degree, to the success of Stoicism. Besides, the Stoic sect acquired great credit and authority from the illustrious examples of many persons of both sexes, who, in those times of civil oppression, bravely encountered death in the cause of liberty and virtue.

Among the heroes of this age, Tacitus mentions the two Arrius, the wives of Cæcina petus and Thraseas, and Pannia, the wife of Helvidius. For these and other causes, the Stoic sect, in the time of Junius, prevailed almost throughout the whole Roman empire. (Sat. xiv. v. 108.) Under Antoninus Pius, schools of Stoicism were supported at the public expense in Athens, Alexandria, and probably too at Rome; for Antoninus, after he came to the purple, visited the house of Apollonius the Stoic to study philosophy. At Tarsus in Cilicia there was also a Stoic school, which produced several celebrated philosophers.

The Stoic philosophy, however, struggled with powerful opposition from several quarters; and from the period when the meteoric Eclectic system was established, Stoicism began to decline; and in the age of Augustine it no longer subsisted as a distinct sect. It was only during the short space of 200 years, that the Roman school of Zeno was adorned with illustrious names which claim a place in the history of philosophy. The first Stoic who merits attention in this period is Athenodorus, of Tarsus in Cilicia (see Athenodorus); Annæus Cornelius, an African, who lived at Rome in the beginning of the reign of Nero, and excelled in criticism and poetry, though philosophy was the principal object of his study (see Cornelius); Cæsius Munonius Rufus, who was banished by Nero to Cyrena, but afterwards called by Vespasian (see Munonius); Chazremos, an Egyptian; Lucius Annæus Seneca (see his article); Dio, of Prusa in Bithynia, called for his eloquence Chrysothom; Ephrates of Alexandria; Epictetus (see his article); Sextus, of Chaeronea in Beotia; and, last of all those whom we shall mention, the great and good emperor, Marcus Aurelius Antoninus. (See his article.) From the time of the Antonines to that of Alexander Severus, there were public schools of the Stoics in Athens and Alexandria; but their doctrine was corrupted by the prevalence of the Ecclesiæ philosophy. In the sixteenth century some attempts were made for reviving the Stoic philosophy by Lipsius; (see his biographical article,) Galper Scipionius, Daniel Heimius, and Thomas Gataker. See Bruck’s Hist. of Philosophy by Enfield, vols. i. and ii.

STOILS, in Geography, a town of Hungary; 10 miles N.W. of Cachau.

STOKAAM, a town of Prussia, in Natangen; 30 miles S.S.E. of Königsberg.

STOKE, a township of Lower Canada, on the St. Francis river, N. of Aletot.

STOKER’S BAY, a bay on the S. coast of Hampshire, between Portmouth harbour and Southampton river, S. of Gofport.

STOKE-COURCY, a parish of large extent in the north-west part of the hundred of Cannington, and county of Somerset, England. One extremity of this parish is a long, narrow peninsula, called Start Point; which stretches nearly four miles into the sea, and terminates at the western edge of Bridgewater bay. The river Parret empties itself into the sea at this point. The town of Stoke-Courcy is confined chiefly of one long street, and is situated at the southern extremity of the parish; it is stilled in ancient records, the borough and honour of Stoke-Courcy, and the above-mentioned street still retains the former of these appellatives; though we do not find that it sent members to parliament more than once in the time of Edward III. It was formerly privileged with a market; this, however, has been long since discontinued; but here are yet held two annual fairs. Near the old crofs, in High-street, are two fine springs, included within cilyers, which, after supplying the inhabitants with water, unite with the brook that runs near the town, and fall into the sea at Stoford. The church of Stoke-Courcy, built at several periods, is a large building, with a tower in the centre, supported by four large arches. The eastern end of this edifice is of great antiquity, and was the conventual church belonging to the priory of Benedictine monks, which was formerly founded near this place. The arcs which separate the body of the church from the north and south aisles are femicircular, and spring from very rich capitals. The name of Stoke-Courcy in Saxo, the former word signifying a village, and the latter the name of its original proprietor; whose ruined manion lies a short distance to the south of the town. This parish, inclusive of Fairfield, contained, in 1811, 1208 inhabitants, and 222 houses. — History of Somersetshire, by the Rev. John Collinson, 4to. 1791, vol. i.

STOKEN, a town of Switzerland, in the canton of Zurich; 16 miles N. of Zurich.

STOKERAU. See Stockerau.

STOKES, a county of North Carolina, in Salisbury district, bounded E. by Rockingham and W. by Surry, containing 11,645 inhabitants, of whom 1746 are slaves. The capital is Germantown.

STOKES, a town of North Carolina, near the Yadkin; 20 miles N.N.W. of Salisbury.

STOKESIA, in Botany, was fo named by L’Heritier, in honour of Jonathan Stokes, M.D., well known as the coadjutor of Dr. Withering, in his Botanical Arrangement of British Plants; and particularly distinguished for his critical acuteness, displayed in his references to figures throughout that work. Dr. Stokes has recently published an elaborate Materia Medica, in four octavo volumes, dif-

1. S. cyanus. Blue Stokelia. Wild n. 1. Ait. n. 1. (Carthamus levis; Hill. Hort. Kew. 57. n. 5.) — Native of South Carolina. Cultivated at Kew from about the year 1705, when Mr. Gordon is said to have introduced this elegant plant. It is perennial, flowering in August, requiring shelter in winter. The flen is erect, simple, leafy, about two feet high. Lower leaves lanceolate, clasping the stem, toothed at the base; upper sessile, heart-shaped, serrated; all smooth, bright-green. Flowers large and very handsome, of a fine blue. It is by mistake that Hill and L'Heritier are cited as having given figures of this plant.

STOKESLEY, in Geography, a town in the west division of the liberty of Langbrough, and North Riding of Yorkshire, at the distance of 242½ miles north-west from London, and 43½ from York. In 1811 it contained 388 houses, and 1459 inhabitants. The herbage of Stokelsley, at an early period, was granted to the family of Balacl, and was poiffed by Guy de Balacl, who came into England with King John. The manor, after defending through the family of Forrester, has since been sold to the Rev. Mr. Hillyard, the present proprietor.

The town is seated on the north side of a large branch of the river Leven, and is formed chiefly by one broad street. The buildings are principally modern, with the exception of the shambles and the toll-booth, which have an appearance of antiquity. Though no evidence of the original foundation of St. Peter's church in this town can now be produced, yet a church is mentioned in the Domeday survey. About 1355, a chantry was founded at the Virgin's altar, within this building, by William de Stokelsey, for the re-ude of the souls of John de Middleton and his wife. There is a church at the eastern extremity of the town, of modern erection, but the ancient town is yet remaining. The rectory-house was rebuilt in the year 1792, and is an agreeable residence, greatly improved by the present incumbent, the dean of York. Adjoining to the church-yard, on the north, stands the manor-house, a square stone edifice, with gardens, and a rising thbeberty in front. This town is endowed with two fairs, and a weekly market, held on Saturday. The petty feisions for the western division of Langbrough are held here. The parish of Stokelsey is of considerable extent, and incloses an area of about seven square miles. Within it are comprised the townships of Stokelsey-Byby and Esby, with the hamlet of Tameton, and a part of Newby. These were manorial reidences held under feudal tenures; little remains of their ancient greattstfes are visible. Elaby Hall, formerly a seat of the lords Eures, now falling to decay, and an ancient chapel at the south end of the village, dedicated in 1340, are the only vestiges left. The environs of Stokelsey are fertile, and the lands near the town chiefly laid to pasture. — Beauties of England and Wales, vol. xvi. Yorkshire; by J. Bigland. History of Cleveland; by the Rev. John Graves, 410. 1808.

STOKILDORFF, a town of Austria; 4 miles N.E. of Sonneneberg.

STOKOLETZ, a town of Croatia; 12 miles S.W. of Petrsz.

STOLATZ, a town of European Turkey, in the province of Servia, on the Morava; 30 miles N.N.W. of Niia.

STOLBERG, a town of Saxony, in the circle of Erzgebirg; 8 miles S.W. of Chemnitz. N. lat. 50° 46'. E. long. 12° 42'. — Allo, a town of Westphalia, capital of a county to which it gives name, and residence of the counts; 40 miles N. of Erfurt. N. lat. 51° 29'. E. long. 11° 5'. — Alfo, a town of France, in the department of the Roer; 3 miles S.S.W. of Efchweiler. — Alfo, a county situated in Thuringa; about 20 miles long and 15 broad. It affords some good pasture and arable land, with some rich mines of copper and iron, some fine woods, and plenty of game; now annexed to the kingdom of Westphalia.

STOLBOVOI, a cape on the E. coast of Kamfchatka; 40 miles E. of Kamfchatkoi. N. lat. 56° 25'. E. long. 165° 44'.

STOLCKERN, a town of Austria; 3 miles S.W. of Eggenburg.

STOLE, Stola, from sole, signifying a long robe, or Vestment, a sacerdotal ornament, worn by the Romish parih-priests over their surplice, as a mark of superiority in their resuive churches.

The stole is worn by other priests over the alb, at celebrating masses; in which case it goes across the lochen; and by deacons over the left shoulder, ferracize.

The flola is a broad lwath, or fip of cloth or stuff, hanging from the neck to the feet, with three crosses upon it. The bishops anciently pretended, that the parih priests were never to appear before them but in their floles. In Flanders and Italy they always preach in floles. It is supposed to be a representation of the borders of the long robe worn by the Jewih high-priests.

The flola of the ancient Romans, &c. was very different from that now in use; the former was a kind of robe fitter for women than men, though it was held a robe of honour among all nations. Kings themselves sometimes used it, and sometimes bestowed it as a reward of virtue.

Stole, Groom of the, the eldhest lord of his majesty's bed-chamber, whose office and honour is to present and put on his majesty's first garment or shirt every morning; and to order the things in the chamber.

Stole, Order of the, an order of knights inluted by the kings of Aragon; though, as to the particular author or time of the institution, we are in the dark. The first time we hear of it is under Alphonso V. who mounted the throne in 1416. Jullianini takes it to have been instituted about the year 1332.

Stole, Order of the Golden, a military order at Venice, thus called from a golden frole, which the knights wore over their left shouder, reaching down to the knees, both before and behind, a palm and a half broad. None are raised to this order but the patricians, or noble Venitians. Jullianini observes, that the time of the institution of this order is unknown.

STOL.
STOLHOVEN, in Geography, a town of Germany, in the district of Baden, not far from the Rhine; 16 miles N.N.E. of Straßburg. N. lat. 48° 45'. E. long. 8° 57'.

STOLLEN, a town of Prussia, in the province of Oberland; 3 miles E. of Lichibad.

STÓLMIRZ, a town of Austrian Poland, in Galicia; 28 miles E. of Lemberg.

STÖLOWICZE, a town of Russian Lithuania; 30 miles S. of Novogrodek.

STOLPE, a town of Prussia, in the province of Ermland; 4 miles N.E. of Allenstein. — Alto, a river which rises in Pomerania, and runs into the sea; 27 miles W. of Danzig. — Alto, a town of Anterior Pomerania; 5 miles W. of Anclam. — Alto, a town of Farther Pomerania, on a river of the same name, which here begins to be navigable to the Baltic. It contains three churches, and a Lutheran convent for ladies. The trade is considerable; 80 miles N.E. of Stargard. N. lat. 54° 25'. E. long. 16° 43'.

Alto, a river of Farther Pomerania, which runs into the Baltic at Stolpemund. — Alto, a lake of Brandenburg, in the Mark of Prenzegg; 2 miles E. of Kyritz. — Alto, a town of Brandenburg, in the Ucker Mark; 6 miles S.E. of New Angermünde. N. lat. 52° 58'. E. long. 14° 14'.

STOLPENMUND, a town of Farther Pomerania, situated on the coast of the Baltic, at the mouth of the river Stolpe; 10 miles N. of Stolpe. N. lat. 54° 32'. E. long. 16° 33'.

STOLPEN, a town of Saxony, in the margravate of Meissen, with a citadel. In 1652, this town was burned by the Croats; and in 1765, the fortifications of the citadel were destroyed by the Prussians; 33 miles W.N.W. of Zittau. N. lat. 51° 3'. E. long. 14° 5'.

STOLTENBERG, a town of Pomerania; 10 miles S.S.W. of Corin.

STOLTZENBURG, a town of Transylvania; 6 miles N. of Herminenstadt.

STOMACACE, in Medicine, from corpus, the body, and stoma, an aperture, an erosion of, and spontaneous hemorrhage from, the gums and internal surface of the cheeks, together with an unifial feter of the mouth; it, in fact, a symptom of fever, or purpura, affecting that part. The term is sometimes used as an appellation of fever. See SCURVY and HEMORRHOEA.

STOMACH, in Anatomy and Physiology, (Ventriculus, Stomachus,) the large membranous bag, constituting the ampler portion of the alimentary tube; intervening between, and communicating with, the oesophagus and duodenum; receiving from the former the food which has undergone mastication, digesting it, or converting it into an uniform pulp, and transmitting it into the latter; situated in the upper part of the abdomen. It may be regarded as the commencement of the digestive apparatus; for in it the food undergoes the first change of properties in that series of changes, which ends in its assimilation to our organs: the oesophagus, which precedes it, serves merely to convey the aliment from the mouth; and the act of mastication is a simply mechanical process, auxiliary, but not essential, to digestion.

The stomach is a conical bag, being large at one end, and gradually decreasing to the other; hence the terms, greater or left, and small or right extremities (extremitas oesophagica, superior, major; cardia; and extremitas pylorica, inferior, minor; pylorus.) It has two openings: a circular one with smooth sides, and no thickened or elevated ring, which is the termination of the oesophagus, and called the superior, cardiac, or oesophageal orifice; a smaller, also circular, surrounded by a thick prominent ring, called the inferior or pyloric orifice, through which the digested aliment is transmitted into the small intestine. The stomach is of an irregular oval figure; the greatest circle is opposite to the termination of the oesophagus; from that point the diameter gradually diminishes to the pylorus, where the stomach is not larger than the duodenum. The stomach also diminishes from the oesophagus in the opposite direction, or towards the great end, and forms a small hemispherical blind bag (fundus, fovea cæcus), palling about two or three inches to the left of the ephaphal orifice. The two apertures, therefore, are differently circumstanced in their relation to the two extremities: the pylorus is actually at the right extremity, while the cardiac opening is placed two or three inches to the right of the left extremity. The conical tube of the stomach is incurvated towards its small end: two-thirds of the bag, from the great end, are straight; but the remainder is bent upwards or backwards, so that the pylorus is turned towards the cardiac orifice: hence these two openings are near together on the upper or back aspect, very far apart on the front or lower. The concave line joining them in the former direction is called the small arch or curvature of the stomach. The curvatures, included between these lines, are called the superior or anterior, the inferior or posterior. — For the best view of the human stomach, see plate xi. fig. 1., in the Phil. Trans. 1807, in illustration of a paper by sir Everard Home.

When the stomach is full, a vertical section of it, at any part, as we have already observed, is circular; when it is empty, its sides, formed of soft membranes, fall together. The organ, in the latter state, is quite flat. The size of the organ depends on the quantity of its contents, since its sides have the power of accommodating themselves to every variation of this kind. When perfectly empty, it is hardly larger than an inch. It is difficult to determine its capacity. Scourmeying says, that in an adult of middle stature it will hold, when moderately distended, from five to eleven pints of water. In various unnatural states, we find its capacity much augmented. Very frequently we find, after death, the great end more or less dilated, and the small extremity empty and contracted; often, too, there is a muscular contrition about the middle, dividing it imperfectly into two compartments.

The stomach is situated in the epigastric region, and chiefly in the left portion of that region; its long axis being nearly transverse, or croosing the axis of the trunk at right angles. The great extremity is placed in the left hypochondrium, with the spleen attached to it behind by means of the peritoneum, and the diaphragm in contact with it towards the front. It stretches across the vertebral column, and ends, by its lesser extremity, in the left hypochondrium. The small lobe of the liver covers it above, being interposed between the stomach and diaphragm, so that these are in contact for a small space only at the left: the pancreas and colon are in contact with it below. The oesophagus lies on the middle of the spine; the small curvature includes, in its curve, the lobulus Spigéli and the aorta. The esophageal cartilage does not answer to the middle of the stomach, but to its right portion: the pylorus corresponds nearly to the fundus of the gall-bladder, or to the notch between the two lobes of the liver. The openings of the stomach are placed farther back than the stomach itself; and this is particularly the case with the oesophageal: the latter is also higher in the body, by about two inches, than the pyloric. From the small arch, which is turned towards the spine, the small
SMSTACH.

Small omentum departs to the liver; the convexity of the great arch approaches to the front of the abdomen, and the great omentum descends from it in its whole length.

The stomach, therefore, occupies the space included between the false ribs, extending across the open interval between those of the right and left side; it does not usually descend lower than the margin of the chells, except when very full.

The relative position of the stomach is subject to change from many causes, particularly from its various conditions of fulness and emptiness. Its position in the dead subject may be called perpendicular; the bowels sink down to the pelvis, the support of the abdominal muscles is lost, and the parts naturally belonging to the epigastrial region descend into the umbilical. The oesophagus descends into the stomach, and the pylorus ascends; the great arch is turned downwards, the small upwards; the upper surface is now anterior, and in contact with the front of the abdomen; the other surface is posterior; the position of the spleen, following that of the stomach, is also perpendicular, with the two extremities turned upwards and downwards. The relations of the organ are different in the living subject; the retinence of the bowels, and the support of the abdominal muscles, carry the stomach higher; the anterior surface is at the same time rather turned upwards, and the posterior downwards; the great arch is forwards, the small backwards; and the oesophagus entering the organ, is rather inclined forwards. When the cavity is dilated, all these circumstances are more strongly marked; the anterior surface is now turned completely upwards, the posterior downwards; the great arch bends forwards against the abdominal parietes, the inferior is turned directly backwards. When the stomach is inflated, it rises upwards to the diaphragm, rather than extends downwards. The oesophagus close to the stomach is now horizontal; the pylorus, which ascends, now goes back transversely, and consequently descends in the supine position; the stomach may be so dilated, that the pylorus will rather descend. The pyloric end is brought up against the gall-bladder. In this state of things, the liver is rather comprised between the stomach and diaphragm. The spleen undergoes a corresponding change; its ends are now anterior and posterior, instead of superior and inferior.

The motions of the diaphragm, and changes of situation in other neighbouring organs, necessarily affect the position of the stomach. When the diaphragm descends in inspiration, the stomach is pushed down into the umbilical region; and this change is permanent, when any permanent cause in the thorax protrudes this muscle towards the chest; as collections of pus or water, enlargement of the heart, &c. When the whole of the great omentum is protruded in a hernia, the stomach is drawn down by it more or less: the pylorus, from such a cause, has been seen at the abdominal ring. The stomach has pilled through fibres of the diaphragm into the chest.

The organ is held in its situation by various connections. The oesophagus, with which it is continuous, unites it to the fluffe of the diaphragm, being surrounded here by a loose cellular tissue. The continuity of the pylorus with the duodenum confines it in a similar way on the opposite side. By the little omentum its small curvature is connected to the under surface of the liver; by the great omentum, the great arch is united to the spleen and colon. (See Epiploon.) Further, two folds of peritoneum are observed, under the name of ligaments; one connecting the termination of the oesophagus to the diaphragm (ligamentum phrenico-gastricum), the other passing between the diaphragm and the spleen and fundus of the stomach (рюсто-гастральное). Thus the two ends of the stomach are connected backwards, and form two fixed points, between which the organ rises and sinks, according as it is full or empty: the principal effect taking place at the great curvature, or the situation most distant from these fixed points.

Structure of the Stomach.—It consists, like the rest of the alimentary canal, of three coats: a serous, a muscular, and a villous; which cannot be better demonstrated than on the cut surface of a simple incision. There is nothing peculiar in the structure and disposition of the former. It is thin, quite transparent, close in its texture, firmly connected to the muscular coat; and it gives the whole exterior of the stomach a polished surface. At the two arches, the serous coat does not adhere so intimately to the muscular: here the omenta are connected to the stomach; and between their two layers the blood-vessels and nerves of the organ run, surrounded by a copious cellular tissue. In this situation, confluence, the stomach is not covered by serous membrane. For some distance from the curvature, on each side, the peritoneal coat can be easily separated by deflection. When the stomach is dilated, it rises in these situations into the intervals of the two omental layers, which are then applied on its surface; while, in the empty state, they are in contact with each other.

The muscular covering is the thickest portion of the organ, enabling it to execute the motions which are necessary in the performance of its functions. It consists of a thin, nearly uniform layer of fibres, spread out into one continuous sheet like a membrane; and it will, of course, appear thicker or thinner, according as the stomach is contracted or expanded. Independently of this circumstance, it seems to be naturally thicker in the pyloric than in the cardiac portion of the stomach. The colour of this fibres is pale, not red, like those of the voluntary muscles. Two orders of fibres are easily distinguished, longitudinal and circular. The former are exterior, and much the fewest in number: they consist of the longitudinal fibres of the oesophagus, expanded in a radiated form in all directions from the end of that canal over the stomach. The most considerable of them run along the small arch as far as the pyloric end, and may then be called circular. Others go towards the great cul-de-sac; and some few are scattered over the two surfaces. These longitudinal fibres decussate the circular ones obliquely at different angles, and mix with them, ending amongst them. The circular fibres are much more numerous, and form a continuous covering over the whole stomach. They are rather thin at the great cul-de-sac, but they increae in thickness towards the opposite end. They form numerous rings parallel to each other, connected together, and extending from one extremity to the other. The individual fibres do not surround the stomach itself; but one ends, and another begins; and they partly turn aside to mix with other fibres. These circular fibres are continuous with those of the oesophagus on one side, and with those of the duodenum on the other. At the pylorus they are collected into a thick ring, which forms the constrictor of the canal at that part.

The mucous membrane, forming the internal surface, is the most important part of the stomach. It does not perform the same power of accommodation to various capacities, as we find in the serous and muscular coats: hence, although it is smooth when the stomach is distended, it is collected all over the organ into numerous prominent folds, or rugæ, when the stomach is empty, and its cavity is contracted. The mucous coat is connected to the muscular by a very copious and loose cellular tissue, so that it can easily accommodate itself to the contractions.
STOMACH.

trations of the latter. These rugae, which we see even in a half-filled stomach, consist merely of the mucous membrane; the feros and muscular have nothing to do with them. When the cavity is very empty, the rugae lie so close that they touch each other laterally: if the coats of such a stomach are dilated in any way, all these prominences disappear. The principal fibres of the stomach being circular, and their contraction consequently taking place in the transverse direction, the folds produced by this cause are longitudinal, or follow the long axis of the stomach: these, which are the principal, are joined by smaller lateral folds. The cellular substance on the external surface of this membrane is the nervous coat of Haller, and other anatomists. It is soft, copious, white in its colour, and raised by inflation into the appearance of a downy or cottony texture. The blood-vessels of the organ ramify in this, before they enter the mucous surface.

Besides the great folds of the mucous membrane, we observe several little considerable ones, composing a net-work with larger or smaller intervals: these are all destroyed by extirpation. The mucous membrane then appears as a smooth surface, but soft and rather pulpy: it is the kind of surface called villous, which is the name usually given to the membrane, although it does not possess the fine pointed processes which constitute the villi of the small intestines. The mucous membrane, in its most recent state, has a tint formed by the mixture of a very light red and a Straw colour. Its true character is not easily seen, as the surface is generally covered by a closely adhering tenacious mucous layer. Soon after death, the transudation of the blood through the blood-vessels gives a different colour to the mucous membrane. Often, even in the healthiest subjects, there is considerable vascularity observable in the mucous surface of the stomach; and more particularly when death has been accompanied by circumstances, which might impede the return of the venous blood. This appearance (which does not indicate any disease of the organ) has been often deemed the result of inflammation. (See a paper by Dr. Yelloy, in the fourth volume of the Medico-Chirurgical Transactions.) The capillary fylem exists in great abundance in the mucous membrane of the stomach; so that it becomes more or less red, when the blood-vessels are injected with size and vermin.

It has been a question, whether the fluids secreted from this surface are exhaled from its capillaries immediately, or are secreted in a distinct apparatus of mucous glands. The latter are not easily seen, but they have been described by several anatomists. After describing them in various animals, Haller says, "they are not equally evident in man: I have generally been able to observe pores, which are visible all over the surface, and more numerous about the pylorus; from these, mucous fluid can be expressed. Others describe excretory ducts, and orifices, and fluids exuded from them. Once or twice I have seen the glands themselves, of the nature of crypts, fimple, round, membranous, hollow, situated in the cellular membrane under the mucous coat, and perforating the latter by their short ducts." (Elem. Physiol. tom. vi. p. 130.) Soemmerring speaks of the orifices of mucous glands as being visible about the pylorus; but not always very conspicuous. (De Corp. Hum. Fabr. tom. vi. p. 223.) Lastly, they are delineated in considerable number, along the small curvature of the stomach, in the figure already referred to, published by Sir E. Home.

The mucous membrane of the stomach is continuous with that of the oesophagus on one side, and with that of the duodenum on the other; but differs clearly in its structure from both. The lining of the oesophagus has nothing villous in its structure, which is compact, smooth, and remarkably white; it is produced into the esophageal orifice of the stomach, round which it terminates in a feathern border. See Sir E. Home’s plate.

The communication between the stomach and duodenum is formed by the pylorus (janitor, punctum), a contracted orifice surrounded by a thick ring. The feros membrane and the mucous are the same in the pylorus as elsewhere: the ring is formed by a thickness of circular mucous fibres. Soemmerring speaks of the pyloric ring being composed of "peculiar glandulose pannus substantia:" but this does not accord with our own observation. The folds of the mucous membrane pass through the pylorus into the duodenum; consequently the orifice is plaited internally. If the stomach and duodenum be laid open after death, without distending the parts, the pyloric orifice will be found about equal in diameter to a goose-quill, and in circumference plaited. The finger can, however, be easily forced through it, enlarging the opening, stretching the muscular ring, and destroying the folds. It then appears a simple circular opening, with a thick prominent edge. If the small end of the stomach and the neighbouring portion of the duodenum be inflated, the pyloric constriction is very visible externally: if such a preparation be dried, it appears as if a string had been tied round, and on cutting the parts open a transverse production is seen, perforated in its middle by a circular aperture. Some unimportant varieties of figure have been observed in this opening: viz. it has been seen oval, or oblong, &c. instead of circular.

The orifice of the pylorus, as its name implies (from κατα, a gate, and ὑπό, a keeper), is to prevent the entrance of the intestine, and prevent the passage of the alimentary matter, until it shall have sufficiently undergone the action of the stomach. Its mucous structure enables it to accomplish this effectually; for it can contract so completely as to shut the opening, in which state it is sometimes found after death; at the same time it has the power of relaxing, and thus allowing the alimentary pulp to pass. This contraction and relaxation are probably regulated by the existence of some relations between digested and undisgorged substances, and the peculiar formibility of the organ: there is no mechanical explanation of the phenomenon, which is quite a vital process. The resistance of this muscular ring is different in the case of solids and fluids; it allows the latter to enter the intestinal canal easily, as we find from the rapidity with which they gain admission into the circulating fylem; and also from the short time after drinking, in which they flow out from the intestine, when an unnatural external opening from its canal gives us the opportunity of observation. Although the pylorus is commonly found after death of the dimensions already specified, we cannot doubt that it is much larger during the passage of the chyme; indeed we occasionally find solid substances of considerable dimensions passing this part. This is principally the case with pieces of coin, swallowed either by accident or design. Vaillant, a celebrated French medallist, swallowed twenty valuable gold medals, when purified by corrosors: the processes of nature restored him the treasure in a short time; and he sold one of them, by anticipation, before it had made its appearance. A boy is mentioned by Habicot, in his "Question Chirurgicale fur la Bronchotomie," who swallowed several pieces of coal, which were recovered in the same way. Half-crowns, we believe also crown-pieces of this country, have travelled safely through the alimentary canal.

The arteries of the stomach are numerous, and some of them large: they are all branches of the celiac, or its primary ramifications: viz. coronaria ventriculi, pylori, galle-
gastro-epiploica dextra and sinistra, arteriae breves. The trunks of these vessels lie principally on the curvatures of the stomach, surrounded by a loose cellular tissu, and at a small distance from the organ, in its empty state: their branches communicate most freely with each other in all directions, both by large and smaller innumerable anastomoses: they are tortuous, and thus can accommodate themselves to the full and empty state of the cavity. They penetrate the muscular coat, without producing very considerable branches to be distributed on it, giving still fewer and smaller to the ferosus, and form an extensive minute network in the copious cellular texture of the mucous coat, from which such an abundance of branches enter the mucous surface, as to occasion it to assume, all over, the colour of any fluid injected into the arteries of the stomach. See Artery.

The veins accompany the arteries, larger in size, and forming larger communications: they are without valves, as is the caesophagus with the vena portarum; and they terminate by several small trunks, either in the splenic vein, or in the trunk of the vena portarum. See Vein.

The nerves of the stomach are from the eighth pair, of which the two cords penetrate the diaphragm with the eocio-phagus, and divide into numerous branches, which form an intricate plexus along the small curvature, closely adhering to the arteries, of which they follow the ramifications. Several branches come to this plexus from the celiac ganglia, and there are also communications with the hepatic plexus. See Nerve.

The absorbing vessels of the stomach are much smaller than those of the small intestines, and have transparent contents, instead of the opaque milky fluid seen in the latter. Like them, however, they may be divided into superficial and deep seated. From both surfaces of the stomach they partly go to the glands of the smaller arch, scattered in the omentum, and partly join the absorbents and glands of the spleen. They unite and form a plexus with the lymphatic vessels of the liver and ferosus omentum, pass behind the pancreas, and uniting with those of the spleen and intestines, end in the thoracic duod. Others accompany the blood-vessels on the great arch, proceeding to glands in the omentum, and having formed various plexuses, proceed above and behind the pancreas, to glands about the celiac and superior mesenteric arteries, terminating in the thoracic duod.

Functions of the Stomach. - The masticated aliment, and the drink, are received into this bag, brought into contact with its mucous membrane, exposed to the action of the fluids poured out by the latter, and variously moved by its mucous fibres. We have to consider, therefore, the phenomena exhibited both by the muscular and the mucous parts of its structure.

The mucous surface of the stomach, as the experience of every individual must have instructed him, possesses the power of secreting warmth and cold. But it is not sensible to the properties of the substances usually received into it, as their weight, their odour, taint, &c. their temperature within certain limits, their state of solidity and fluidity, &c. &c. So far as the stomach is concerned, we could not distinguish fugar from jasolp, or wine from medicine. Spirituous and tpicy substances are, however, perceptible by a kind of warmth which they excite. The stomach is the seat, on the other hand, of feelings peculiar to itself, resulting from relations between various substances and different states of the body, and its organisation and peculiar senstibility. Hunger and thirst, satiety, squeamishness, nausea, &c. are examples of these.

Different chemical and vegetable substances produce specific effects on the stomach, which are not in proportion to any of their sensible qualities: various substances, insipid or nearly so, disturb it most vehemently, while others of powerful taste and acrid nature, as the strychnine and phenter mine, which heat the whole frame, do not affect it. The distilled water of the laurocerasus, emetic tartar, and several others, are of the former kind, although they hardly excite pain in the conjunctiva of the eye. Cinnamon, pepper, and mustard, of which the slightest contact with the eye would produce excruciating agony, are not felt in the stomach.

Great variety is observed, in different animals, in the effects of various substances, both chemical and vegetable, on the stomach. Conium maculatum, hyofozymus, euphorbium, and hellebore root, are poisons to man; while conium affords wholesome food to the cow and hare, hyofozymus to the pig, euphorbium to the goat, and hellebore to the quail. A quantity of opium or arsenic, that would destroy a man, may be taken with impunity by a dog, which, on the contrary, is much more affected than man by a given dose of jalap or nux vomica. Bitter almonds, which we eat with impunity, are poisonous to dogs and various birds: the mountain parsley is fatal to parrots.

Like other parts, the stomach becomes accustomed to stimuli, and can bear larger and larger quantities of opium, of aromatic, and tpirituous substances.

Although, in its natural state, the stomach possesses but slight animal senstibility, it exhibits the most acute feeling under disease. Cramp of the stomach, and inflammation of the organ, are as painful as any affections of any parts of the body.

The most important circumstance in the physiology of the stomach, is the secretion performed by its mucous membrane. The nature of this, and the changes it produces in the food, are considered in the article Digestion.

It is an interesting subject of inquiry, how far the secretions of the stomach, and consequently the process of digestion, are influenced by the brain, which is the immediate source of its nerves. It is not easy to determine the point, because the eighth pair supplies the lungs as well as the stomach; consequently the division of these nerves produces effects on the process of respiration, which are too fatal. On the other hand, if they are divided on the eocio-phagus in the abdomen, the injury is too great for the animal to survive in such a way as to enable us to judge of its digestive powers. The experiments hitherto made tend to shew, that the brain influences the stomach through the eighth pair. Le Gallois divided one nerve in a Guinea pig of eighteen months: the animal breathed tolerably well, and continued to eat; but the belly increased proportionally in size. It died four days and five hours after the operation: the stomach occupied nearly the whole abdomen, dilated with food very little altered from the state in which it had been swallowed. Experiences for le Prinpe de la Vie, p. 214.

Mr. Brodie found, that the mucous and watery secretions, which delfend the stomach and intestines in animals poisoned by arsenic, do not take place if the nerves of the eighth pair be previously tied, either in the neck, or in the cardia. Phil. Trans. 1814, p. 102.

It is well known that emetic tartar, injected into the veins, produces vomiting as certainly, as when introduced into the stomach: it has the same properties when brought in contact with any mucous or serous surface, or with a wound. Mr. Magendie found that twelve or eighteen grains injected into a vein will kill a dog in half an hour. But if the nerves
nerves of the eighth pair be immediately divided, death does not take place till three or four hours after the injection. This physiologist selected three animals of the same age and weight, and injected into the veins of each twelve grains of emetic tartar. He divided one nerve in one dog; both trunks in another; and neither in the third. The latter died first; then the first, and the animal in whom both nerves were divided, lived the longest.

The muscular fibres of the stomach contract its cavity, and thus propel its contents, when they have been sufficiently acted on by the gastric fluid. Being longitudinal and circular, they can diminish the tube both in its length and breadth. The fibres contract and relax in various situations successively, and thus produce an appearance similar to that of the contractions and relaxations of the intestines; this is called the peristaltic motion of the stomach. These motions are not only visible when the organ is irritated in a living animal, but they may be seen on opening the abdomen of those recently slaughtered. The power of contraction continues for some time after apparent death, on the application of stimulants; and it may even be excited in a portion of the stomach cut out from the rest.

This contraction is completely foreign to the will: it takes place without our consciousness, and seems to result from the presence of the digested aliment. If diseased of the pylorus, or any other cause, prevent the passage of the food into the intestines, its presence irritates the stomach, and provokes its rejection by vomiting.

While the stomach is empty, it remains at rest; when the gastric secretions have acted on the food, we have already said that the muscular contraction of the organ expels the chyme through the pylorus. What is the state of the stomach, in respect to its muscular part, while digestion is going on? Is the organ at rest? or is there a peristaltic motion, by which its contents are agitated, expelled successively to the mucous surface, and more intimately mixed with the gastric secretions? Physiologists in general seem to admit the latter opinion, but we believe without any very direct proofs; which, indeed, it is not easy to obtain, as the division of the abdominal muscles, and the exposure of the stomach, cause an universal disturbance, instead of unveiling to us the natural state and actions of the animal organs. "It must be allowed," says Haller, "that for some time the action of the stomach does not direct the food to any certain point, but that the contents are driven to and fro by a peristaltic and antiperistaltic motion, which latter has been by some writers improperly disallowed. So long as both its orifices are shut, either the stomach must rest, or the food must be driven backwards and forwards. This agitation lasts while the oesophagus is closed, and the pylorus remains contracted; it ceases, when either the former or the latter gives way to the food." (Elem. Physiol. lib. xix. sect. 4. § 10.)

The stomach may contract in such a manner as to give its contents a direction contrary to their natural passage downwards; this is called the antiperistaltic motion. In this way air is expelled from the stomach in eructation, and an acid liquor rises into the throat after feeding on indigestible matters, or in the affection of heartburn. In indigestion, the breath is often tainted in this way by stomachic impurities. Vomiting was considered also a result of this antiperistaltic contraction of the fibres of the stomach. Experiments on living animals, however, made this latter point doubtful. Bayle put his finger into the stomach of a dog, after giving him an emetic, and fearlessly found the organ move; he observed further, that vomiting was stopped by opening the abdomen, and renewed when the wound was closed up. Chirac found that the stomach, by its very feebly, if at all, under the action of an emetic; so that the violent symptoms of vomiting could not be explained from this cause. Other experimenters met with similar results, finding that the irritation of the stomach did not produce vomiting; that very little antiperistaltic motion of the stomach took place, or came on late in the process. Such was the result of Haller's investigations. The action of the respiratory powers was pointed out by Weffer as the explanation of the phenomena of vomiting; he observed it in different animals, and has expressly referred to the diaphragm and abdominal muscles as the cause of this action, the stomach being nearly inert. The refarches and observations of other inquirers led them to the same result. "If," says Haller, "you observe a man who is sick, you will soon see that the stomach and respiratory muscles are both concerned. The original cause is in the stomach: the nausea, anxiety, feeling of depression approaching to fainting, and taking away all power of exertion, with pale face, small and weak pulse, have their seat in the stomach, and in the nerves affected by sympathy with the stomach. The organs of respiration come into action, and a violent effort or straining takes place, marked by the most unequivocal signs: a deep inspiration, congelation of blood in the head, and pain, redness of the face, heat of the forehead, not infrequently actual rupture of vessels, and copious sweat as from the greatest excretion. The effects of vomiting are too violent to be attributed to the stomach: among them we may mention rupture of the oesophagus, protrusion of the stomach through the diaphragm into the chest." (Elem. Physiol. lib. xix. sect. 4. § 14.) To the same effect, Sommerring calls vomiting "motus ventriculi peristaltico inverius, cuius vis, adjuvante cum vehementissima diaphragmati et muscularum abdominis actione, contenta in ventriculo per oesophagum atque oesophagio impetu ejiciuntur." De Corp. Hum. Fab. t. vi. p. 269.

The examination of this subject has lately been resumed in France, and an interesting series of experiments, presented to the National Institute, has been published by their author, M. de Mazenod, in order to prove that it is all together inert in the act of vomiting. When one or two fingers were introduced through an opening in the abdominal parietes, it was found that the stomach did not act in vomiting; but that the diaphragm and abdominal muscles compressed it so as to expel its contents. At each retching, the action of the respiratory muscles could be felt, while the stomach was emptied without any diminution of volume, atmospheric air supplying the place of its rejected contents. When the incision was enlarged, so that the stomach could be brought out through it, vomiting was at end. The retchings and efforts at vomiting could be renewed by placing the hand so as to compress the stomach. When brought out of the abdomen, and not compressed, it remained quiet, although emetic tartar was injected into the veins. The abdominal muscles being removed, vomiting was full produced by the action of the diaphragm compressing the stomach against the linea alba. If the phrenic nerves were divided fo as to render the diaphragm motionless, vomiting could no longer be excited. Lastly, having tied the arteries of the stomach, Mr. Magendie removed it, subliniting in its place a pig's bladder, containing a coloured fluid, which he connected to the oesophagus by means of a cannula, then fewed up the abdomen, and injected emetic tartar into the veins. In a few minutes nausea was produced, and efforts at vomiting, and the animal actually vomited the contents of the bladder. On opening the abdomen again, it was found, that, on each effort
effort to vomit, air passed into the bladder as if it had been the stomach itself. The author concludes from these facts, that emetic tartar injected into the veins does not act on the aliment as is generally believed; but determines a convulsive action of the diaphragm and abdominal muscles. Mémoire sur le Vomissement, 8vo. 1815; or Journal de Corvisart, tom. xxviii. p. 184.

Another inquirer has taken up the same investigation, and has arrived, by experimental inquiry, at conclusions directly contrary to the preceding. After opening the abdomen, and removing the abdominal muscles, he strangled a portion of the intestines, and thus produced vomiting. When he had divided the pericolic nerves, and confirmit the intestines through a small opening in the abdominal parietes, vomiting still took place. It even took place whenever any thing was introduced into the stomach, after cutting the pericolic nerves, dividing the abdominal muscles, and taking away a portion of the diaphragm, as far as the tendinous portion of the intestines was strangulated, as in the preceding experiments. He produced vomiting by injecting tartar emetic into the veins, after the abdominal muscles and diaphragm had been removed; so that the effect could not arise from any action of the emetic on those muscles, as is asserted by Magendie. Thence and other experiments in the same effay restore the stomach to the full enjoyment of its former rights, from which it seemed on the eve of being degraded, and to prove, that the diaphragm and abdominal muscles are altogether inert in the act of vomiting. Mem. for le Vomissement, par M. Maingault, 8vo. 1815; or in Corvisart's Journal, tom. xxviii. p. 193.

As the two experimentallists, whose researches we have just detailed, do directly contradict each other, we suppose that the point cannot be settled without a fresh slaughter of dogs, and a renewal of these truly barbarous and disgustful experiments. Our own opinion inclines to the side of Mr. Magendie, from observing the phenomena of vomiting both in ourselves and others; and the muscular power of the stomach, apparently calculated for the mere purpose of expelling the food through the pylorus, seems to us quite inadequate to account for the vehement and forcible rejection of the alimentic contents in vomiting. Yet we cannot but entertain doubts about the (at first sight certainly) paradoxical statement, of vomiting being excited when the stomach had been removed.

The causes that excite vomiting are numerous and various. Overloading the organ, and particularly with unusual mixtures of food and drink; the introduction of various animal, vegetable, or mineral substances called emetics; warm water, or atmospheric air; the injection of emetics into the veins, or the application of them, at least of arcanis, to a wounded surface; the dragging of the omentum in a hernia, the irritation of a broken rib pressing on it; obstruction in the course of the alimentary canal, &c.; inflammation of the stomach, or disease of the pylorus; injuries of the head; calculi passing the ureters; pregnancy; particular motions of the body, as swaying, riding backwards in a carriage, turning round; to this head we may also refer fea-fickenes; certain impurities on the organs of sense, as touching or seeing a disgusting object, disagreeable smells or tastes, tickling the fauces, &c. &c.

The causes of vomiting now enumerated are so different from each other, that we cannot expect to find out any circumstance in which they will all agree. There can only be three characters of circumstance of their action on this viscus; they irritate it, and vomiting seems to be the common result of such irritation. Is the vomiting produced by an impression terminating in the stomach itself; or does it take place through the medium of the nerves? There are not, we believe, sufficient facts to determine this point.

As the digested aliment supplies the blood, which affords to all parts of the frame the materials of nutrition, growth and action, the right performance of digestion is a matter of the highest importance to the whole body; hence all parts sympathize with the stomach, which, in its turn, is affected by the various fluxes of all other organs. When it is healthy and vigorous, we have a general feeling of strength and capacity for exertion. On the contrary, every faculty of body and mind seems to languish, when the stomach fails, as in dyspepsia and nausea. Acute diseases of this vital organ testify its importance by the alarming sympathetic disturbance of the whole economy. A violent blow on it is sometimes immediately fatal. As digestion is ill or well performed, we are more or less sensible to external heat and cold, to the qualities of food and drink; the senesces are more or less acute, and the passions of the mind affect us more or less easily. The fame morbid causes produce different effects according to the condition of the digestive function: when it is unhealthy executed, wounds, even in the most dilatant parts of the body, are much more dangerous; and their state will be immediately changed, as soon as healthy digestion returns. The existence of impurities in the stomach, as indicated by a foul tongue, tainted breath, flatulence, &c. during any great suppurations, is not unfrequently attended with delirium and convulsions. In a word, there is hardly a disease, which is not either produced or aggravated by disorder of the stomach, indigestion as it is called.

The fact is so obvious, even to common observation, that the general debilitation and oppression of the frame from a loaded stomach have been described by poets.

At simul affici
Mifericus elixa, simul conchylia turbidis;
Dulcia se in blem vertent, stomachoque tumultum
Lenta feret pituita. Vide, ut pallidus omnis
Cana defurgat dubia? Quin corpus omnium
Heclernis vitis, animam quoque praegravat una,
Atque affigit humo divinae particularis urae.

No part is more quickly or remarkably influenced than the stomach, in all important general affections of the frame; and the state of this organ affords an important indication in the attack, progress, and decline of the disorder. Sicknese is an early symptom in most fevers; the appetite is entirely destroyed; its return and increase are the surest criteria of abated disease and convalescence.

Hardly can any part be disordered, as the eye, nose, &c. or any internal organ, or a joint, without sympathy of the stomach.

The sympathy between the head and the stomach is seen in the effects of various poisons, which, when introduced into the latter, quickly put an end to sensation and voluntary motion (see Poison): in the phenomena of feb head-ache, as it is popularly and properly called (see cephalalgia); in the fibroflatus, dilated pupil, itching of the nose, headache, palefnes, delirium and even convulsions produced by worms in the stomach: in the palsy and apoplexy produced by a full meal: in the squeamishness and even fickenes caused by seeing or thinking of a disgusting object, &c. &c.

Numerous phenomena evince the influence of the stomach upon the heart: as the hurried circulation from eating or drinkingstrong or warm substances; the intermittent pulse, palpitation of the heart, &c. caused in some individuals by particular articles of food. We fee the heart influencing the stomach, when sickness attends syncope. The cough
arising from a loaded stomach, and even called the stomach cough, or from a wound of the stomach, and the effects of emetics in distresses of breathing, together with analogous occurrences, exemplify the mutual influence of the stomach and lungs. In hiccup, the diaphragm is influenced by the stomach, ticknails attends inflammation of the kidney, and the passage of calculi through the ureters. How powerfully the uterus acts on the stomach, is seen in the nausea, ticknails, heartburn, and depraved appetite attending pregnancy. The state of the skin in dyspepsia and other stomach affections, and the numerous cutaneous diseases, either caused or aggravated by disturbed digestion, clearly shew us the great mutual influence of these parts.

Respecting the circumstances which attend the introduction of poisons into the stomach, and the manner in which they prove fatal, we refer the reader to the article Poison.

STOMACH. Diseased of the. The principal diseases to which the stomach is liable, are, inflammation; the various modifications of dyspepsia, or indigestion; and some chronic changes of its structure, which are not readily influenced by physical remedies. The two former classes of these maladies have been treated of at considerable length under their respective heads, to which we refer the reader. The acute inflammation of the stomach is described under its nosological term Gastritis: and the varieties of Indigestion are detailed under that head; and more particular explanations of certain modifications or symptoms of it, under the heads Cardialgia, Hematemesis, Gastrodynia, Nausea, Pyrosis, &c. It remains in this place only to notice those chronic diseases of structure in the stomach, which could not be included under these heads, and which are not capable of being much relieved by art. The nature of these is chiefly ascertained by an examination of the organ after death.

Both the apertures of the stomach are liable to be contracted, or to be the seat of stricture, as it is technically called, under which considerable suffering is produced. A stricture of the cardia, or upper aperture of the stomach, may be distinguished, according to Dr. Pemberton, from other diseases of that organ, or of the neighbouring parts, by the production of pain on any attempt to swallow solid food. This pain has something peculiar in its nature, and is described by the patient as very different from what is generally understood by the word pain. It is a sort of tender, circumcised sensation about the pit of the stomach, striking through to the back, and producing a feeling of incipient suffocation. This continues till the food is rejected, which is done by an effort very unlike vomiting. It seems to approach nearer to that effort which occasions hiccup. After this rejection of the food, the patient obtains relief. In consequence of the inability to pass a sufficient quantity of nourishment through the contracted passage into the stomach, the body becomes very much emaciated into a degree, that a tumour surrounding the cardia may be discovered by a careful investigation in the region of the stomach.

A more common situation of stricture is in the lower aperture of the stomach, leading into the intestines, which is called the pylorus: this, however, fortunately, is also a rare disease. Dr. Baillie mentions one case, which fell under his observation, in which the contraction was so great as hardly to admit a common goose-quill to pass from the stomach into the duodenum, and it had prevented a number of plum-romes, which were therefore detained in the stomach; and he supposes that the pallage may in some cases be entirely shut up. This stricture occurring in the pylorus may be distinguished from stricture of the cardia, by the food readily passing into the stomach without exciting pain; and when it is thrown up it is by vomiting, and not by the peculiar effort before mentioned, when speaking of stricture of the cardia. After the stricture of the pylorus has continued some time, the body generally becomes emaciated, as but little nourishment can pass into the intestine to be taken up by the lachesis, and the tumour, as in the former case, can then be discovered by examination of the abdomen. Pemberton on Diet of Abdom. Viscerae, chap. vii.

Ulcers of the stomach occasionally occur, and have been described by Dr. Baillie as sometimes resembling common ulcers in any other part of the body, but frequently having a peculiar appearance. Many of them are scarcely surrounded by any inflammation, nor have they irregular eroded edges, such as ulcers have generally, nor are they attended with any particular distended alteration in the structure of the stomach surrounding them. They appear very much as if, some little time before, a part had been cut out from the stomach with a knife, and the edges had healed, so as to present an uniform smooth boundary round the excavation which has been made. These ulcers sometimes destroy only a portion of the inner coat of the stomach at some one part; but occasionally they destroy a portion of all the coats, forming a hole in the stomach. It is probable that these ulcers of the stomach are often flow in their progress. They are attended with pain, or an uneafy feeling in the organ, and what is swallowed is often rejected by vomiting. This state of disorder often continues for a considerable length of time, and is little relieved by medicine, which may serve as some ground of distinction between this disease and a temporary deranged action of the stomach. Baillie's Morbid Anatomy, chap. vii.

Schirius and cancer of the stomach are not uncommon affections at an advanced period of life. They appear to be more frequent in men than in women, which Dr. Baillie supposes may arise from the greater imperfection of the one sex than of the other. He admits, however, that these diseases are not entirely produced by intemperance, but only where intemperance concurs with a strong predisposition to them. It is surprising to find the very extensive mischief which the stricture of the stomach has in some instances undergone without the constitution being sensibly affected by it, provided the mischief is so situated as not to interrupt the palage of the food. Dr. Pemberton mentions that he has seen a large schirius in the stomach, near the pylorus, with an open cancer in one part of it, which had made its way through the stomach, and through the left lobe of the liver; and an adhesion had taken place between the fides of the abscess and the peritoneum: to that had not the patient been carried off by a disease in the aorta, it was probable that this abscess would have made its way out through the integuments of the abdomen. Still however, though this must have been a disease of very long standing, the body was but little emaciated, and the patient had never shewn any one symptom, by which such a disease of the stomach could possibly have been suspected. The writer of this article witnessed the existence of a most extensive cancerous condition of the interior coat of the stomach, in which many large tubercles were found in a state of ulceration, in an elderly man, who, however, was not much emaciated, and who had never exhibited any more feverish symptoms, than those of flight indigestion, and, therefore, none that could lead to a fulmination of such an extensive and formidable disease. In general, however, when the schirius has ulcerated, and formed what is called open cancer, there is a constant pain, though varying in degree, and which is increased by taking
STOMACHIC, a medicine that strengthens the stomach, and promotes the office of digestion.

Of this kind are wormwood, rhubarb, mint, mallow, aloe, pepper, cinnamon, and aromatic bitters: good wine is also a stomachic.

STOMACHIC, in Anatomy, a name sometimes given to the arteries, nerves, &c. of the stomach.

STOMACHIC Corrosion. See CORROSION.

STOMACHIC Elixir. See Elixir STOMACHIC.

STOMACHIC Pills. See PILLS.

STOMACHIC Water. See WATER.

STOMACHICA Fever, the stomachic fever, a name given by Heister, and some others, to a species of fever, called by others a melenetic fever, and by our Sydenham nova febris, in a peculiar treatise. See FEVER.

STOMATIA, in Natural History, the name of a genus of shell-fish, frequently confounded with the ear-shell.

The shell of the stomatia is formed of one piece, has no perforations in any part of its surface, and is of a depressed flat figure; and its mouth is the most patent of all the univalve shells, the limpet only excepted. It has a short spiral turn running into the mouth at the head.

There are several species of this genus.

STOMATICA, a term used by fome for all medicines used in disorders of the mouth.

STOMBLE, in Agriculture, provincially a term which signifies to trample or poach, as a wet foil by means of cattle flock, or in the time of ploughing, &c.

STOMOXYS, in Entomology, a genus of insects of the order Diptera: the generic character is: Sucker with a single-valved sheath, enclosing bristles in their proper sheaths; two feelers which are short and tefaceous, with live articulations; the antenna are tefaceous. There are sixteen species, in two divisions.

Species.

A. Sheath convolute and geniculate at the Base, with two Brilles.

MORIO. Black; fore-part of the thorax hairy, ferruginous; wings black, with white spots. This is found in Brazil. A specimen of it exists in the museum of Sir J. Banks. The head is ferruginous, with black proboscis, antenna, and femmata; abdomen black, with a blue glofa; the tips of the wings are whitish.

GRISA. The antenna of this species are feathered; hairy, grey, with tefaceous thighs. It is found in Germany. The proboscis is black, a little tefaceous at the base; the head is white, with a tefaceous line on the front; the wings are whitish; the legs black, with rufous thighs.

SIBIRIA. Antenna feathered; hairy, grey; sides of the abdomen pale diaphanous. It inhabits Germany. Orbits brown; legs black, with pale thighs.

CALCITRANS. Antenna slightly feathered; grey, with black legs. This very much resembles the common fly, and is the insect which buzzes about the legs of cattle, making them continually flap with the feet; and which flings our legs in autumn.

TESSELLATA. Hairy, cinereous; abdomen grey, telfelate with brown. It inhabits Kiel, and is larger than the S. irritans, next to be described.

IRITANS. Cinereous, slightly hairy; abdomen spotted with black. This is found in many parts of Europe, as well as in our own country, and is extremely troublesome on the backs of cattle.

MUSCARIA. Antenna slightly feathered; hairy, black; abdomen paler, with deep black bands. This is found in Denmark.
STO

Denmark. The segments of the abdomen are black at the base; the wings are white.

PENGUINS. Cineous, with black 'thighs. It is found in divers parts of Europe, and harlees cattle, though it is of a diminutive size. The body is lightly hairy; the wings whitish.

Asiliformes. Antennae facetous; the body is dusky; wings with black marginal spots. This is found in Italy. Theucker is short and yellow; the antennae are yellow, with a long filpne hair; the legs are yellowish, hind-thighs black.

Stylata. Cineous; abdomen rufous, with a projecting style, black at the end; wings hyaline, with five brown bands, every other one abbreviated. This inhabits Barbary.

Dorsalis. Black; abdomen mowy on the back, with three pair of black dots. It inhabits France, and is small.

Longipes. Orbits white; thorax grey; abdomen grey-brown; legs ferruginous, black at the ends.

B. Sheaths covering the Mouth, with five Bristles.

Rostrata. Thorax with obscure lines; probosces, abdomen, and legs, telfaceous. It resembles the common fly, and is very troublesome to cattle.

Lineata. Thorax black, with four white lines; abdomen black, with three lateral yellow spots, and tail. It is found in Germany. The proboscis is yellow, the tip emarginate and black.

Musiformis. Thorax brown, with four whitish lines; abdomen black, with three pair of white lunules. This is also found in Germany. The antennae are black, with a broad compressed fuscous club; the mouth is hairy; the head is brown; the tail is bluish; legs yellow, spotted with black.

STONED, in Rural Economy, the provincial name of a bearing tub, or any similar sort of vessel of the same kind.

STONE, EDMUND, in Biography, a native of Scotland, the place and time of his birth being unknown, and an excellent mathematician. He was the son of the Duke of Argyile's gardener, and probably born in the times of Argyile, about the beginning of the last or end of the preceding century. He was eight years old when he began to read; but afterwards he made very rapid progress by his own almost unrivalled efforts. Before he attained the age of eighteen years, he had acquired a knowledge of the most sublime geometry and analysis without a master. When he was asked by the duke of Argyile, how he had gained this knowledge, he replied, "I first learned to read; and the masons being at work on your house, I faw that the architect used a rule and companions, and that he made calculations. Upon inquiry into the use of these things, I was informed there was a science named arithmetic; I purchased a book of arithmetic, and I learned it. I was told there was another science called geometry, and I learned that also. Finding that there were good books on these two sciences in Latin, I bought a diction, and learned Latin. I also understood there were good books of the same kind in French, and I learned French. This, my lord, is what I have done; and it seems to me, that we may learn everything when we know the twenty-four letters of the alphabet." The duke, pleased with this simple answer, drew Stone out of obscurity, and provided for him an employment which allowed of his favourite pursuits. He soon discovered that Stone polished the same genius for music, painting, architecture, and all the sciences that depend upon calculations and proportions. The works of Stone, partly original and partly translations, are as follow: viz. "A New Mathematical Dictionary," first printed in 1726, 8vo.; "A Treatise on Fluxions," 1730, 8vo.; the direct method being translated from the marquis de l'Hospital's "Analyse des Infiniment Petites," and the German method supplied by Stone himself; "The Elements of Euclid," 1741, 8vo., with an account of the life and writings of Euclid; besides some smaller works. Stone was a fellow of the Royal Society; and communicated to it an account of two species of lines of the third order, not mentioned by Sir I. Newton or Mr. Stirling, which was printed in the 41st volume of the Phil. Trans. Hutton's Math. Dict.

STONE, HENRY, known by the name of Old Stone, to distinguish him from his younger brother John, was the son of N. Stone, a flatuary. He is principally known as the copyist of many portraits by Vandyck; and they are exceedingly close in their resemblance to the originals. He passed several years in Holland, France, and Italy; but died in London in 1673.

STONE, in Geography, a market-town in the hundred of Pirehill, and county of Stafford, England, is 141 miles N.W. of London, 7 from the county town, and 34 from Birmingham. In the year 1811, this parish contained 463 houses, and 2314 inhabitants. At a remote time, Stone was distinguished by some monastic foundations. Wulfere, king of Mercia, after murdering his two sons, was induced, by the persuasion of his queen and St. Chad, to embrace the Christian faith, and founded a monastery, in 673, at this place, in expiation of his crimes. This became a college of regular canons of the order of St. Augistine. His queen, Ermehilda, next established a nunery here; but both these houses were injured, and the inmates dispersed, by the Danes. After the Norman conquest, the college and nunery were repleted with monks and nuns; at least it feems evident that Enfyan, a Norman, brought canons from Kenelworth, and made the establishment at Stone a cell to the more eminent house at Kenelworth. Robert de Stafford, about the year 1260, rendered the former independent of the latter. Several perfons of the Stafford family were interred in the church at this place, to whom some fine and curious tombs were raised; but these were removed, at the dissolution of the priory, to the church of the Augufines at Stafford-Green. A new church has been erected on the fette of the old structure.

Stone confifts mostly of one long street, in which is a newly formed market-place. In the town is a free-school, or charity-school, and an endowed alms-house. Here are a weekly market on Tuesday, and three annual fairs. By means of the Trent and Mersey canal, which comes to this place, there is regular and cheap communication with many of the great manufacturing and commercial towns of Lancashire, Staffordshire, Warwickshire, and more distant counties.

Near Stone, lord Archibald Hamilton, in the year 1772, built an elegant house, called Sandon-Hall. This was formerly the property of the Erdefwick family, one of whom, Sampfon Erdefwick, was author of a topographical account of this county, and lies interred in the church of Sandon. Statues of himfelf and his two wives constitute parts of the monument, on which is a long and curious Latin inscription. He was born in this village in the middle of the sixteenth century, and died here April 1603. See Fuller's Worthies of England. Alfo Chalmers's Biographical Dic-
STONE.

&c. vol. xiii. from Shaw’s History, &c. of Staffordshire; and Pemberton’s Journal from Chester to London, Svo, 1781.

Stone, in Natural History and the Arts, is an inerudated mass of earth. The solid parts of the globe are principally composed of stones, formed of the different earths more or less combined with each other, and in different states of induration. The physical and chemical properties of stones fall properly under the investigation of the mineralogist: and the order in which they are arranged over each other in the great stone mausole which compose rocks and strata, constitutes a part of the science denominated geology.

The ingenuity and industry of modern naturalists have led them to form a variety of systems in the arrangement of fossils in general, and of stones in particular; none of the principal of these it may not be improper to enumerate. Some have founded the basis of their system on the figure, colour, structure, and other external and visible characters; calling in the aid of chemistry, so far as the mineral acids would afford them. Others, as the professed chemists and metallurgists, have established their arrangement chiefly on chemical principles, as more immediately leading to the origin of fossil bodies in general. And, at present, mineralogists seem more intent on this view than ever; and probably the due consideration of the volcanic system will open new sources of information in this way.

With respect to the systematic arrangement of stones, Browne, in 1755, divides them into such as are permanent in the fire, such as the lapsi glaris, amiantus, aëblius, and fusorii; calcinable, such as the calcareus, fissilus, morum, gyphum, iptam, flatactic, fissilis, and fpecularis; and those that are vitreous in the fire, such as the arena, arenarius, gemma, granatus, silex, quartzum, crytallus, and fluor. The other fossil bodies he ranges under the several classes of earths, faltis, fulphurs, figured stones, petrifactions, calculi, semi-metals, and metals.

Wallerius, in 1747, distributes stones into calcareous, as the calcareus, marmor, gyphum, and iptam; into the vitreous, as fivelis, cos, silex, petriform, quartzum, and crytallus; the appreus, as mica, talcum, ollaris, conormes, amiantus, and aëblius; and falsa, or rocky stones, as the silexica, mixta, grisea, and petrosa. The other bodies pertaining to the fossil kingdom, he classifies under the general heads of earths, lean, fat, mineral, and arenaceous; minerals, fulphurs, semi-metals, metals, concrete substances, such as the pori, petrifactions, figured stones, and calculi.

Wolterdof, in 1748, divides stones into the vitreous, as gemma, crytallus, quartzum, arenarius, conornes, iptam, vitrefus, fuxum, and pumex; the argillous, as the fmicetis, aëblius, talcum, mica, and schilitis; the gyphus, as gypus, alabaland, and iptam gyphum; and the alkaline, as calcareus, marmor, iptam alcalinum, topus, flatactic, and margodes. The other fossil substances he distributes under the titles of earths, argillous and alkaline; faltis, acid, alkaline, and mean; biturmus, fluid and soli; semi-metals, fluid and solid; metals, noble and ignoble; and petrifactions of fomiculous animals, of infects, of teflallaneous animals, of vegetables, and of marine bodies.

Cartheuder, in 1555, distributes stones into the lamellous, as iptam, mica, and talcum; filamentosus, as amiantus, aëblius, and inolothus; foid, as silex, quartzum, carnormal, gyphus, fissilis, and fmicetis; and granulated, as arenarius and jaspis. The other fossils he classifies under earths indifolable and indifolable; faltis, alkaline, acid, metallic, and purgious; fylpectis; inflammables, both genuine and fomulated; semi-metals, not maleable, sub-maleable, and fluid; metals, flexible, hard, and fixed; and heteromorphia, including the true and fpiritious petrifactions, and the figured subfactions. Juli, in 1757, distributes terrene bodies into the noble, as the adamas, sapphirus, sapphire, amethystus, topazius, turcois, opalus, crysolfilus, and ligeiactus; the semi noble, acryrallis, carnormal, aëblius, aëmetals, and fmicetis; malaehites, and lizali; appreus ignobil, as talcum, mica, molybdiana, vitrum mofhout, illetites, conornes, jalpis, and aëblius; calcareus, as marmor, gyphum, and iptam; and vitreus, as cos, quartzum, silex, schilus, torterinus, triplea, pumex, granites. fuxus, argilla, marga, limus, and umbra. The other fossil bodies rank under the heads of metals, noble and ignoble; semi-metals, fluid, hard, and mineralized; faltis, acid, alkaline, and mean; and petrifactions, animal, plants obscure, figured, and crytall.

Conrad, in 1758, arranges fossils under the clades of earths, calcareous, silexicus, granate, argillaceous, micceous, fluid, aëblius, veolitic, and magnesius; faltis, acid, and alkaline; phlogistic bodies; and metals, perfect and semi-metals.

Vogel, in 1762, distributes stones into the argillaceous, calcareous, margaceous, silexicus, pyromaeus, ichillious, folious, plumous, pale, metallic, fulle, petra or rocky, and new; and the other fossils under earths, argillaceous, calcareous, silexicus, margaceous, silexicus, micceous, inflammable, pale, metallic, and mould; petrifactions of animals, plants, lithophyous, lithotomous, and pors: faltis, idyptic, fulle, such as are capable of being hardened, volatile, and alkaline; combullibles, as fulminous, biturmus, levum, and belan; and metals, perfect and semi-metals.

Pott, in his "Lithogogoeufa," distributes stones into calcareous, gyphicus, aëblius, and appreus.

It has been doubted by some of the most respectable mineralogists, whether we ought to defend below what are called general definitions in the fossil kingdom, because the subjects are infinitely various, and the gradation by which they run into one another is in general imperceptible in the various combined forms in which they are found in the earth. Nevertheless, some distinctions of this kind seem to be quite necessary in systems established principally on external characters.

Linnæus and Wallerius have been among the first who attempted the arduous task of fixing the specific characters. For this purpose, Linnæus has formed a set of terms that express all differences in the figures of fossil bodies, in their crista or outward appearance, their superficies, their corresponding particles or fibres, in their texture, whether plated, silex, &c. in their hardness, or in their colour, and in the alterations they undergo by solution, both by acids and by fire.

The chemical fyllematies and metallurgists, in their arrangements, usually begin with the earths, considering them as the basis of stones: Linnæus begins with the latter, proceeding to take a middle way between the mere metallurgists, and those who characterize from external appearance only. He divides the whole regnum lapidum into three classes, under the names of petra, minera, and fossilia, each being subdivided into several orders, and comprehending in the whole fifty-four genera.

To the first class belong petra, or stones, which he defines to be fossil bodies, originating from a terrene principle by cohesion: these are simple, as in their composition they are definite of simple, inflammable, and metallic principles; they are fixed, as not being entirely and intimately soluble in any mercurial; and in the time, as they confit of homogeneous component parts. Of these there are five orders; viz.

1. The brumusa, or flaty stones, which originate from vegetable earth, are combullibles, and leave gros light after. Under this order there is one genus, viz. the silex, or flate,
flate, including thirteen species, among which the most distinguished are the table-flate, black flate, blue house-flate, and black crayon.

2. The calcareous, or calcareous flones, which originate from calcareous marine animal bodies, become light and porous in the fire, and fall into an impalpable powder, and effervescence, and are soluble in acids, unless they are previously saturated with an acid, as the gypsum. This order comprehends four genera, viz. marble, of which there are fifteen species, such as the black flaty marble, the Parian marble, and all its varieties; the Florentine marble, the white lime-stone, the flaky line-stone, &c.; argyrum, or plasters, flone, of which there are three species, such as the common plaster, alabaster, &c.; flitum, or fibrous alabaster, including four species, as the fibrous gypsum, or English talc, &c.; and psittum, or fpar, of which there are fourteen species, some soluble in aqua fortis, as the soft fpar, refracting fpar, or island crystal, subdiamagnetic compact fpar of different colours, pulvulic coloured fpar, as purpulic topaz, emerald, and taffhire, &c.; and some not soluble in aqua fortis, as the felpar, &c.

3. The argillaceous, or argillaceous flones, which originate from the viridiferous sediment of the sea, are somewhat unctuous to the touch, and hardened in the fire. To this order belong the three genera, viz. talcum, or soap-earth, including twelve species, as the reddle, smectis, or French chalk, or soap-earth, ferpent-flone, and hornblende, &c.; anitumnus, or earth-flax, of which there are ten species, as the amebole, pluofo abfolos, mountain cork, and aluta, or mountain leather, &c.; and mica, or tale, of which there are ten species, as Mucovys glafs, gold glimmer, and green tale, &c.

4. The arenaceous, or sand-flones, which originate from the precipitation of rain-water, are extremely hard, strike fire with ease, and by tribute, yield a very rough powder. This order comprehends three genera, viz. the ca, or whet-flone, of which there are sixteen species, as the grind-flone, filtering-flone, mill-flone, building-flone, &c.; the quartz, including eight species, as the pellucid rock quartz, coloured rock quartz, red, blue, yellow, &c. milky quartz, granulated quartz, pebble quartz, &c.; and the fale, or flint, of which there are sixteen species, some being vague or loose fints, as the common flint, gun-flint, Egyptian pebble or Mocoa-flone, opal, onyx, or cameo, chalcedony, cornelian, &c.; and some being rock-fints, as the agate, petro-delix or chert, jasper, &c.

5. The aggregate, or rock or compound flones, which originate from a mixture of the four preceding orders variously conglutinated; the interfaces, usually filled up with quartz, fpar, or gimmer. Of this order there is only one genus, viz. the fayum, or rock-flone, including thirty-nine species, as the porphyry of different colours; the trapezium, or trap-flone, the granite, the fusorium, or founder's-flone, the silicium, or pudding-flone, &c.

The second class of foffle bodies are the mineræ, or minerals, which Linnaus defines to be foffle bodies originating from a saline principle by crystallization; they are compound, as conglutinating of a base, united with saline, inflammable, or metallic principles; and they are soluble, perfectly, in an appropriate menstruum; of these there are three orders, viz.

1. Saltæ, faltæ, or crystæls, which are fapid bodies soluble in water; distinguished from each other by their different effects on the organs of taste: under this order there are fix genera, viz. nitre, of which there are nine species, as the saline, or native faltpetre; the quartzofe, or mountain crystal: flvor, or coloured crystal, from the varieties of which are the true hyacinth, the fale topaz, ruby, amethyst, fapphire, beryl, and emerald; and the calcareous, as the hexagonal truncated flpar, the fulium, or fparry fwine-flone, &c.; natron, including fourteen species, as the saline, or native mineral alkali, apntronitrum, and Eption falt; the lapidofe, or ipatofe, decahedron natron, the gyppeous, pellucid, fusform natron, the selenite, or rhomic natron, the hydon, or pyramidal, or dog-tooth fpar, &c.; borax, of which there are fix species, as the saline, or tincal, or native borax; the lapidofe, to which belongs the gemma nobilis, or lapidofe, prismatic, pellucid borax, with truncated pyramids, and as varieties of this species, the yellow or topaz, the pale green or chrysole, the sea-green or emerald, and the deep green or emerald, the bafalties, the tourmalin, the garnet, and the mangodes, or opaqne, argillaceous, telledoltor borax; the mario, or sea-lalt, of which there are nine species, as the saline, or sea-sofil, fountain, and hot-bath falt; the lapidofe, or Bononian flone, fparry floror, or Derbyshire fpar, &c.; alumen, or alum, including six species, as the native, or native alum, plumofo, &c.; soluble, or alum-flate, flone-alum, or calcareous alum-flone, called Roman alun: and lapidofe, to which belong the ipatofe alun, or faile amethyf, the gemma, pretiof, or diamond, ruby, and fapphire, &c.; vitriolum, or vitriol, of which there are eight species, as the simple, or ftole of iron, copper, and zinc; the compound, or triple vitriol of iron, zinc, and copper; the aternation, i.e. vitriols mineralized with ftriable flone, such as red hallatus, grey flary, black melanteria, and yellow mifly, &c.; and the lapidofe or ipatofe vitriol of zinc.

2. Sulphura, or inflammable bodies, flaming and odorous while burning; soluble in oil; and distinguished from each other by their different effects on the organs of smell: of this order there are five genera, viz. ambra, or ambergris, including two species, as the grey and the brown; fuccinum, or amber, of which there is one species, as the electric amber, and the varieties of diaphanous, opaque, yellow, brown, and that which includes infectæ; bitumen, of which there are ten species, as the naphtha, petroleum, or rock-oil, maltha, or Jew's pitch, mumia, or feum mineral, asphaltum, or folfie pitch, ampollæ, or peat, lathanthras, or common coal, or schifofe bitumen, gagas, or jet, fulinium, or calcareous fetid bitumen, of which there are the varieties of compact, granulated, squameous, and cryftalline, and the hepaticum, or liver bitumen; pyrites, or sulphurs, including seven species, as native sulphur, orpiment, cryftallized pyrites, or marcasite, figured pyrites, iron pyrites, copper pyrites, of which there are thirteen varieties, and aqueous, or liver-coloured pyrites; and arsenic, comprehending eight species, as the solid tenaceous arsenic, the fandaraca, or red arsenic mineralized with sulphur; the arfential marcaite, the arfenicum albicans, or arfenic mineralized with iron, &c.

3. Metalla, or metals, which are fiving heavy bodies, fulfure in the fire, and soluble in appropriated acid menftrua; distinguished from each other by infecption: of this order there are two subdivisions, into semi-metals not melable, and metals melable. The firt subdivision includes fix genera, viz. hydrygryrum, or mercury, of which there are five species, as virgin, or native quickfiver, cubic cryftallized quickfiver, cinnamon, with the varieties of laminated, granulated, and cryftallized, and pyrrhical, cuprous, flone mercury, &c.; molybdanum, wadd, or black-lead, of which there are three species, as plumbago, or black-lead, or wadd, or sulphur faturated with iron and tin, manganofa, or black manganofe, and ipuma lupi, or red manganofe, or wolfram; fthium, or antimony, of which there are four species, such as native regulus of antimony, cryftallized fthium, fibrous, or common antimony, and red antimony mineralized with sulphur and arsenic; zinc, or tutenac, of which there are eight species, as cryftallized zinc, that mineralized with sulphur
STONE.

flour and lead, or iron, that mineralized with sulphuretted iron, fibroite zinc, calamine, or flint zinc, or zinc mixed with marl calcareous, or mock-lead, or black jack, or semi-telluride black zinc, and red zinc, or micaeous liver-coloured zinc: bismutum, or bismuth, of which there are four species, as native bismuth, common bismuth, mineralized with sulphur and arsenic, or bismuth, and bismuth mineralized with sulphur only: and, chalcite, or chalicoch, or chalico or chalico of which there are four species, as crystallized cobalt with sulphur, arsenic, and iron, cobalt mineralized with arsenic and iron, pyrite of cobalt and flag-cobalt.

The second subdivision comprehends malleable metals, and of these there are six genera, viz. plumbum, or tin, including four species, as crystallized tin or tin-grains, tin-flake, ipatose tin, &c.; plumbeum, or lead, of which there are ten species, as native lead, cubick lead crystallized, cubick lead mineralized with sulphuretted silver, or galena, fliated lead-ore, greenish arsenical lead-ore, sparry arsenical lead-ore, &c.; ferrum, or iron, including twenty-seven species, as native iron in grains, crystallized iron, such as obey the magnet, to which denomination belong helc-grained iron-ore, fine-grained iron-ore, common iron-ore, pyritic iron-ore, talcy iron-ore, calcareous iron-ore, emery, &c.; such as do not obey the magnet, of which there are red micaceous iron-ore, blood-flake, blood-flake, purpere iron-ore, &c. and magnetical, or the magnet; cuprum, or copper, of which there are sixteen species, as copper precipitated upon iron, native copper, crystallized octahedral copper, pyritic yellowish-green copper-ore, pyriticfloe copper-ore, soft pyritic grey copper-ore, lootty, pyritic, arsenical copper-ore, white arctic, pyritic copper-ore, indurated ochraceous red copper-ore, which is sometimes liver-coloured; findy ochraceous copper-flake, green and blue copper-flake, lapis lazuli, lapis armenius, or blue calcareous copper-flake, malar-ches, or green gyposious copper-flake, nickel, or copper mineralized with sulphur, arsenic, and iron, &c.; argentum, or silver, of which there are nine species, as native silver in various forms, born silver-ore shining, submalleable, and somewhat diaphanous, mineralized with sulphur and arsenic, glais silver-ore, or lead-coloured malleable silver-ore mineralized with sulphur, red silver-ore mineralized with sulphur and arsenic, white silver-ore mineralized with sulphur, arsenic, silver-ore mineralized with arsenic, copper, and sulphur, grey silver-ore mineralized with sulphur, antimoniy, copper, and iron, silver-ore mineralized with arsenic and iron, silver-ore mineralized with sulphur and arsenic, and footy silver-ore mineralized with arsenic and copper; and aurum, or gold, of which there are two species, as native gold, found in various forms, as in thin plates or leaves, solid, or in thick pieces, and a crystalline form; it is also found imbedded in quartz, talc, and cinnabar, and in rivers in loofe grains and lumps, called gold-duff; and mineralized pyritical gold-ore.

The third class is fofills, which are bodies originating from different modifications of the subject comprehended in the preceding classes: of these there are three orders, viz.

1. Petrifacies, or such fofill bodies as represent in figure certain animals or vegetables, or parts of them. The true petrifactions are such as have the texture and organic parts of the bodies entirely filled up with floyy particles, either of a calcareous or flinty, and sometimes marcasitical nature: there are others in which the bodies are preferred and unaltered, as having lost only the animal gluten: others, again, are only bodies incrusted with flalice, or calcareous matter; and frequently they are only impreitions received in their soft state. Of this order there are eight genera, viz. sonoibus, or the petrifactions of mammalia, including four species, as bones of men, remains of the rein-deer, foill, ivory, and turquoise, or teeth incrustad with copper: ornitholithus, or petrifactions of birds, in whole or in part, and of their nefs, of which the firl species are fearce, and are usually, flalice or calcareous incrustations: amphibolithus, or petrifactions of amphibia, of which there are six species, as of an entire tortoise, of a toad, of the skeleton of a crocodile, of an entire serpent, of various nantes, as of the raia, ballites, &c. and glossopepra, or thark's teeth: ichtholithus, or petrafactions of fishes, including three species, as those of entire skeletons, with the fins in flate, and in marbre, and the buofines, or grinding teeth of the wolf-fish: entomolithus, or petrafactions of insects, including three species, as the cancri or petrified crab, lobster, &c. paradoxus, or unknown insect, petrified, and insects inclosed in amber, which indeed are not proper petrifactions: helmintholithus, or petrifactions of worms, including twenty-four species, as the corum ammonis, orthocerates, or straight nautilus, ane-mites, or various anomax, gypylites, or crow-flake; Jew's flake, supposed to be fipes of echnites, madrepores of various kinds, entrochas, flar-flakes, belemnites, &c.: phy-olithus, or petrifactions of plants, of which there are seven species, as of the entire plant in coal-flate, of fere in flate, of roots in marble, of wood in various flates, as of lime-flake, agate, flint, sand-flake, and flate; of leaves in flate and marbre, of flowers in flate, and of fruits in coal flate, commonly cones of the pine, nuts, acorns, &c.: graptolithus, or flones resembling pictures, including eight species, among which are Florintine marble or flate, refumbling ruins; dendrites, representing woods, landscapes, &c. arising from vitriolic fulzations interminated between the plates of fife flines, or in marble.

2. Concreta, which are slight conglutinations of different kinds of earths, whose specific differences arise principally from the nature of the component parts: of this order there are six genera, viz. calculi, or animal concrections, including eight species, as the flone in the kidney, or bladder; tartar of the teeth, of the lungs: hecoar-foles, formed in the abomasus, or fourth fomach of ruminating animals; agagropila, or hair-balls, formed in the fife fomach; bile-flones, pearls, and crab's-eyes: tartari, or vegetable concretes, of which there are two species, as yeall, and red and white tartar: zetites, or concretions within the cavity of fones, of which there are the true, having a loofe nucleus, as the geodes with an earthy nucleus, and the aquilus with a floyy nucleus; and the fipurious, as the hamachates, or fipitous zetites, with a fixed crystalline nucleus, marble zetites, including dog-tooth par, and echinated zetites, including fluor crystals: pumex, or concretions by means of fire, including eight species, such as black flate pumice, white pumice of iron-furnaces, red copper pumice, foot, ashes of volcanoes, Rheinifh mill-flate, vitreous pumice, or black and green Iceland agate, &c.: fialacities, or concretions by means of air, including twelve species, as vegetable incrustations, drop-flake, foid and branched marmorose fialacte, foid fipate fialacte, red fipate fialacte, or oxolite, &c.: and topus, or concretions in water, including twenty-two species, of which there are the metallic topus, as the mardy topus-flake, the tubular, marly, ochraceous tophi-flake, the sandy ochraceous sea top-flake, the bog iron-ore in various forms, &c.; and the fimple topus, as alum topus, concretions of teas-kettes, pea-flake of hot springs, oftocollia, or bone-binder, folid black fchilote toph, &c.

3. Tere, or earths, which are fofill substance not conglutinated, but usually in a slightly cohering or pulverized state;
STONE.

flate: of this order there are five genera, viz. ochra, or ochres, or clays, or earths of metals, of which there are fifteen species, some in the form of powder, as ochre of iron, green and blue ochre of copper, native cera, ochre of cobalt, &c.; and others plomoe, or gerninating ochres, as copper blue, or plomoe copper, flowers of antimony, plomoe silver-ore, with sulphurised antimony and arsenic, &c.: argile, or clays, including fourteen species, as sea-fand, coloured sands, sand of heaths, fulvous, or common sand, micaceous, or glittering or writing sand; gold, iron, and slitt sand, &c.; or argile, or clays, boxes, and marles, including twenty-one species, some simple, among which are porcellain clay, tobacco-pipe clay, China porcelain earth, Lemnian fuller's earth, tripoli, or rotten stone, brick-clay, potters' clay, boxes of different colours, &c.; others mixed, as fermenting clay, marle, umbre, marle of the Nile, &c.: calx, or chalk, comprehending nine species, some soluble in acids, as creta or chalk, mineral agaric, shell-chalk, or mouldered shells, &c.; some not soluble in acids, as true mineral agaric, gypsumous grt, or lac lume; and others granulated, as alabaster, chalk, soluble arenaceous calx of the isle of Ascension, and lentricular granulated calx; and hamus, or mould, of which there are fourteen species, as the impalpable vegetable mould, common black mould, depauperated mould of heaths, spongy mould of marbles, alpine earth, turf, mould of lakes, or mud mould, red mould, animal mould, &c. See Linnæi Systema Naturæ, tom. iii. 1770, passim; and Pulteney's General View of the Writings of Linnæus, 1781, p. 131—166.

M. Da Costa, in his Natural History of Fossils, 1757, distinguishes stones into four general classes. The first class comprehends those stones which are found forming continued strata, coarse, hard, and rough, of a lax texture, of a visible grit or grain, resembling sand in form, usually imbedded in a cementitious matter, of little brightness, and scarcely capable of any polish: of this class there are two genera, viz. stones hard and rough, composed of a visible grit, not of a laminated structure, and splitting equally in any direction, called perversaria by Hill, of which there are the alkaline sand-stones, as the Portland-stone, freestone, &c.; sand-stones not acted on by acids, as the whetstone, flint, mill-stone, grind-stone, &c.; and sand-stones imperfectly described by authors; and stones hard and rough, composed of a visible grit, of a laminated structure, and splitting only horizontally, or into plates. See Flag. See also each stone respectively.

The second class includes stones that are found forming continued strata, of a close, solid, smooth texture, or composed of no visible grit, and generally delitute of brightness, though in some degree capable of a polish: of this class there are two genera, viz. stones of a close solid texture, of a plane uniform structure, and splitting with equal ease in any direction, distributed, according to their colours, into black, white, ash, and grey, red, brown, blue, green, and variegated, each of which is again subdivided into alkaline stones, and those which are not acted upon by acids, comprehending the Purbeck-stone, oil-stone, &c. and stones called flates.

The third class comprehends marbles and marmoroides. The fourth class includes the marmor-profera, the granites, and the porphyrtes. See Fossils.

For an account of the modern systems of geology, see Rock, Strata, and System of Geology.

In the sequel of this article, we shall consider stone as applicable to architecture and sculpture.

STONE FOR ARCHITECTURE AND SCULPTURE. The application of stone to the construction of buildings, appears to have been almost coeval with the establishment of civilized societies. The advantages which stone possess'd over wood, in hardness, strength, and its capability of resisting the action of fire, would naturally direct those tribes or nations that resided in countries where stone was plentiful, to employ it in architecture. Thus we find in America, where the human race was in its rudest state, no sooner were men collected in large bodies, under the kings of Mexico and Peru, than they began to build houses of stone.

In Asia, where one of the first great monarchies was founded, the people were deprived of the use of stone, the ground being formed to a great depth of alluvial soil brought down by the rivers Tigris and Euphrates. To overcome this difficulty, they made artificial stone, by baking square masses of clay in the sun. Bricks formed in this, or in any other manner, are properly artificial stones, and have been formerly used to supply the absence of natural stone, by the Egyptians, the Allyrians, and the Romans, as well as by the moderns.

In the choice of different stones for public or private edifices, the contest and nature of certain stones, and the use with which they could be obtained and worked, would be first attended to, particularly in the early periods of architectural science; but there cannot be a doubt that durability and beauty were then regarded as essential qualities of building stone, and those stones which possessed these properties in a remarkable degree, were sought for with great affluency, and conveyed to distant countries at a great expense.

Such was the care of the ancients to provide durable materials for their public edifices, that, had it not been for the degrading hands of modern barbarians, and the inevitable destruction attendant on warfare, many of the temples and other public works of the Greeks and Romans would have remained perfect to the present day, uninjured by the action of the elements during a period of more than 2000 years.

On the contrary, in modern Europe, and particularly in Great Britain, there is scarcely a public building of recent date which will be in existence a thousand years hence. Many of the most splendid works of modern architecture are hastening to decay, in what may be justly called the very infancy of their existence, if compared with the date of public buildings that remain in Italy, in Greece, in Egypt, and the East. This is remarkably the case with the three bridges of London, Westminster, and Blackfriars, the foundations of which began speedily and visibly to perish in the very life-time of their founders. The same observation is applicable to Somerset-house, and many other public buildings in London; the fine sculpturing of the altrelievos figures having already disappeared by the action of the elements mouldering away the stone. The most careful observer may notice, that this effect is more rapidly taking place in stone stones than in others in each of these buildings, though they are all of Portland stone, a calcareous stone, called roo-stone by mineralogists, and obtained from the isle of Portland.

We have reason to know, that very little attention was paid to the selection of the stones during the building of Somerset-house; and the damaged ones, or those which contained hollows lined with clay, were not rejected, but the hollows were filled up with mortar. No soft calcareous stone, such as Portland stone, can be very durable in a climate like that of England, where it must be exposed to the action of frequent rain; and for the foundation of bridges, scarcely any stone could be more unfit.

The qualities requisite for building-stone in bridges or water-works, are hardnes, tenacity, and compactness, with the
the property of refilling the decomposing effects of water and the atmosphere. Before the strength necessary to support their own weight in such buildings, they may also have to refill the impetus of floating bodies, and particularly of large masses of ice. These stones which are the hardest, are not precisely those which have the most tenacity or toughness, of which we have a familiar illustration in common lime-stone and glass; the latter, though much harder, is far more easily fragile than the former.

In public national buildings, intended to preserve the memory of the ages in which they were constructed, and to perpetuate the state of the arts at the period of their erection, before the properties which ensure durability, we require a certain degree of beauty in the stone itself.

The causes that accelerate the decay and destruction of stone in buildings, are nearly the same with those which occasion the destruction or wear of rocks on the surface of the globe: they may be classed into two kinds, those of decomposition, and those of disintegration. By the former, a chemical change is effected in the stone itself; by the latter, a mechanical division and separation of its parts. The decomposition takes place, when the stone contains parts that are more or less soluble in water, or which enter into combination with oxygen or acids. To have a distinct idea of the decomposition of stones, we must first consider the elementary parts of which they are composed: these are either felspar, albume, or lime, (see Silex, Alumine, and Lime,) to which we may add magnesia, which, though of more rare occurrence, enters largely into the composition of serpentine and some lime-stones. Iron, in different states of oxidation, and in different proportions, enters also into the composition of almost all stones, and is frequently an important agent in their decomposition. The different kinds of building-stones may, therefore, be classified as felsicous, argillaceous, calcareous, and magnetit.

Of these, the felsicous are the least liable to decomposition; felspar being insoluble in water, or any of the acids, except the fluoric, which is never found in a free state. Stones composed almost entirely of felspar, if compact, may be considered as the most durable; but they are frequently brittle, and extremely difficult to work. When the felspar is combined with a certain portion of albume, as in some horn-felspar and jasper, it constitutes a stone which may be regarded as imperishable, when compared with the duration of states and empires. Such stones frequently contain imbedded crystals of quartz and felspar, and are then denominated porphyries. Porphyry, with a compact felsicous base of horn-felspar or jasper, is far more durable than granite, and is peculiarly appropriate for columns or obelisks, designed to transmit the events of former times to distant ages of the world. Some porphyries are also very beautiful, and take a high polish.

Granite (see Granite) is a compound felsicous rock, which varies much in the proportion of its constituent parts; and its degrees of induration. Compared with many rocks, granite may be considered as forming a durable building-stone; but those granites that contain much white felspar, and only a small portion of quartz, like the greater part of the granites of Cornwall and Devonshire, are liable to decomposition and disintegration much sooner than many of the Scotch granites, in which the quartz is more abundantly and equally disseminated. In the selection of granite in Cornwall and Devonshire, the preference is given to that which can be raised in the largest blocks, and worked with the greatest ease; and for common purposes, or for paving stones, it may answer very well; but for the foundations and piers of bridges, the harder granite will be found much more durable. The present state of Cornwall proves the rapid disintegration and decay of its granite rocks. The felspar in that granite contains a large portion of potash, and to this its more rapid decomposition may be principally ascribed. The naval hospital of Plymouth (an establishment which does honour to the country) is built of Cornish or Devonshire granite, which appears to have been well selected. It has been erected about 70 years, and exhibits no symptoms of decay, except in the columns forming the colonnade in front of each building: here, on their more exposed sides, we have observed the felspar to be disintegrating, and lichen has already attached their roots to some parts of the surface.

With granite may be classed all granitic rocks containing a large portion of felsicous earth, particularly felspar. (See Sienite.) This rock was extensively quarried by the Egyptians at Sienna, in Upper Egypt, and afterwards by the Romans; and many works constructed of this stone, preserve the marks of the chisel fresh to the present day. Of the rocks here enumerated, we have abundance in various parts of the British empire; and in the construction of national works, the selection of the stone should not be left to the disposition of architects, few of whom have made mineralogy any part of their studies. Many of the sand-stones, in what are called the secondary strata, are composed of grains of felspar, and where these are united by a felsicous cement, they are almost as durable as granite. In felsicous sand-stones, the coarser or fine parts of the grains is of far less importance than the substance by which they are united. Those which are united by ferruginous clay, are very liable to perish by exposure to the atmosphere. Some felsicous sand-stones appear to be of alluvial formation, and have their parts so loosely cemented, that they are quite unfit for architecture: such is the sand-stone rock on which the town and castle of Nottingham are built. In the series of strata which alternate with coal, there are considerable beds of felsicous sand-stone, which vary much in their quality; some containing a large portion of clay and iron, others being almost purely felsicous. Of the latter kind are some of the lowest beds in Yorkshire and Derbyshire, which have been denominated mill-stone grit, being formerly used for coarse mill-stones. Kirkstall Abbey, near Leeds, is built of this stone: it is now a ruin, but the stones which remain are perfect, and preserve their angular sharpness as fresh as if they had been recently worked, though five hundred years have elapsed since the erection of this building. There is a quarry of similar stone in the neighbourhood, extensively worked at present. It may be proper to observe, that in all quarries of sand-stone, the strata vary considerably in their power of resisting the effects of the atmosphere. Some strata are marked with stripes and veins, and these are frequently found to be more perishable than the general mass of the stone. We have known such stones preferred for the fronts of buildings, on account of their supposed beauty; but, in the course of a very few years, the coloured parts began rapidly to decay, by the action of water on the iron, which these parts contain more abundantly than the rest of the stone. From what has been stated, it may be seen that stones, which are purely felsicous, are of all others the least liable to decomposition; but where there is an admixture of felspar with different substances, great skill is required in their selection for durable architecture. Some directions for the choice of such stones will be subsequeatly given.

Argillaceous stones, or those which contain in their composition a considerable portion of clay, are generally found to contain also a large portion of iron. This metal appears

\[ \text{K} \ \text{K} \ 2 \]
to have a greater affinity for argil or clay than for any other earth, and is frequently combined with argillaceous stones in the proportion of one-fourth of the whole mass. The iron is frequently in the state of black oxdy, and in this state rapidly combines with a larger portion of oxygen, when exposed to the atmosphere, and thus occasions the surface of the stone to swell and shiver away. We have seen stones of this kind in their native beds, some hundred feet under the surface, so extremely hard that they resisted the point of the pick, and could only be removed by blasting; yet when the same stone was exposed for some months to the air, it became soft, and shivered into small pieces. It rarely happens that builders or engineers have sufficient mineralogical science, to enable them to anticipate the changes which will be effected by air and moisture on the materials they select. The lofts which this ignorance has occasioned in the construction of many public works is well known. A remarkable instance of this kind took place a few years since in Paris. A gentleman was walking with an eminent mineralogist in one of the newly erected public edifices. They were particularly struck with the appearance of some large columns that supported the roof. On a closer inspection, the mineralogist predicted that they would perish in less than three years. About ten months afterwards, the gentleman had occasion to pass through the same building, and observed workmen were then removing the columns, and replacing them with a different stone: the decay having been so rapid, as to render their removal necessary.

In forming the tunnel of the Huddersfield canal, in Yorkshire, through Pule Mof, a lofty mountain three miles in breadth, the workmen, in one part, had to cut through a dark argillaceous stone, so extremely hard, that they were obliged to remove it by blasting. On account of its hardnefs and compactness, it was deemed unneeceary to wall the passage in the part which was cut through this bed; but in a few months after the access of air, it shivered and fell in, and the removal and repair occasioned much delay and expense. Many bafaltic rocks, which are almost as hard as flint in their native beds, on exposure to air or moisture, are soon covered with a brown encrustation, which penetrates deeper and deeper into the stone, till the whole is reduced to a soft pulvulent mass: this is occasioned by the rapid absorption of oxygen, the iron in the basalt being in a low state of oxygenation. On this account, basaltic stones are ill suited for durable architecture, though there are some stones of this class which appear more perfectly vitrified, and refit the action of the atmosphere for ages. This is also the case with lavas which are nearly allied to bafalt: some lavas rapidly decompose and form a fertile foil, others remain unchanged for centuries. In all stones called argillaceous, the quantity of alumine, or pure clay, is, in fact, generally less than that of the other earths. Alumine or clay, when pure, is soft and unctuous, and absorbs more than 2½ times its own weight of water. It communicates, in a greater or less degree, its own properties to stones, where it is combined in the proportion of from 20 to 30 per cent. The properties of clay are lost by vitrification, or by exposure to a strong heat, as we may observe in the process of brick-making. In the West Riding of Yorkshire, it is frequently the practice to mend the roads with argillaceous sand-stone; but it is soon reduced to mud: to prevent which, it is piled in heaps, with alternate layers of coal, and burned before it is laid upon the roads: this makes it more durable, but the heat is seldom sufficiently powerful to vitrify the stone, and the roads frequently want repair. The remains of vitrified parts in some parts of Scotland, prove that the North Britons were acquainted with the durability imparted to argillaceous stones by exposure to great heat. In situations at a great distance from durable building-stone, it would be advantageous to have the bricks employed in the construction of bridges exposed to a greater degree of heat, and vitrified on the surface. This may be more easily effected by a mixture of calcareous earth with the clay.

Calcareous stones include all the different kinds of lime-stone, from the most crystalline marble, to chalk and calcareous sand-stone. Of marbles, there is an almost infinite variety; indeed every variety of lime-stone that admits of a good polish is denominatned marble. (See Marble.) The lime-stones or marbles that occur in primitive mountains, among blocks of granite, gneifs, and mica-flate, are generally the most durable, as they are highly crystalline; and many of them contain a considerable portion of fibrous earth, which communicates a greater degree of hardnefs to such marble. Though calcareous earth is in a certain degree soluble in water and carbonic acid, yet in its most indurated state, as in primitive marbles, the action of the atmosphere produces less change in the course of centuries; but when exposed to the constant action of water, the decomposition is more rapid. Those marbles which are the most uniform in their texture, which polifhes the greatest degree of specific gravity and hardnefs, and which will receive the highest polish, are those which will prove the most durable. There is another test applicable to marbles, and all stones purely calcareous, which affords no bad proof of their durability.

Let a given weight of different marbles be cut into cubes, or any other regular figure, and immered in dilute muriatic acid of the fame degree of strength: that marble which dissolves most slowly, will be the least liable to decay.

Some lime-stones consist of calcareous earth, combined with a considerable portion of magnesia, the primitive lime-stones which contain this earth have a milky whiteness. All lime-stones of this kind dissolve very slowly in acids; and such of them as polifhes the other properties of hardnefs, and an uniform texture, may be considered as the most durable of all marbles. The importance of an uniform texture is evinced in the different durability of the Parian and the Pentelic marbles. They were both extensively employed by the sculptors and architects of ancient Greece. In the age of Pericles, the preference was given to the latter. The Parthenon was built entirely of marble from mount Pentelicus (Pentelic marble), near Athens. Many of the Athenian statues, and the temples of Ceres or Eleusis, were of this marble. The preference arose from its superior whiteness, and probably from its vicinity to Athens. It is remarked by Dr. Clarke (Travels, vol. iii.), that while the works executed in Parian marble remain perfect, those of Pentelic marble have been decomposed, and sometimes exhibit a surface as earthy and rude as common lime-stone. This is principally owing to veins of extraneous substances which intersect the Pentelic quarries, and which appear more or lefs in all the works executed in this kind of stone. The Parian marble has somewhat of a waxy appearance when polished; it hardens by exposure to the air; it receives with accuracy the most delicate touches of the chisel, which it retains for ages, with the mild luster of the original polish. The Medicean Venus, the Diana Venus, the colossal Minerva (called Pallas of Veletri), and the hand, called Capitoline, are of Parian marble. The Parian tables at Oxford are also of this stone. Of the marbles of South Britain, those of Devonshire are by far the most beautiful; for the Anglesea marble, as it is called, is principally pure serpentine (see Serpentine); though it is called by professor Jamelot,
STONE.

in the late edition of his Mineralogy, with granular lime-
tone. The Devonshire marbles have scarcely been noticed
by mineralogists, but many of them poise a degree of
beauty scarcely inferior to any of the foreign marbles, par-
ticularly those of Babibon. They are veined and spotted
with a variety of colours, from a brilliant red to a beautiful
dove-colour, and are susceptible of a very high polish. The
altar, and the interior of Lord Clifford’s elegant chapel at
UGbrook, near CHudleigh, are executed in this marble, which
may vie with the most costly marbles of Greece or Italy.
The great national work called the Break-Water, at Ply-
mouth, is formed of blocks of Devonshire marble: it is an
artificial mole of vast extent, intended to form a bay, where
our largest fleets may ride in safety. The marble is pro-
cured at Cat Down quarries, close to the water’s edge, from
whence it is conveyed in boats about two miles, and thrown
into the sea. The blocks are raised of vast dimensions by
blasting, and from their hardness and size may resist the
decomposing effects of sea-water for ages, particularly if the
western side should get a covering of time. The continuity
of the flone necessarily determined the choice where some
million tons were wanting to complete the work, but there
cannot be a doubt that the granite of Cornwall would have
made a more durable barrier.

Among the secondary lime-stones, there are some which
contain a considerable quantity of magnesia, particularly in
the counties of Nottingham, York, and Durham. These
lime-stones have generally a yellowish colour: they diffolv,
slowly in acids, and form a very durable flone for architec-
ture. York Minster is said to be built of this flone.
The rock-flone, particularly that of Portland and Bath,
is extensively employed in architecture: it can be worked
with great ease, and has a light and beautiful appear-
ance; but it is porous, and poises no great durability,
and should not be employed where there is much carved or
ornamental work, for the fine chiselling is soon effaced by
the action of the atmosphere. On account of the ease and
cheapness with which it can be carved, it is much used by
our English architects, who appear to have little regard for
futurity.

The chapel of Henry VII. affords a lamentable proof
of the inattention of former architects to the durability of the
flone.

All the beautiful ornamental work of the exterior had
moulder away in the short comparative period of three
hundred years: it has recently been cased with a new front
of Bath flone, in which the carving has been correctly copied;
but from the nature of the flone, we may predict that its
duration will not be longer than that of the original. Pro-
ably the architect was limited by contract, which precluded
the use of a more durable, but more costly flone. Portland, as
well as Bath flone, varies much in its quality; and we think
greater attention was paid to its selection in the construc-
tion of St. Paul’s church, than in many of the modern edifices
built of this flone. Though we have observed many flones in
the upper part of the building mouldering away, yet, on
the whole, it is less injured by the weather than Somerst-houfe.
In buildings constructed of this flone, we may frequently ob-
serv some of the flones nearly black, and others presenting
a white clean surface. The black flones are those which
are more compact and durable, and prefer the coating of
smoke: the white flones are decomposing, and presenting a
fresh surface, as if they had been recently scraped. This
effect is strikingly exhibited in the columns of Somerst-
houfe, in which black and white flones may be seen alter-
nating in the same column.

Some of the lower beds of chalk are occasionally used for
building-flone; though, from its loose texture, it cannot
poise great durability. We have seen the cloisters of Weif
minster Abbey repaired with a flone of this kind, so soft as
to yield to the nail; and on inquiring of the workmen
why they made use of such a material? the reply was, “the
cheapness of the cutting.”

Alaballcr or gypsum is sometimes employed for orna-
tmental architecture. The same alaballer is also given to
Italaritical lime-flone. (See Stalactite.) This variety of
time-flone poises nearly all the properties of granular
lime-flone. The gypsum alaballer is a sulphate of lime, and
poises a considerable degree of solubility in water. Dr.
Watson, in his Chemical Essays, states, that he suspended
two ounces of this flone in a pail of water forty-eight hours,
changing the water several times, and found at the end of
that time it had lost one-thirtieth part of its weight. From
the solubility of gypsum, it is obviously improper for any
purpose where it is to be exposed to the action of rain or
water.

Of the magnesian flones, there is only one applicable to
purposes of architecture; this is Portland, which has been
fully described under that article.

The disintegrating caufe to which building-flones are
exposed are moisture, variation of temperature, and vege-
tation: the action of these is distinct from that of decom-
position. The earths which are not soluble in water are
capable of being mechanically suspended in it, when mi-
utely divided. A drop of water, conflantly running along
the harden flone, marks its path by cutting a furrow in the
surface, according to the well-known adage:

“Guttae caeae lapidem non vi sed fepe cadendo.”

This cause is, however, flow, compared with others
which are constantly operating. Water infuses itself
into the minute pores and crevices of flones, and being ex-
anded by variation of temperature, and particularly by
frost, breaks aunder the harden flone, or thivers off a
portion of the surface. Thofe flones which have a lam-
inated structure are most liable to be injured by the effects
of froll, from the facility with which water infuses itself
between the lamine.

Lichens and mosses fix their roots on the surface of flones,
particularly on those alaballer flones which yield a
earthy smell, when breathed upon. By infusingating their
roots, they accelerate the decay of fuch flones, and prepare
a vegetable mould for plants of a larger growth.

In calcarious and other land-flones, where the cementing
material is of a soft kind, it is washed out by rain, and the
flone falls in pieces, or moulders away. In general, thofe
flones which are the moft hard, compact, and uniform, in
their texture, and which can be brought to the smoothest
surface, are thole least liable to disintegration. In order to
form a judgment of the durability of any building-flone,
which has not had the test of experience, it is desirable to
examine it in its native bed, particularly those parts of the
bed which have been long exposed to the air. This may
not unfrequently be done in some part of the country where
the flone is quarried; for as each stratum rises in a certain
direction, it will come to the surface somewhere, if not
covered by foil. The flone, in such situation, offers cer-
tain indications of the effect which atmospheric agency
produces upon it. Where this examination cannot be made,
all flones that are not calcarious may be in some degree
proved, by observing what effect is produced by immer-
ing them in water for a given time, by exposing them to a red
heat, and to froll, or by covering them with dilute nitric
acid for several days. Thofe flones which absorb the
smallest quantity of water, and which are left changed by
the
the action of heat, frost, or acids, may be fairly considered as most capable of retarding the decomposing or disintegrating effects of moisture and change of temperature. We have before suggested a test in the choice of calcareous stones. It has recently been the practice to rub the calcareous sand-stones with oil; and this must to a certain degree retort the adsorption of water, and contribute to the durability of the stone.

Foreigners generally class building-stones into two kinds, hard and soft. In the latter they comprize all stones that can be cut with the faw in any direction, and with some degree of ease: the hard stones are all those which cannot be worked by the stonecrafs. In England, the name free-stone is given to all the softer stones, which can be cut easily with the sawl into large blocks suited for building-stone; it includes a variety of sand-stones very different in their nature.

Experience has taught our architects, that all stratified stones last much longer, when laid in the same direction which they had in their native quarries; a circumstance which ought always to be attended to by the mason. As stratified stones generally split with the greatest ease in the direction parallel with the surface of the strata, it is obvious that they will bear less pressure in this direction than in a line perpendicular to their natural position.

The following table shews the value at Rome of marbles, alabaster, and hard stones, regulated by the cubic Roman palm, which is about nine inches in each dimension. The fcudo, which contains one hundred bajoci, is about 45. 6d. English.

The prices of the above stones are enhanced not only by their fize, but by any extraordinary beauty of colour which each specimen may posses.

**Stone, in Agriculture.** It is a point not yet determined, whether stones are hurtful or beneficial to arable lands. Examples are not wanting on both sides of the question, though, in general, it teems rather to be carried for them. However, nothing can excufe leaving a stone in any ground so large as to interrupt the plough. If they are very large, they should be blown to pieces with gunpowder, and then be carried off. Some pots, very fertile in several kinds of grain, seem to confid of nothing but stones; and instances are given of fields being rendered barren, by taking away the stones which covered them. Theophratus accounted for this in a hot country, where it happened to the Corinthians, by laying that the stones sheltered the earth from the scorching heat of the sun, and thereby preferred its moisture. The fame holds true even in our colder latitude, where the heat of the sun is less apt to hurt us. And Evelyn is clearly of opinion, that husbandmen rather impoverish than improve those grounds which are almost covered with stones, especially where corn is fown, if they pick them off too minutely; because they thereby expel the land too much to the effects of heat and cold. Certain it is, that a moderate mixture of small gravel prefers the earth both warm and loose, and prevents too fudden exhalations. But it teems highly probable that there must be some farther reafon, beyond what has been yet asigned, for the benefit arifing from the stones.

However, the concealed stones should be always removed from lands that are to be kept in a state of tillage, otherwise many accidents must happen in ploughing, by the intraining and breaking of the ploughs, and the destruction of other implements. And where the lands require under-draining, it may often be proper and beneficial, as well as a cheap method, to have the stones made use of, and gathered from the ground; as, by such means, two objects may be accomplished at once. See Clearing of Land, and Draining of Land. See also Spring and Surface Draining.

An opaque imperfectly crystallized fort of stone, probably of the quartz kind, is found very troublesome to the farmers, in many parts of Cornwall. It lies, it is said, loose on the surface, in all fizes, from that of rocks to granules.
In some places it is met with a few inches under the surface, like a clove pavement. In whatever position or size these stones infest the land, it is there the prevailing opinion, that until it shall have been in some measure cleared, by digging, or ploughing and picking, little hopes of success can be entertained, even from the best modes of cultivation; although instances of the contrary may sometimes be produced. Lands have been cleared of this stone, by fcreening the whole mass of stony matter and earth as deep as the yellow clayey sub-stratum, in the same manner as masons screen the sandy materials for their mortar, with very great success and advantage, though at much expense. The refuse stones, in this or other ways, are purchased at one shilling the lead from the farmers, for their use in repairing the roads. The round cobble stones, picked from the land, are much used in the south of Lancashire, and probably in some other places, for paving the roads.

Whatever be the cause of the productive veins of tillage-lands, so beget with loose round stones as scarcely to have any appearance of earthy matter or mould amongst them, the writer of this article has over and over again seen vast crops of different sorts of excellent grain produced on such land. See Stony Land.

Stones, as to the Origin and Formation of, M. Tournefort, on his return from the East, in the year 1702, proposed to the Royal Academy a new theory. On a curious survey of the famous labyrinth of Cretes, he observed, that several people had engraved their names in the living rock, of which its walls are formed; and what was very extraordinary, the letters whereof they consisted, instead of being hollow, as they must have been at first, (being all cut with knife-points,) were prominent, and stood out from the surface of the rock, like so many balla-relevors.

This, he says, is a phenomenon no otherwise accountable for, than by supposing the cavities of the letters filled insensibly with a matter issuing from out of the fulbility of the rock, and which even infilled in greater abundance than was necessary for filling the cavity. Thus is the wound made by the knife healed up, much as the fracture of a broken bone is consolidated by a callus, formed of the extravasated nutritious juice, which rife above the surface of the bone; and this resemblance is the more just, as the matter of the letters was found whitish, and the rock itself greyish.

Something very like it is observed in the barks of trees, in which letters have been cut with the knife; so that the poet had reason to say, that the characters grew as the trees themselves grew: "Crepent ille; crefcent amores." M. Tournefort supports his opinion by similar calluses apparently formed in several other stones, which had re-united after, by accident, they had been broken.

From these observations, he says, it follows, that there are stones which grow in the quarries, and of consequence that are fed; that the same juice which nourisheth them, serves to rejoin their parts when broken; just as in the bones of animals, and the branches of trees, when kept up by bandages; and in a word, that they vegetate.

There is then, says he, no room to doubt but that they are organized; or that they draw their nutritious juice from the earth. This juice must be first filtered and prepared in their surface; which may be here esteemed as a kind of bark; and hence it must be conveyed to all the other parts.

It is highly probable, that the juice which filled the cavities of the letters, was brought thither from the bottom of the roots; nor is there any more difficulty in conceiving this, than in comprehending how the sap should pass from the roots of our largest oaks to the very extremities of their highest branches.

It must be owned that the heart of these trees is exceedingly hard; and yet those of Brazil, called iron-wood, guiaucum, and ebony, are much harder. Coral is as hard in the sea as out of it; and sea-mushrooms, which every body allows to grow, are true stones, and so, like the common stones, are used in America to make lime.

Some stones, then, he concludes, must be allowed to vegetate and grow like plants. But this is not all; he adds, that probably they are generated in the same manner; at least, that there are abundance of stones, whose generation is inexplicable, without supposing that they come from a kind of feeds, in which the organical parts of the stones are wrapped up in little; as those of the largest plants are in their seeds.

The stones called cornu Ammonis, lapis Jaudicus, &c., those of Bologna and Florence, the several kinds of pyrites, cryflals of the rock, and an infinity of other stones, he supposes to have their several feeds: as much as mushrooms, truffles, and various kinds of mollusc, whose seeds were a long time before they were discovered.

He continues, how should the cornu Ammonis, which is conically in figure of a volute, be formed without a feed, containing that same structure in little? who moulded it so artfully? and where are the moulds? Far from this, these kinds of stones are found in the earth, like common flints. Nor were either their moulds, or any thing like them, ever discovered.

M. Tournefort examines the several sorts of stones above mentioned, and finds them under the fame necessity of feed. Again, that immense quantity of pebbles, with which the Crauf of Arles is covered, he thinks a strong argument in behalf of this theory.

The country there, for twenty miles round, is full of roundish pebbles; which are still found in equal abundance, to whatever depth you dig. M. Pierre, who first proposed the generation of stones by means of feeds, (though he took the word feed in a very different sense from M. Tournefort,) first brought this extraordinary collection of them as a proof of it. In effect, how could so many similar pebbles be formed? There is no saying they are coeval with the world, without ascertaining, at the same time, that all the stones in the earth were produced at once; which were to go directly contrary to the observations above mentioned.

Among the feeds of stones, M. Tournefort observes, there are some which do not only grow soft by the juices of the earth, but even become liquid. These, then, if they penetrate the pores of certain bodies, grow hard, petrify, and assume the figure or impression of the body; thus, what we call petrinites, conchites, mytilites, operculites, nautilites, echinates, &c., are real stones, the liquid feeds of which have infunited into the cavities of the shells called petten, conches, mytilus, operca, nautilus, and echinus. On the contrary, if those liquid feeds fall on flints, on shells, sand, &c., they enframe those several bodies, and, fixing between them, form a kind of cement, which yet grows like other stones. It is highly probable, that such rocks as are only an assemblage of cemented flints, have been formed by a number of these liquid feeds; in like manner as the quarries full of shell, unless the rocks have enveloped these bodies in their growth.

He even supposes, that there are feeds of real stones enclosed in the spawn of certain shell-fish; as well as that hard solid matter defined for the forming their shells.

There is, says he, a particular kind of shell-fish, called pholas,
STONE.

Poem, which are never found anywhere but in the cavities of flints, which are always found exactly fitted to receive them. Now, it is highly improbable that the fish would come and dig such a notch to spawn in; it is much more likely, that the flones are found enclosed in were at first soft; and that the matter of which they are formed, was originally found in the spawn, in like manner as the matter which forms the egg-shell is really found in the feed thereof.

From the whole he concludes, that the feed of flones, and even of metals, is a kind of dust which probably falls from them while they are alive; i.e. while they continue to vegetate as above. This dust may be compared to the seeds of several plants, which no microscope ever yet discovered, though their existence is not at all to be doubted.

Probably, flints and pebbles are among flones, what trifles are among plants; nor is this opinion new: Pliny affures us, that Theophratus and M. T. Plinianus believed, that flones produced flones; and Gregory Nazianzen adds, that there were authors who even believed, that flones made love, Gει και αὐτοκτόνας καὶ δίορα, κρύσταλλον. Poem. de Virgin.

All this, however, is founded on the imperfect knowledge of those times.

Since M. Tournefort's days, we have discovered other ways of formation for the lapis Judaicus and cornu Ammonis; the first being only a petrifaction of the spines of an echinus marinus, and the other of a shell-fish nearly allied to the nautilus kind. See Fossil, Judaicus Lapis, and Cornu Ammonis.

M. Geoffroy accounts for the origin and formation of flones in a different manner. He lays it down as a principle, that all flones, without exception, have been fluid; or at least a soft paste, now dried and hardened: witness the flones in which are found foreign bodies; witness also figured flones, &c.

On this principle, he examines the formation of the different kinds of flones; and shews, that the earth alone suffices for the fame, independent of all falt, sulphurs, &c. The metallic particles contained in flints give them their colour; but these are only accidents: for proof of which, he infances the fapphires and emeralds of Auvergne, which lose all their colour by a moderate fire confuming their metallic parts; but without any damage to their transparency; they being hereby rendered mere crysals.

To view rock-cryystal, indeed, one would not take it for earth; and yet earth it must be, not water congealed, as the ancients imagined.

M. Geoffroy conceives two kinds of primitive particles in the earth. Thofe of the first kind are exceedingly fine, thin lamellas, equal to each other, or nearly so. Now, when these meet together, from any caufe whatever, in a sufficient quantity, the regularity and equality of their figures determine them to range themselves equally and regularly; and thus to form an homogeneous compound, which is very hard, from the immediate contact of the parts; and very transparent, by reason of their regular disposition, which leaves a free passage to the rays of light everywhere: and this is crystal.

The parts of the second kind have all sorts of irregular figures; and must accordingly form assemblages that are much more opaque, and less hard. Now crystal is formed wholly of parts of the firit kind; and all other flones of a mixture of the two kinds of parts together: this mixture is absolutely neceffary, in order to unite and bind together the parts of the second kind, and give them a hardness and confidence, without which they would only make a sand or duff. Water now appears the fittest vehicle to carry the parts of the firit kind. This is seen from several petrifying springs, which incrustate the pipes through which their water is conveyed, or even solid bodies laid in them for some time. The water does not diffolve those earthy parts; it only keeps them in fusion, as it does the juices with which plants are fed.

This water, thus charged with earthy particles of the first kind, M. Geoffroy calls the flony, or crysalline juice, of which those bodies are primarily formed. See CRYSTAL.

Some look upon flones as unorganized vegetables, and that they grow by the accretion of falt, which often shoot into angular and regular figures. This, it is said, appears in the formation of crystals on the Alps; and that flones are formed by the simple attraction and accretion of falt, appears by the tartar on the insides of a claret-veil, and especially by the formation of a flone in the human body. Henkell has thrown together some very ingenious thoughts on this subject, in a treatise published in the year 1734, where he builds no opinions on any other basis than that of falt, observations of nature, and experiments. He supposes that the earth was at first every where soft on the surface, and that this soft matter by degrees hardened, and formed flones of several kinds. He seems to imagine, that the surface of the earth was all reduced to this soft flate by the universal deluge at the time of Noah, and that this matter afterwards hardening into flones of various kinds, included the shells of sea-fishes, and other animal remains of the produce of the seas, in flints, in lime-flone, or in whatever other substance the matter, among which they lay, chanced to harden. Thus may the sea-flones, found fingly in the middle of hard fllints, or lodged in vast numbers in the strata of earth, lime-flone, or marble, be accounted for.

Nur is water alone the agent that may have made these changes in the once soft parts of the earth's surface; we can by fire reduce the poorer earths into a fort of glafs, a hard transparent body, not a little refembling the nature of flint, or the other semi-pellucid flones. Fire is of power to do great things in the bowels of the earth, and the way to learn what changes it may there make in flones, is to try its effect upon the several different kinds of flones and earths here. By experiments of this kind we learn, that of the several species of flones in their prefent flate, some are reduced to a friable mass, and finally to powder, by the force of fire; others are hardened by it; others are melted, and become a kind of glafs; and by experiments on the other foillible substances, it appears that the original matter of all flones has been earth, either of the nature of chalk, marl, or clay; and that many of them have been greatly altered by receiving metallic or other mineral matter into their earthy matter, at the time of their formation; and all seem to have owed their change into their hard flate, either to fire alone, or to saline, oily, metallic, or saline sulphurous matters, either conjunctly with the force of this agent, or alone. Henkell, Lithogena.

Thofe flones which are formed in their prefent flate, immediately out of fluids, have been produced either by congelation, a rude coalition, or crysallization; and that all the gems have been once fluid is plain, from their imperfections in certain infinities, as from their containing grains of land, or the like extraneous substances, firmly embodied in them. If thefe, the hardet of all flones, have been once fluid, there is no reason to dispute, but that all the other kinds may have been so, which are lefs hard and lefs perfect. For the formation of flones, according to modern systems of geology, see ROCK, STRATA, and SYSTEM of Geology.

STONE. Formed, among Naturalists, mineral or flony matter,
STONE.

matter, cast in the cavities of certain sea-shells, or other parts of marine animals. - Of these, some are found quite naked and bare; others have the remainder of the shell about them; and among these there are also found many real shells, scarcely at all altered from their recent state, buried at great depths in the earth, far from seas, and even on the tops of mountains.

This is by no means an effect of the general deluge, and by many is thought a convincing proof of the truth of that hillory; but there have been many who have asserted, that these bodies can convey no such proof, since, as they affirm, they are not, nor ever were, marine bodies, or owed their form to fish, but mere "fossil nature," bones formed in the places where they are found, having no relation to animals of any kind, but only accidentally resembling them. But the allusions of the former opinion have rather the better side of the argument.

It seems, indeed, contrary to the great wisdom of nature, which is, in all its productions, to design every thing to some determinate end, that these bodies should have been so nicely formed by a mere plastic virtue in the earth, or endowed with all the characters and necessary parts of animal coverings, &c. for no other end but merely to exhibit such a form, without having any relation to the uses these particular parts are appropriated to in the animal. But if the origin of these shells found in the shape of shells, be doubtful, yet the real shells found in the earth cannot be supposed to have been formed there; yet these are found at as great distances from the sea, and not only in the low grounds and hillocks, but in the highest parts of the loftiest mountains, even without the least particle of flinty matter about them; mere shells unpetrified, uncorrupted, and of the exact figure, structure, and confidence of the sea-shells, which are now habitations of living animals of the same species.

That nature should form real shells, without ever intending them for the covesing of an animal, seems no way probable; and indeed, were it true, would give great strength to the atheist's opinion, that all things are exiled by mere chance, and were intended for no end or use. Nor are the shells the only instances of these fossil bodies perfectly resembling animal ones, but we find with them other parts of animals, as the teeth of fishes and land animals; which, though met with buried in earth, or on the tops of mountains, are plainly the same with the substances produced by the fishes, &c. Of this kind are the teeth of the several species of sharks, called *glissopetera;* those of the wolf-fish, called *byfoniace;* the vertebrae of several fish, and the like.

The very inspection is abundantly sufficient to prove, that these were once parts of animals; but were that insufficient, they have not, even in this their fossil state, so far divested themselves of their animal nature, but that they carry proofs of it; and Columna has evidently proved their true origin from these. He observes, that all animal and vegetable substances, whether of a woody, bony, or fleshy nature, by burning, are changed first into a coal, before they go into a cask of ashes; whereas the flinty substances, on the contrary, do not burn into a coal, but are reduced at once into their true coal, or elce into glasses. But these teeth, supposing by some mere productions of the earth, all burn first to a coal, while the flinty matter adhering to them does not; whence alone it is sufficiently plain, that they and that substance are of very different kinds, and that they are truly of a bony, not a flinty matter. It is also repugnant to that great maxim, that nature does nothing in vain, to supposing these teeth formed in the earth where they are now found, since they could there have no use as teeth, nor the vertebrae, or other bones, as bones. It is very certain, that nature never made teeth without a jaw, nor shells without an animal inhabitant, nor bones without the cell of the body they belong to: these things are not made in this separative and useless state in the element to which they naturally belong, much less in a foreign one.

Their very substance and place also evince plainly, that they were not formed where they are now deposited, for they are usually lodged in stones, and stones contain not the matter of which they are made: and to their place, they might have been lodged there either when formed, which proves our asserting, or else they must have been at some time generated all of a sudden there, or have grown from a small origin, increasing by little and little, as the animal substances which they resemble do. Now, if the stone, in which they lie, was formed before them, and they were formed on a fudden in it, how came the cavity there just to correspond to their size? and if they grew by little and little, how could they form a cavity in the stone, without bursting or cracking it?

It is also no small proof of these teeth being of a marine or animal origin, that they are not regularly shaped at the base, but are all broken, and that in various manners; which proves very plainly, that there has been no vegetation on the earth, because in all other figured fossils they are never found mutilated or imperfect. It cannot, with any flow of reason, be supponed that these teeth were thus broken within the body of the stone where they now lie, but it is plain that they were lodged in the stone at a time when it was soft, and were before that broken off from the jaw of the creature in this irregular manner.

It is likewise no weak argument, that these bodies are not formed at this time in the stone, that they are all found perfectly alike; for, if they were continually increasing in size and number, it is probable that the new formed ones would be some way different from those which were of older date. The variety of species in the gliosopetera alone may evince, that they belong to the animal to which they are attributed, since they are of very different kinds. See *Glossopetera, and Serpents' Tongues.*

The perfection of the figures of these bodies is a further proof of their origin from animals which they represent, since in all crystalizations there are many imperfect and mutilated figures, ray more than perfect ones.

To all this it may also be added, as an unanswerable proof of the fossil shells having been marine, and having lived in the sea, that they are found with injuries which could have been no way else received. The purpura, and some other shells, have bony tongues, with which they bore regular holes through the shells of shell-fish of other kinds, in order to make their way in, and prey upon their flesh. These holes are always easily known by their regularity and shape; and shells bored through in this manner are not only frequent on our shores, but there are such as also found fossil, bedded in the strata of earth or stone; and surely, if half-likely could be allowed to have shot into the figures of sea-shells, they could never be supponed able to shoot into the figures of such wounds, as a few of those shells have received in their recent state from other animals.

The general opinion is, that the deluge brought all these shells into the places where we see them; but this seems not easily conceived; and as there is no argument so good, but that being carried too far it will make against its purpose, so the laying too much to the effects of the general deluge, has made many believe it has done nothing at all.

These formed stones and real shells are both found in vall flata on the tops of the highest mountains, the Alps, Appennine,
STONE.

Apennines, and others in different parts of the world. The deluge failed only ten months, and probably the tops of mountains were not covered half that time; and these immense quantities of shells cannot be supposed either to have been thrown in that time, or to have been carried so high in such prodigious numbers. It is more probable that these tops of mountains were once not firm, but bottoms of the sea. The history of the marine bodies they contain is then very plain, and earthquakes may have raised them, or they may indeed not be so high above the level of the sea, as we at first might suppose. If, indeed, we adhere to the letter of the text, in the Scripture history of the creation, we can find no account for these bodies from that time; for if the creation of fishes succeeded the separation of the land from the water in all parts of the globe, they could not be then deposited there; but it is probable, that at the creation the whole earth was not all at once uncovered, but only those parts where Adam and the animals were created, and the rest gradually afterwards, perhaps not in many years, as there seems no necessity of understanding the account of the creation to have been in fix natural days. If we may thus understand, and conjecture in this respect, it is not difficult to conceive, that during the years in which the earth remained covered with sea-water, shell-fish might breed and multiply abundantly over all its bottom; and this bottom being afterwards elevated, deflected by the sea, and made dry lands, these shells must be elevated with it, and retained in those strata, which afterwards hardened into the various kinds of earth and stone; and something of this kind seems to have been the case, much rather than, according to Dr. Woodward, that all stone matter should have been dissolved by the deluge, and afterwards have concreted again. Ray's Physico-theological Discourses.

For other hypotheses and observations relating to this subject, see Adventurous Fossils, Marine Remains, Petrifactions, Seminum, and Shells.

Stones, Solutions and Colours of. The various beauties of the form and colour of the several more precious stones, cannot but have been always the admiration of the curious part of the world, and the ingenuity of the ablest chemists hath been tried, in attempting to counterfeit them; and much may be gathered even from their attempts, which have not succeeded, toward the learning of the true nature and history of these beautiful bodies. The beautiful figures of the Florentine marble, whose veins represent trees, rivers, and ruins of buildings, are well known; as are also the delineations of trees and shrubs in those species of white agates, called Mocca stones. All the stones of this kind are natural, for art has yet not been able to come up to any counterfeit of them; but it is not so in regard to those agates which represent regular figures of beaux, &c. these are all artificial, and that by a very simple and easy process; and M. Du Fay, in the Memoirs of the Paris Academy, has given at one view the several ways, then known, to penetrate into the sublimes of agate, marble, &c. and to lodge figures in them. The stones subject to be tinged he divides into two classes, the harder and the softer. Of the harder kind, are those which reflect the force of acids, even of the most powerful kind; and of this class are agates, onyxes, and all that are vulgarly comprehended under the general name of the gems, or precious stones, with crystal, porphyry, granite. These, and the like stones, are not soluble in any of the known acids, yet these same acids, impregnated with the solutions of metals, are capable of penetrating very deeply into them, and tinging them with different colours. The simple agates and jaspers, and other stones of the like uniform structure, are easily coloured in an uniform manner; but those which are variegated with veins are composed of several different parts of matter, and therefore are lefts easily, and left evenly stained. As the tinging matter does not penetrate the several beds, or veins, in the same manner, therefore, all that can be done to thefe, is to add spots and veins to their natural ones, but they cannot be tinged throughout to one uniform colour, as the chalcedony or white agate may.

If a small quantity of a solution of silver in spirit of nitre be poured upon one of these agates, and the stone exposed to the sun, it will in a few hours be tinged to a reddish-brown colour; and if more of the same solution be added, and it be again exposed, the colour will become stronger, and will penetrate deeper into the body of the stone; and if the stone be not too thick (e.g. more than a fifth part of an inch), and the solution be rubbed on both sides, it will tinge it throughout. Nor is this all the effect, for it will give it several veins and lineations, which were not distinguishable in it before; the reason of which is, that in all these stones there are some parts harder than the rest, and consequently more difficultly coloured, and these remaining, therefore, paler than the rest of the mafs, make the lines and veins in it.

If there be added to the solution of silver, used for this purpose, a fourth part of its quantity of foot, and as much salt of tartar, the colour becomes grey; and if, instead of this foot and tartar, the fame quantity of plums or alum be used, the stone will be tinged to a deep violet colour, tending to black.

A solution of gold gives agate only a pale brown colour, and that penetrates but a little way into it; and a solution of bitum gives a colour, which appears white when the light falls directly upon it, but brown when it is held against the sun; and, or a candle; and all the metallic and mineral solutions, employed in the same manner, affect the stone more or less in the same way.

The expelling of the stones to the sun is a very necessary article in the process, since without that the tinge is but very faint, and penetrates but to a very little depth. To trace in the chalcedony, or white agate, figures of any determinate kind, the usual method is this: before the agate is polished, mark out the intended figure with the point of a fine needle, and afterwards with a brush, or a pen, follow those lines with a very strong solution of silver.

One would imagine that the dendrites, or delineations of trees in Mocca stones, might be imitated in this manner; but it is difficult to give the due blackness of colour, and to mark the figures with a like precision and exactness. See Agates.

If any stone should, however, be supposed to be adulterated, or counterfeited in this manner, it is easily brought to the trial; for if it be thus made, a small heat over the fire will almost entirely destroy its colour, and the rubbing a little spirit of nitre or aqua fortis over it will have the same effect. In both cases the stone may, however, be restored again to its beauty; in the first, by tinging it abroad with the same liquor, and in the latter, by exposing it for several days to the sun.

It is well known, that by means of fire alone the amethyst, the sapphire, and the other gems, may also be wholly divested of their beautiful colours. The method of doing this is, to put the gems into a crucible, surrounding them with sand, or with lead-flings, and then putting them into the fire, they lose their colour as they become hot, and are taken out wholly colourless. If the white agate be calcined in this manner alone, it becomes of a cloudy or opaque white;
STONE.

white; but if it has before been flained with the solution of silver, those spots or flaws become of a yellow colour, which aqua fortis afterwards has no power to take away. If the agate be calcined first, and afterwards rubbed over with the solution of silver, it receives some spots and lines of brown. The cornelian loses a great part of its redness by calculation, and becomes of a dullish flesh-coloured white; and the Mocoa flone, treated in the same manner, loses all its colour, and the delineations of trees disappear.

There are many flones on which the solution of silver has no effect; of this number are all the gems, rock crysral, and the like. The dcndrites of Catalonia is also of this kind; and of this flone the artificers relate an odd phenomenon, which is, that if it be fawn under there are very few delineations observed in it, but if it be split by a blow, it is usually found full of them. The reason of this is only that these delineations are so many flaws and cracks, and the flone breaks easiest in these places.

The effects of the solution of silver are different, as to degree of colour, on different flones. The oriental agate receives from it a deeper and blacker tinge than the common chaledony. Some agates, naturally distingumed by their yellow spots, receive a purple colour from it. The jade flone, used by the Turks, takes only a faint tinge of brown. The common prime emerald, or root of the emerald, becomes blackish with it. The oriental granite is tinged in many places with a violet colour by it; this is principally effected in the white parts. The solution does not act much on the black ones, only that it takes some of them away. The serpentine marble receives an olive colour from it; but it is remarkable that the amathustes, and the talcs, and other folaceous flones, are wholly unaffected by it.

There is another method of staining flones of a colour more truly black than that which the solution of silver communicates to most of them, and with this farther difference, that the colour being produced by fire, has not been destroyed (says Dr. Lewis) either by moderate fire or by aqua fortis. Pieces of different flones, marbles, pebbles, flint, &c. may be washed over with a faturated solution of copper, made in aqua fortis; when dry, let them be put into a crucible, and kept for a little time in a fire just sufficient to make the veffel almost red-hot. All of them will be thus stained in the parts moistened with the solution of a black colour, durable, and pretty deep, though it penetrated only a very little way into the subsidence of the flones.

Dr. Lewis furnishes, from some experiments on the solution of silver applied to different flubstances, which he has mentioned (Phil. Com. of Arts, p. 350.) that this solution stains flones only in virtue of their containing a calcaceous earth, or such an earth as the acids is capable of dissolving; if this be the case, there is no wonder that some of the hard flones should be stained, and some of the soft unaffected by it.

Marble being a substance much softer than agate, receives the colours with much greater ease, and the doing of this in an accurate manner has been the subject of the attempts of many eminent men.

Kircher has given some directions for the staining of marble, which have been translated word for word in the Philosophical Transactions; but they are so indeterminate and uncertain, that nothing can in reality be learned from them.

See Colouring of Marble.

Many others have written also on the same subject, but M. Du Fay is the only one whose experiments are plainly and clearly laid down, and may be followed by any body.

This gentleman chose the common white marble without veins for making his experiments, for the same reason that he chose the plain agates, because in the veined ones there are several different sorts of matter, all of which are not to be penetrated with equal ease. The solution of silver penetrates into marble to the depth of an inch, or more, and gives a tinge, reddish or purple at first, and afterwards brown, from which colour it never varies afterwards. It always takes off the polish of the marble, eating away a part of its surface. The solution of gold does not penetrate so deep into marble as that of silver, but it gives a beautiful violet colour.

Both these operations are much affisted by exposing the marble to the sun. The liquors usually diffuse themselves, and spread every way in the marble, so that it is not easy to make any figure with them that shall keep its outline tolerably regular. And this imperfection appears to be the lefs, according as the solution is the more satured, fo as to dry or crystallize the more quickly. An easy method of obviating this inconvenience, says Dr. Lewis, is furred by the practice of the engraver; for the means, by which he confines the aqua fortis on his copper-plates to the minutest strokes, would doubtles answer the fame intention here. The surface of the flone being coated with a proper tenacious flubstance, which the acid cannot act upon, as the composition called etching-wax, which consists of refined flubstances melted with wax, or boiled with oil to a due confilence; and the drawing being made in this ground, fo that each stroke may reach down to the flone, it may be presumed that the solution of silver, afterwards applied, will no where spread farther than the parts thus laid bare. See Colouring of Marble.

The solution of copper gives marble a beautiful green tinge, but it does not penetrate deep, and on the application of boiling water becomes black; when the surface is polished off afterwards, however, it becomes again of a beautiful green. Befide the powerful acid muriarts, there are many other liquors which have a power of penetrating deep into marble. Of this nature are all the oily fluids; but the expressed oils have this disadvantage, that they leave a fattiness in the marble which will not suffer it afterwards to take a good polish.

All flubstances which can penetrate marble, can carry colours into it; but such are not eligible, which having lodged the colours, evaporate, and leave them there, without injuring the flone. Spirit of wine is of this number; it is excellently qualified for the extracting of beautiful tinctures, and sinks them very deep. Oil of turpentine also has for its value, but it does not take tinges so well as the spirit. Some have recommended lixiviurns of the fixt alkaline salts, but they very rarely produce any beautiful colour. In the using of these fluids the marble is to be gently heated, and the spirit is by that means evaporated before it is cooled, leaving its colour always behind.

White wax penetrates very deep into hot marble, and conveys colours into it in a very beautiful and determinate manner. There are, however, but few bodies, which will impart their colours to wax, and therefore this valuable means is of a very limited use.

Several of the gums alone are able to tinge marble very strongly. Dragon's blood, and gamboge, if rubbed on hot marble, penetrate to the depth of about a twelfth of an inch; the gamboge requires the marble to be hotter than the other, and tinges it to a very beautiful yellow; the dragon's blood tinges to a red in different degrees, according to the heat of the marble.

If these gums have been used to polish marble, there is no farther caution necessary than the cleaning them off.
from the surface with a little spirit of wine; but the way to
make them sink deeper into the stone, is to take off the
polish by rubbing the surface with pumice, or the like, and
then the gums sink much farther, and the colours appear
very beautiful when the marble is polished again.

Though the gums set alone, yet they will succeed much
better if distilled in spirit of wine, and applied with a
penetrate for by this means they sink deeper in, and the
figures traced out will keep their determinate form and out-
lines, these solutions fixing immediately, without spreading
any way. It is also remarkable, that the solution of dra-
gon's blood hardens the marble, and renders it less soluble
in acids than before: so that if a piece, stained in part with
this solution, be afterwards rubbed over with an acid dif-
solvent, and its surface eaten away to some depth, the parts
which are coloured will stand out above the rest.

A tincture of Brasil wood in spirit of wine tinges marble
red; and if the heat given to the marble be greater, it be-
comes purple; but both these colours fade a little in keep-
ing; but tincturing with gold gives a purplish-red; and the
more the marble is heated, the farther the colour penetrates,
and the deeper it is.

In oil of turpentine, the colour of cochineal penetrates
much deeper into the marble, but it has a brownish cast.
Alkanet root, by means of spirit of wine, gives also a red
colour, which, if the heat be too great, changes to brown;
and this, and most other of the like matters, tinge the
marble, in tincture with spirit, to a flight depth; and in oil
turpentine they sink much deeper, but then the oil leaves
a greatly appearance upon the marble.

If verdigris be boiled a considerable time in white wax,
it tinges marble, when rubbed hot upon it, to a beautiful
green, little inferior to that of the coarser emeralds, and the
colour spreads itself very equally, and penetrates to a third
of an inch deep; if the marble be made too hot, the colour
becomes that of the jasperone. Alkanet boiled in white
wax gives a flesh colour, which penetrates very deep; and
the ronceau boiled in wax makes a permanent yellow, which
also sinks very deep. The best way of heating marble for
this purpose is to lay the piece, intended to be stained, upon
a bed of sand, a fifth of an inch deep, upon an iron plate:
this is to be set over the fire, and when of a proper degree
of heat, the colour is to be applied. The jasperone can only
be found by experience, and it varies indeed in almost
every colour; but, in general, the finer colours require the
marble to be of such a heat, that the hand can just bear to
be laid upon it, and the others require a somewhat greater
degree than this.

Black is, of all colours, the most difficult to be given in this
manner to marble; and perhaps, indeed, it is impossible to
impart that colour in any degree of perfection; and that for
this plain reason, that all these colours only fill the inter-
fices between the granules of the marble, those granules
themselves, being unaltered: thus, in the other colours,
the whitening of the granules is only a heightening to the
tinges, making it brighter, and a little paler; but the white-
ness can never fail to appear distinguishably as such in black,
and by that means destroy that colour.

Dr. Lewis observes, that he has stained the porous
marbles, which admit water to sink into them, of a full
black colour with common ink, either by applying on the
warm marble an ink already made, or by the alternate appli-
cation of astringent liquors and solutions of iron; but
with the more compact marbles this method did not succeed,
though they were heated so far as to make the liquors boil
upon them; however, by a solution of copper, managed as
above related, and by a solution of the metallic part of co-
balt in aqua regia, employed in the same manner, the most
compact pieces were flained black; though the process re-
quires too great a heat to be practised on marble without
danger of injuring the stone. The colour which solutio-
nes of gold communicate to marble, in its deep shades, obtained
by repeated applications of the solution, approaches very
near to black.

Next to black, blue seems the most difficult, of all the
colours, to be given to marble. M. Du Fay, however, hav-
ing found by M. Geoffroy's experiments, that oil of
thyme, by long standing with spirit of gal ammoniac,
acquired a blue colour, tried this mixture, and found it suc-
ceeded very beautifully; but this is one of those colours which
require the marble to have but a very small degree of heat,
and a greater would evaporate them before the colour had
time to penetrate.

When the oil of thyme is digested with the volatile spirit,
it becomes brittle yellow, then red, then violet, and at last of
a deep blue. In six weeks' digesting it had acquired a pale
blue, and in this state gave a little colour to marble: after
staining for fix months, it was deepened almost to a black
hue, and being now applied on warm marble, gave the flain
defined.

M. Du Fay also flained marble of a blue colour with
tincture of archel. The tincture of it in water is applied
on cold marble, and renewed as it evaporates, till the
colour is sufficiently deep. He says, that he had pieces of
marble thus flained, which in two years were not feibly
changed.

The colours of the gums may be laid on when the marble
is cold; and on heating it afterwards, they will sink into it.
See Colouring of Marble.

There is another very elegant sort of workmanship to be
performed on marble, that is, the tracing of figures in relief
in it; and this is done much more easily than might be ima-
gined, there being nothing more required to it, than the
faying of the parts which are to be left in relief, by covering
them with a varnish, and eating away the relief by means
of an acid. For this purpose, let the defined figures be
traced in chalk upon the marble, and cover them with a
bed of varnish, made by dissolving a piece of common red
fealing-wax in spirit of wine; then pour on the marble a
mixture of equal parts of spirit of salt and ditilled vinegar,
and this will eat down all the ground, and leave the figures
standing, as if engraved with intenue trouble. The add-
ing of the colours before described, to these marbles after-
wards, in a regular manner, will give them a surpining
beauty. Mem. Acad. Par. 1728 and 1732. Lewis's Phil.
Com. of Arts, p. 435. &c.

Mr. Muller, in grinding some aurum fulminans, made by
dissolving gold in aqua regia, and precipitating it with fall
of tartar, together with some red glas powdered, and a
little water added, found, that this mixture flained the onyx,
or chalcedony, of which the mortar was made. He was
rubbing this mixture together to make an enamel colour,
and leaving it three or four days in this little mortar, he
found, that not only where it had been rubbed against the
bottom of the mortar, but where it had accidentally splashed
against the sides of it, and on the surface of the pestle, it
had tinged them both very deeply to a fine red, leaving the
intermediate parts of a true onyx, or chalcedony colour,
wholly unaltered. The polish of the flane was not injured
in the places where it was thus flained, nor could any art
get out the colour, though it was tried with alkalies and
other sharp liquors. This colour was not given to these
parts of the flane of the mortar in simple blotches, but
formed itself into regular lines, as we see the natural colours

of
of flones do; but this not in the same degree of colour, but some of the lines were deeper, others paler.

This experiment was repeated in several other mortars of the fame flone, but without success; on which the flones, of which they were composed, were examined with the help of gravers, and it was found that this mortar chanced to be made of a more flaky chalcedony than any of the others, though it appeared equally solid and beautiful to the naked eye, and bore a polish to wear inferior to them. It may be worth while, on this occasion, firstly to examine flones of this chalcedony kind, and on meeting with a plate of one of them of this flaky kind, to cover it with this mixture, and by that means give it a series of lines, which would make it a very beautiful and valuable flone. The polish will not be injured by this; or, if it should, the adding of a new polish will not at all affect the colours. In the fame manner the texture of flones, intended for any other experiments in leavening, should be considered, and the choosing of proper ones may make this process succeed on them. Phil. Trans. No. 1799.

Stone, Medical, a term used by some to express those particular flones, which for their real or imaginary virtues have, at one time or other, been made ingredients in medicinal preparations.

The opinions of the ancients, in regard to the virtues of gems and precious flones, were very whimsical. They suppositied that they had certain sympathetic properties, and that the wearing of them on the finger, or carrying of them in the pocket, would cure diseases, render the gods propitious to their prayers, or save them from thunder. These have been derisively laughed out of the world in our more enlightened times; but it has remained a question, and does so even to this time, whether or not some of the gems have not real medical virtues, naturally resulting from their parts, and constituting matter. See Gem.

Stone, Meteoric, in Meteorology. Meteoric flones, or aerolites, are those flones which have been observed to fall from the atmosphere. (See Falling Stones.) In addition to the description of these flones, and the particular phenomena attending their fall, under that article, we shall state that numerous facts of a similar kind have since been noticed in various parts of the world; and the evidence of their actual descent from the atmosphere is full and satisfactory, though the mode of their formation still remains involved in much obscurity. The opinion that these flones are of atmospheric origin, and that the elements of which they are composed have been either held in solution in the air, or were formed there by the union of gaseous fluids, appears to us to agree better with the phenomena than any other which has yet been advanced. Though it may be difficult to explain the sudden formation of a solid mass of stone in the air, yet we have instances of a formation somewhat analogous occurring very frequently; thus, during violent thunder-storms, masses of ice fall down in the hottest months of summer, sometimes weighing several ounces, and even pounds; and were the temperature of the earth constantly below 32° of Fahrenheit, they would remain as solid flones on the surface of the earth. The matter of which these masses of ice are formed, exiled previously in a state of elastic aqueous vapour in the atmosphere; but by what procxes it was suddenly condensed, during thunder-storms, is at present almost as inexplicable as the formation of meteoric flones. The nature of our atmosphere is but imperfectly known; for though we are acquainted with the proportions of oxygen and azote which it contains, we are not certain whether they are chemically combined, or only mechanically mixed: and with respect to the aqueous vapour, and other substances which are diffused through the different regions of the air, our knowledge is still more imperfect. Thus, though we know that, in the hottest months of summer, an immense quantity of water is railed into the atmosphere from the surface of the earth and sea, yet when this evaporation has continued for several weeks without rain, and consequently the atmosphere is charged with water, yet if it be examined by the hygrometer, it appears in its dry state. The important agency of electricity, in all atmospheric phenomena, is universally admitted; but the mode of its operation is very little known. When these subjects are better understood, we have no doubt that the formation of meteoric flones will receive much elucidation. From the examination of rain, collected at a distance from towns, it is proved that lime and other substances exist in the atmosphere; and it is not improbable that the elements, of which meteoric flones are formed, may be abounded from volcanoes, and diffused through the higher regions of the air, intermixed with hydrogen, or other inflammable gases (of greater levity) at present unknown. When these explode suddenly, large concrescences may be formed; or, by slow combination, they may form flowers of sulphur, or other substances, in a diffused or less compact state. In the Annales de Chimie, tom. lxxxv. p. 262, many curious instances of this kind are related, from which we selected the following, as intimately connected with the descent of meteoric flones.

We ought probably to rank with meteoric flones the ignited bodies, or fire-balls, which are only distinguished from them by their substance not being metallic. Like meteoric flones, they generally fall in the warmest months, and in calm weather; they burn in the same manner, and traverse their path with the same velocity; their explosions are nearly similar, and that of 1772 had a rotation round its centre. These ignited globes have a roundish form and gelatinous consistence. A globe of fire which fell in the East Indies, in 1218, left, after a dreadful explosion, a round large heap of gelatine, of tolerable consistence. A similar mass, but grey and spongy, was found at Coblenz, after the explosion of a ball of fire. Journal de Physique de Gilbert, tom. vi.

Silberenschlag relates having seen the residue of an ignited globe, which presented a gelatinous appearance, of a whitish colour.

The meteors called falling stars, do not appear to differ from globes of fire; they leave behind them gelatinous mafes,
STONE.

Maltese, falsely attributed to birds of prey, since they contain nothing which announces an animal origin. If igneous globes do not always leave similar residues, it is owing to their being composed of entirely combustible elements, and to their being consequently diffused before they reach the ground. We may refer to this kind of phenomenon, the globe of fire which, according to Geoffroy, burst in the Palace du Quénoy on the 4th of January, 1717; that which was observed in America in 1800, and in the county of Suffolk in 1802. With these globes of fire may be clafled the flowers of fire, which can only be distinguished from them by their greater diffusion. In the fire-balls, the flame diffused substance is concentrated in one mass. A flower of fire made great ravages in Germany in the year 1825, and burnt up whole villages. Another flower of the same kind fell, in 1571, in the grand duchy of Hesse; after a dreadful explosion it flowed through the streets, but without causing the destruction of the houses. A third flower of fire took place, in 1678, at Sachfen-Haufen, and the inflamed matter burnt half an hour in the streets before it was extinguished. Finally, that which fell over the city of Brunswick in 1721, was so violent, that they attacked in vain to extinguish it by means of water. The difference remarked between flowers of fire, and those of an oily substance, which have frequently occurred, appears to confit in this,—the substance of the former is in a state of pho- phorecence, which is not the case with the latter. We may place after these singular flowers, those of a medicinal nature. As chemistry shows that mucilage approaches to the nature of honey and sugar, we might refer the honey-dews, as they are called, to the same phenomena, for it is difficult to consider them as excretions of plants, as fome have asserted. One of these flowers of dew took place at Ulm so recently as 1802, and in such abundance, that every thing expelled to it, as well as the surface of stagnant waters, was covered with it. It may, perhaps, be presumed, that the matter of which meteoric flowers and fire-balls are formed, is sometimes precipitated, in a very minute rate of division, in flowers of sulphur or fand, and what have been falsely called flowers of blood.

The flower of brimstone which fell at Copenhagen in 1646, was accompanied with heavy rain, and the air was infected with the smell of sulphur. A flower of the same kind also took place at Copenhagen in 1665, after a very violent storm: the brimstone precipitated, emitted a strong smell of sulphur when thrown into the fire, and with spirit of turpentine it formed a kind of balfam of sulphur. In 1801, the rain which fell at Raffelt was so fulphurous, that it was used to prepare matches. A red mineral flower fell in Welfphalia in 1543, at Lozen in 1560, and at Embden in 1751: the latter was so extensive, that over the circumference of 10 or 12 leagues, all bodies exposed to it were dyed red. Similar flowers fell in Russia, Swabia, near the lake of Conflance, and at Lucarno, in Upper Italy, in the latter end of 1755. At Lucarno the atmosphere became quite red previously to the flower. The rain was almost as thick and heavy as snow, and the residue left by it was reddish, with an earthy appearance. In January 1810, a similar flower fell in the mountains of Piac , its first appearance was white, but after some claps of thunder it became red, and finally white again. In certain places it was of a flesh colour, but in others it was of a very deep red, and it always pervaded the colour after having been melted. There are too many testimonies in favour of flowers of sand having fallen, to allow us to deny the fact. One was observed at Bagdad in 1930. (Quatre- mère Memoires fur l'Egypt.) Long before it fell, the sky was darkened by a red cloud, from which an immense quantity of reddish sand was precipitated, entirely different from the sands which exist in that country. A flower of ferruginous rain was observed in the Atlantic, lat. 45° and long. 32°, at a distance of five or fix leagues from the main land: this flower was preceded by a strong light; it lasted upwards of nine hours, the air being calm during the time.

Showers of sulphur appear to admit of a more easy explanation than many of the above phenomena. Sulphured hydrogen gas is constantly emitted into the atmosphere from volcanoes and other sources; were this collected and exploded, or slowly burned, a quantity of liquid sulphur would be precipitated.

The writer in the Annales de Chimie, before referred to, has attempted to generalize the circumstances attending meteoric flowers, but he appears to want sufficient data to establish some of his conclusions.

"First: The fall of these flowers," he observes, "is most frequent in the months of June, July, and August. Of 65 or 70 of these recorded flowers of flone, nearly two-thirds have occurred in the above months; and the influences of their occurrence in the winter months are very rare indeed.

"Secondly: From a catalogue drawn up with great care it appears, that only seven influences occur of flowers falling between midnight and noon. On one occasion only, this phenomenon was observed between 11 o'clock in the evening and 6 o'clock in the morning, whilst we have evidence of thirty-six having taken place between noon and midnight, and the greater part of these fell between 3 o'clock in the afternoon and sunset." We may observe, that the descent of these flowers could not be so frequently noticed in the night as during the day, and therefore we do not think the author's conclusions on this head entitled to much notice.

"Thirdly: The number of these flowers of flone decreases with the distance from the equator. These phenomena are more frequent in Italy, France, and Germany, than in the northern countries of Europe.

"Fourthly: We know," says the author above referred to, "of no falls of flones having taken place in cloudy weather, or during a light wind, or a heavy continued rain or snow."

The weather has been noticed during forty-three falls of flowers; twenty-nine fell in warm and ferene weather, and two when the sky presented some scattered and inflamed clouds; the remaining twelve were accompanied by violent storms of rain and hail. Out of twenty-nine falls of flowers which took place in ferene weather, twenty seemed to issue from a very extensive but round cloud, black or variable in colour, according to the colour of the flowers themselves. Thus, the cloud was white in the fall which took place at Burgos, and the flowers were also white. At all times the cloud seems essential to these meteors, for from it proceeds the noise which accompanies or precedes the fall of the flowers, as also the flowers themselves.

It may not be improper to remark, that the great flone which fell on the wolds of Yorkshire, was unaccompanied with any meteor or light, and the sky was hazy. The progress of the great meteor in 1783, was unattended with any cloud; and though it exploded in various parts of its course, no defect of flowers was noticed. The cloud which, from various authentic accounts, appears to be generally attendant on the fall of meteoric flowers, is formed by some philosophers to contain these elements in a vaporous state. This cloud has sometimes been observed to have a rapid motion round its centre. During a very considerable fall of flowers in the department of the Lot and Garonne,
STONE.

Gygonian, in France, Sept. 5th, 1814, a small white round cloud, but greyish in the centre, appeared to move with great rapidity over the district where the stones fell; explosions, accompanied by lightning, immediately succeeded: the sky in other parts was feniace; at the same instant, the cloud appeared to divide into three or four parts, and fall to the ground, leaving behind a train of rainbow-coloured light, with a red point at the top. The stones in their fall appeared to diverge, striking the ground obliquely in various directions. They do not differ in their composition from other meteoric stones. We have thus endeavoured to select some of the most interesting facts that have been recently noticed in this department of meteorology; and in the present state of information on the subject, it is of far greater importance to perceive to collect facts, than to advance the most elaborate speculations on the mode by which these singular bodies are formed.

It has been stated by Mr. Bakewell, in his Introduction to Geology, that what we already know with respect to the formation of stones in the atmosphere, may elucidate, in his opinion, the appearance of new stars, which have fallen for a few years and then disappeared. The simplest form of matter with which we are acquainted, is of gas or vapour.

"Let us for a moment consider the elements of which all terrestrial substances are composed as existing in this simple state, when the flat of Almighty Power impressed upon the whole the various affinities by which they coalesced, and formed a fluid or solid mass. During their union, intense light and heat would probably be evolved, preventing to the distant inhabitants of the universe the appearance of a star of great brilliancy, but of short duration. The sudden concretion of stone masses in the atmosphere, with the intense light attending their formation, may be analogous to the production of a planet." As we conceive, however, that the phenomena of the appearance and disappearance of stars are satisfactorily explained upon other principles, we shall content ourselves with referring to the publication above cited, and to the article STARS.

Stones, Portland, Panama, Purbeck, and Roll-rich. See Portland, &c.

Stone, Rocking or Logan, in Antiquity, a name given to a mass of rocks, the uppermost of which, from relying on a small point, or pivot, was incapable of being moved, or rocked to and fro, with very little force. These stones appear to have been objects of curiosity, wonder, and superstition, in remote ages, and in different countries. Many of them are still remaining in the mountainous parts of England, Wales, and Scotland, as well as on the European continent. Some of the ancient writers have noticed these singular objects; and certain modern antiquaries have avowed themselves, and triumphed with their readers, in affixing to them different supernatural properties. Pliny says, that at Harappa, a town of Asia, there was a rock of such a wonder-ful nature, that if touched with the finger it would shake, but that it could not be removed from its place with the whole force of the body. Ptolemy Hepheidian mentions a Gygonian stone near the ocean, which might be agitated by the fluke of an aphantin, but could not be removed by the greatest human force. Dr. Stukeley considers the word Gygonius to be purely Celtic; and says, that Gwynog signifies Motitana, the rocking-stone. Although it is very evident that most of these rocking-stones are strictly natural in form and situation, yet it is generally supposed that others are artificial, or placed in their respective positions by human art. In the parish of St. Levan, Cornwall, on the coast, on a promontory called Castle Trelyn, are three groups of rocks, on the top of one of which was formerly a very large stone, so even poised, that by a very slight pressure it might be moved from one side to another. It was popularly called the Logan-stone, and has generally been visited as an object of curiosity; but it is now immovable. There are other rocking-stones, which are so peculiarly shaped and situated, that Dr. Borlase, and some other antiquaries, consider they were erected by human strength. Of this kind the doctor thinks the great Quoit, or Carn-bhan, in the parish of Tywidneck, Cornwall, to be. It is thirty-nine feet in circumference, and four feet thick at a medium, and stands on a single pedestal. There is also a remarkable stone of the same kind on the island of St. Agnes, in Scilly. The under rock is ten feet fix inches high, forty-feet feet round the middle, and touches the ground with no more than half its base. The upper rock rests on one point only, and is so nicely balanced, that two or three men with a pole can move it. It is eight feet fix inches high, and forty-feet feet in circumference. On the top there is a basin hollowed out, three feet eleven inches in diameter at a medium, but wider at the rim, and three feet deep. From the globular shape of this upper stone, the doctor thinks it highly probable that it was rounded by human art, and perhaps even placed on its pedestal by the strength of man. In Sittney parish, near Helston, in Cornwall, stood the famous Logan or rocking-stone, commonly called Men-Ambert, g. d. Men-an-Bar, or the top-stone. It was eleven feet in length, six feet wide, and four feet deep, and so nicely poised on another stone, that "a little child (as Mr. Scawen in his MS. lays) could instantly move it, and all travellers that came this way defined to behold it; but in the time of Cromwell, when all monumental things became defecible, one Shrubll, then governor of Pendennis, by much ado, caused it to be undermined, and thrown down, to the great grief of the country." Borlase says that it has marks of the tool on it. There is a rocking-stone in Perthishire, near Balvaird Castle, in the Ochil hills, Scotland, on the eftate of Mr. Murray of Conland.

That these rocking-stones were employed by the Druids, to fascinate and deceive the credulous, is very probable; but tradition has not informed, us for what express purpose they were intended. Toland thinks "that the Druids made the people believe that they only could move them, and that by a miracle; and by which pretended miracle they condemned or acquitted the accused, and often brought criminals to confess what could in no other way be extorted from them." Carew, in his "Survey of Cornwall," 1630, thus apostrophises the Logan-stone:

"Be thou thy mother Nature's work,
Or proof of giant's might,
Worthies and raged rough thou show,
Yet art thou worth the fight.
This bigy rock one finger's force
Apparently will move;
But to remove it, many strength
Shall all like feeble prove." 1769.

Borlase, in his "Antiquities, &c. of Cornwall," folio, has devoted a chapter to this subject, and gives an excellent view of different rocking-stones.

STONE of Scandal. See Scandal.
STONES, in Mythology, were objects of religious worship among the ancients, before flatulence was invented. They were unknown to the ancients, called by Sanchoniathon Batillia. (See Bætys.) Pananias speaks of the statues of Hercules and of Cupid, which were merely such masses of stone. He adds, that there were seen, even in one place, 30 square stones, which had the names of so many divinities.

STONES for Mills, Preparation of, the means of forming them for the purpose of grinding. In small corn-mills, where only one pair of stones is in use, they are, it is said, roughed on the surface, to enable them to tear, bruise, and reduce the grain, by the use of a small hand-pick. Stones thus prepared and dressed, serve well for making of oatmeal, which is built and most relished when rough, and large in the grain; but they are not capable of grinding barley or peas to that fineness of flour which is necessary for some uses. It is requisite to have a separate pair of stones for this purpose, which are dressed on the surface, with a small chisel, in grooves running in from the circumference to the centre, as in the stones of wheat-mills; the edges of these grooves clip the grain like scissors, and there is no interstice through which any of the grain can escape, until it is reduced to the required fineness of meal which is proper.

STONE-Dikes, in Agriculture, that fort of dike or mound which is formed with stone and earth. These dikes should, it is said, consist of a double face to two-thirds of their height, and the other third be of single stones, built up in an open form and manner, so as to hang firmly on each other. They are made in the Highland sheep districts, where this manner of forming them is much had recourse to, five or five feet and a half high from the surface of the ground. A dike thus built, when well executed, and filled with through-bands, bids defiance, it is said, to most kinds of animals, none of which are fond of venturing over it; whereas a green feed on the top of a double-faced wall invites the sheep to attempt clearing it, which they not infrequently do with facility. These dikes are equal in durability and cheapness; even more so than the turf or sod covered or coped stone-walls, while they are greatly more effectual. They are the most proper for confining of sheep, and on farms purely of this kind, are perhaps the best fort of contrivance for restraining them of any yet known. They have different names in different sheep districts.

The term is sometimes written Stone-dyke.

STONE-Drain. See Spring-Drain and Surface-Drain.

STONE Picker. See Picker.

STONE Picker, the name of such persons as are employed in picking stones from off the ground. In order to prevent the loss of time in filling and emptying the baskets, and that of having recourse to the team, the use of one horse and a light cart is advised, which attending seven or eight women, boys, and girls, may run over forty acres in about four days. It is advised by Mr. A. Young, that constantly in a dry season, an opportunity should be taken to stone-pick the grass and clover fields intended for mowing.

In this work, no stones are, he says, however, to be taken, but such as would impede the leythe. It is of the better, he adds, that the pickers, who generally like this work, will over-pick if they are not attended to, and propose to pick fields which are not to be mown; but this is on no account to be permitted, if the stones be not much wanted. It has been often remarked, and is a known fact, that too much stone-picking has done a very sensible mischief, in many cafes where picked by authority of parliament for turnpike roads. And Mr. Macf, of Suffolk, ascertained it experimentally.

Observations have been made in other places, which clearly shew that the stones should not be wholly picked off many farts of land.

STONE-Roller. See Roller.

STONE Arabia, in Geography, a settlement in Montgomery county, New York, on the N. side of the river Mohawk, four miles from it, begun by some Germans; situated on an eminence about 54 miles W. of Albany. The soil is excellent, and the people industrious. It has two churches, a Calvinistic and a Dutch Reformed. Stone Arabia is a part of the post-township called Palatine, (which inc.) 51 miles from Albany, separated from the W. part in 1808. This township is well watered, and has many fine mill-feats, the land of which is under high cultivation. It was first settled by some German families in 1724. Palatine village has about 35 dwellings, some stones, &c. and a stone church 55 miles from Albany. In 1810 the population of Palatine was 3111.

STONE Creek, a river of West Florida, which runs into the Mississippi, N. lat. 32° 8'. W. long. 91° 13'.

STONE Indians, Indians of North America, situated on the Almbibon river. See Assinibois.

STONE Island, a small island near the E. coast of Newfoundland, near Cape Broyle, and one of the three islands which lie off Caplin bay.

STONE Mountain, a mountain that lies between the flats of Tennessee and Virginia. N. lat. 36° 40'. E. long. 81° 40'.

STONE's River, a river of Tennessee, which runs into the Cumberland, fix miles N.E. of Nashville. N. lat. 36° 57'. W. long. 87° 49'.

STONE's Fort Gut, a creek on the S.W. side of the island of St. Christopher's, E. of Old Road bay, and between that and Bloody Point, with a fort on a point of land, on the W. side.

STONE Reef, a small island and rocks of Denmark, in the Little Belt, near the N. coast of the island of Alien.

STONE River, a river of North America, which runs into lake Athapecos.

STONE, in Commerce, denotes a certain quantity or weight of some commodities.

A stone of beef, at London, is the quantity of eight pounds; in Herefordshire, twelve pounds; in the North, sixteen pounds.

A stone of glass is five pounds; of wax, eight pounds.

A stone of wool (according to the statute of 1 Hen. VII.) is to weigh fourteen pounds; yet in some places it is more, in others less; as in Gloucestershire, fifteen pounds; in Herefordshire, twelve pounds.

Among horse-couriers, a stone is the weight of fourteen pounds.

The stone, troy, in Scotland, contains sixteen pounds, the pound being two marks, or sixteen ounces.

The stone, called Stein in Germany, varies very much in different parts of the continent: at Amsterdam, a stone or stone is eight pounds: at Berlin, the centner or quintal weighs
weights five fenns or felines, each of twenty-two pounds: at
Hamborough and Prague, a feline of flux is twenty pounds,
and a feline of wool or feathers is ten pounds. See
Weight.
Stone, in Medicine. See Lithotomy.
Stones of Animals, in Rural Economy, the organs of
generation in them, which, in all those that are intended
for this purpose, should be quite in a complete state of
production, and not in the rigid condition. See Testicles.

Stone-Plant. See Lithophyton.
Stone-Sucker, in Ichthyology. See Petromyzon.
Stone-Ware. See Pottery.
Stone-Blue, a preparation used in washing of linen. See
Blue, Indigo, and Smalt.
Stone-Brick, in Agriculture, a term sometimes applied
to a loose stivert of soil or land. It has a surface of
greater or less depth, mostly of a loose, dry, friable sort of
fandy, lime-fonny, chalky, or loamy materials, which seem to
be formed from abraded matters of these fomy kinds, and
abounding with many fragments of them. In many dis-
tricts and places, the lands of this sort are chiefly of the lime-
flute and chalk kinds. It is a sort of land that prevails
much in some counties, as in Oxfordshire, Someretheire,
Bedforshire, and probably in some others. It is sometimes
of a springy, fnewy nature, reeplit upon deep beds of a blue
clayey, mery quality, under which is a vein of white marle,
extraordinary rich in calcareous matter, and below that rock
of the rough white lime-foone kind. The blue and white
matters have occasionally been spread out over the surfaces
of these lands, and found very beneficial. These lands, in
some eafes, form excellent soils for the turnip husbandry, and
are very productive in wheat, especially where they are of
the more calcareous kinds.

They answer well for incoying too in some instances, in-
stead of being cultivated on the common field plan, as is still
too much the case in many places, notwithstanding the im-
provements which husbandry has lately undergone.

A variety of different covenants are suppoofe syllarcey
for tenants in cultivating stone-brick farms, as may be seen
in the Corrected Report of the Agriculture of the County of

Stone-Break, the name of a perennial plant of the
weed-kind, common in pailure grounds. The root has a
sharpish and aromatic taste. The flails are round, fleshed,
and reddish towards the bottom. The leaves are smooth,
of a dark green, and divided twice, into long, narrow, firm
segments. The flower spikes are membranous at the base. The
flowers grow in loose umbels, and are of a pale yellow col-
our. The seeds are oval, fleshed and red at the top. It is
a plant of the saxifrage kind, which has been suppoofed
beneficial in meadow lands, as improving the qualities of
the cheese and butter which are made from the milk of the cows
which are paitured upon them.

Stone-Chatter, in Ornithology, the name of a small
bird of the cananthe, or fowlo-finch kind, the motacilla rubi-
cola of Linnaeus, called by some authors rubetra and mu-
sicina, and in some cafes the stone-mitch and the moor-sitting.
See Motacilla.

The head, neck, and throat are black, but on both sides
of the latter there is a white bar; the feathers on the back
are edged with tawny; the lower part of the back, jilt
above the rump, is white; the end and exterior side of the
two outermost feathers of the tail are of a pale rufus-colour,
the rest are black; the breast is of a deep reddish-yellow;
the belly of a lighter hue; the quill-feathers dusky, edged
with dull red; those next the body marked with a white
spot near their bottoms; and the covenets of the wings are
adorned with another. The head of the female is ferrugine-
ous, spotted with black, and the colours in general less
vivid: in both sexes the legs are black.

These birds are common during summer, on heaths and
gory grounds, but in winter differ to more marlises, &c., with-
out quitting the island: they make a very loud and often
repeated noise. Pennant.

Stone-Curlew, in Ornithology, the English name for the
redicrus, a bird of the colour of the curlew. See Stone-
Curlew.

Stone-Snitch, a common English name for that spe-
ces of cananthe, which we more frequently call the stone-
chatter.

STONEHAM, in Geography, a township of Middlesex
county, Maffichufetts, incorporated in 1725, and containing
467 inhabitants; 10 miles N. of Bolithon.

STONEHAVEN, a sea-port town in the parish of
Dunottar, and county of Kincardine, Scotland, is 107 miles
N. by E. from Edinburgh. It consists of two large streets
of houses, built on fofts granted by the earls marishal,
within whose citate, before their forfeiture, it was situated.
There is a fine harbour formed by a natural bafin, defended
by a high rock upon the S.E., which extend to the sea,
and upon the N.E. by a quay, very convenient for the un-
lading of goods.

A manufacr of house-linen has been established here,
and the town has been improving for some years past. The
sheriff's court for the county was removed from Kincardine
to Stonehaven in 1660, and in consequence of the gaiol for
the county, and county courts held here, the town is much
benefited. The public revenue of Stonehaven consists
chiefly of hire due, which amount to about 45 £ annu-
ally. A great deal of lime is brought to this part; and
from four annual fairs, the revenues of the town are aug-
menced.

Stonehaven is a borough of barony, of which the juridic-
tion is by the charter veiled in magistrates chosen by the
superior and feuars. In 1792 the town contained 1672 in-
habits, independent of the additional suburb.—Beauties
of Scotland, vol. iv. Carlyle's Topographical Dictionary of
Scotland, 2 vols. 4to. 1813.

STONEHENGE, in Antiquity, an affemblage of up-
right and proflrate fones on Salisbury plain, England, sup-
poofed to be the remains of an ancient Drudical temple, which
claims particular notice in this work, as being often referred
to in foreign and English books, and from having been very
accurately described in most of those publications. Next
to the wall and far-famed pyramids of Egypt, Stonehenge,
and other remains of the same class, rank among the most
curious and most remote monuments of antiquity. These
are all anterior to written evidence, and are confequently
involved in the most abitrue mystery. Hence they have
also occasioned much speculation; and many volumes and
copies have been written by English and continental anti-
quaries, with a view of explaining the origin and ufe of such
structures. On the present occasion, it is intended to de-
scribe clearly and explicitly what Stonehenge is, and
what it has been; to detail the opinions of different writers
on the subject, and thence endeavour to deduce a probable
shape.
and rational inference respecting this and other similar monuments. Stonehenge, situated about two miles directly west of Amesbury, and seven north of Salisbury, in Wilshire, is an ancient and certainly very extraordinary monument of a remote age. From its singularity, and the mystery attending its origin and appropriation, it has excited more surprise and curiosity than any other relic of antiquity in Great Britain. When viewed at a distance it appears but a small and trifling object, for its bulk and character are lost in the extensive space which surrounds it; and even on a near examination, it generally fails to alluith or gratify the expectations of the stranger, who initially visits it with exaggerated prepossessions. To behold this "wonder of the world," as it has been termed, with interest and satisfaction, it should be viewed with an artist's eye, and contemplated with a mind flored with antiquarian and historical knowledge.

In various parts of the United Kingdom, and also in foreign States, several circular enclosures of upright stones are to be found, some of which consist of a single, and others of complex circles; but Stonehenge is of a distinct and different character and clafs, and is, we believe, wholly unlike any other monument now remaining in Europe. Many of the stones in this temple have been squared or hewn by art; and on the top of the outer circle has been raised a continued series of squared stones, attached to the uprights by mortises and tenons, which regular cavities in the horizontal stones, and projecting points on the perpendicular ones; whereas nearly all othcr examples, of what is generally called Druidical circles, are composed of rough, unhewn stones, and are without impoits.

By the plans, view, elevations, &c. in Plate Stonehenge, it is presumed the reader will be enabled to comprehend clearly and readily the original and present form, arrangement, and proportions of Stonehenge. A is the ground plan of the temple, as remaining in 1816; the darker parts shew thefe that are standing, and the light tints the fallen stones, or fragments: whilst the dotted lines indicate the impoits, or stones refting on the uprights. B is a view of the structure from the south-west, showing part of the ditch and vallum; also two stones attached to the vallum, and remote from the body of the temple. C is a geometrical elevation on the north-west side, to shew the distance between the temple and the vallum C, the stone D, within the ditch, and the stone E, still farther from the temple. These two stones, one now standing, E, and the other fallen, D, is it presumed, formed part of a long avenue, similar to others at Avebury (see Avebury); F, a barrow; C, the vallum, rising on the outside of the sacred area.

D is a ground plan of the temple, as supposed, by Dr. Smith, to be in its original state. E is a perspective elevation from the same plan. F is a section of the work on the line A B of plan D.

The present appearance of this monument (see view B, taken from the south-west) is that of a confused heap of erect and fallen stones. The original arrangement of thefe (see plan D, view E, and elevation C) may, however, be readily understood; for by the position and situation of the yet standing and prostrate members, we are enabled to judge of the number and fect of thefe which have been removed. The whole consisted of two circular and two other curved rows, or arrangements of stones, the forms and positions of which are laid down in the plan, elevation, and section, D, E, and F. (See Plate Stonehenge.)

Horizontal stones, or impoits, were laid all round, in a continued order, on the outer circle; and five similar impoits on ten uprights of the third row. According to the plan referred to, Dr. Smith represents two other smaller trilithons, as forming part of the third row. The whole is surrounded by a ditch and vallum of earth, connected with which are three other stones. The vallum does not exceed fifteen feet in height, and is exterior to the ditch. Through this line of circumvallation there appears to have been one grand entrance from the north-east side, and this is decidedly marked by two banks and ditches, called the Avenue. Approaching Stonehenge in this direction, the attention is first attracted by an immense unchilled stone, called "The Friar's Heel," which is now in a leaning position, and measures about fifteen feet in height, C, a. Immediately within the vallum is another stone, lying on the ground, three sides of which bear the same marks of tools as the large uprights, and was evidently once flanding. In length it measures twenty-one feet two inches, of which three feet six inches appear to have been formerly under ground when it stood upright. Its distance from the stone last-mentioned is one hundred feet; and it is nearly the same distance from the outside of the outermost circle of the monument. Each inch of this row has two mortises in it, to correspond with two tenons on the top of each vertical stone. The impoits were connected together in such a manner, as to form a continued series of architraves. The uprights in this circle differ from each other in their forms and fizes; but their general height is about fourteen feet, and the measure of their fides seven feet by three. The space between them also varies a little; that between the entrance-stones (see Plan D, a) is five feet, being somewhat wider than in the others. The diameter of this circle is one hundred feet, and the number of upright stones it originally contained, thirty; of which seventeen are still standing, but there are no more than six impoits. (Plan A, g.)

At the distance of eight feet three inches from this outer circle, is an interior row, which, Dr. Stukeley remarks, consisted in its original state of forty upright stones. Wood, in his account of Stonehenge, states their amount at twenty-nine only, and affirms that they were formerly covered with impoits; but Smith, in his "Choir Gaur," specifies thirty. The stones of this circle are much smaller, and more irregular in their shapes, than those of the outermost row, and also differ from them in species. The number standing is only eight, but there are the remains of twelve others lying on the ground. A few particulars respecting this circle claim attention. Dr. Stukeley, in his ground plan of Stonehenge, has placed the two stones at the entrance (Plan D, b, b') a little within the range of the others, and observes, "that the two stones of the principal entrance of this circle, correspondent to thefle of the outer circle, are broader and taller, and set at a greater distance from each other, being rather more than that of the principal entrance into the outer circle. It is evident, too, that they are set somewhat more inward than the rest: so as that their outward face stands in the line that marks the inner circumference of the inner circle." A stone lying near the above, and apparently belonging to this circle, resembles the impost of a small trilithon, and most probably gave rise to the attention of Wood, that all the stones of the smaller circles had impoits. See Plan A, g.

Within the circles just described are arranged two inner rows of stones, one of which constitutes the grandest portion of Stonehenge. It was formed by five distinct trilithons, or two large upright stones, with a third laid over them as an impost. Dr. Smith conjectured that this arrangement consisted of seven pairs of uprights, with an impost to each pair; whilst Dr. Stukeley gave them the name of trilithons, or three stones. The largest trilithon was placed in the centre, opposite the entrance, and measured, when
when standing, exclusive of the impolt, twenty-one feet six inches in height (Plan D, d): these next it, on each side, were about seventeen feet two inches (D, r; t): but the others were not more than fifteen feet three inches (D, j, f). Thus we perceive a progressive rise in the height of these barrows. Besides, the stones are evidently more regular in their shapes, and more carefully formed, than those in the outer circle. At present, we find that only two of these barrows are perfect. (Plan A, 2, and 3.) One of the uprights is standing at 4: but leans inwards, and rests on 10. The next barrow, 5, fell down in the year 1787, and it is remarkable, that this is the only alteration recorded of Stonehenge. At 6, one of the uprights is standing; but its corresponding stone and the impolt have fallen, and are broken into several pieces.

The interior row of stones which next claims attention, consisted, according to Stukeley, of nineteen uprights, without impolts; but their original number is differently stated by other authors. These stones "inclined to a pyramidal form." The most perfect among them, according to the measurement of Sir Richard Hoare, is seven feet and a half high, twenty-three inches wide at the base, and decreases to twelve inches at the top. Another is remarkable as having a regular groove from top to bottom, and as being "bevelled almost at an angle on the inner side." For what purpofe the groove has been formed, it is impossible to conjecture; and it is equally difficult to say whether the hollow has been formed by nature or art. (D, g; and A, 10.)

The altar-stone, as it is usually called, lies flat on the ground, and occupies the core, or adytum of the temple. Two other stones belonging to this monument remain to be noticed: they are situated close to and within the vallum, one on the south-east side, and the other on the north-west side; the former measures nine feet in height, and has fallen from its base backwards on the vallum; but the latter is not more than four feet high; and both are rude and unshaped.

Two small hollows likewise appear adjoining the bank, which merit particular attention in a description of Stonehenge. Dr. Stukeley considers them to have been the feites of two flone vales, and the cavities round them are conjectured to have received the blood of victims. The fallacy of the doctor's opinions, however, on this subject, is sufficiently proved by the investigations of Sir Richard Hoare, who, upon digging into them, found one to contain a simple interment of bones.

The total number of stones of which Stonehenge was composed, according to Dr. Smith's plan and calculation, in its complete state, was one hundred and twenty-nine. Thus, the outer circle contained thirty, with thirty impolts; the second, or inner circle, thirty; the third interior row fourteen, and seven impolts; and the fourth interior row thirteen: the remainder are the altar-stone, the three stones adjoining the agger, and the large flone in the avenue.

Natural Quality of the Stones. - Thofe of the outer circle, and third row, with the flone in the avenue, and those adjoining the vallum, are, according to Dr. Townson, in Tracts and Observations on Natural History, &c., all "of a pure, fine-grained, compact flnad-flone, and only differ a little in their colour; some of them being white, and others inclining to yellow." These stones resemble precisely in their quality the grey-weathers, and numerous other detached masses which lie on the surface of the Downs, in the vicinity of Avebury and Marlborough. The second circle, and the interior row, consist of "a fine-grained pyramidal flone, imperfected with black hornblende, felspar, quartz, and chlorite, excepting four in the circle; one of which is a fliceous felicitus, another an argillaceous felicitus, and the others horn-flone, with small specks of felspar and pyrite. - The flab, or altar-flone, is different from all thefe, being a kind of "grey cor, a very fine-grained calcareous flad-flone," which strikes fire with ilex, and contains one minute fragment of silver mica. Many perfons have absurdly supposed that these flones are artificial, and formed in moulds.

The mystery of Stonehenge, the legendary flories connected with it, and the natural and artificial features of the surrounding plains, are certainly calculated to make itsogn impressions on the mind of every spectator. The area of the temple, as may be readily supposing, has excited the attention of the curious in a high degree, and, consequently, has been examined with considerable care by different antiquaries. Stukeley, indeed, informs us, that a tablet of tin was found there in the reign of Henry VIII., and would wish it to be believed that it was a memorial of the founders, because the characters engraved upon it were unintelligible to the most learned antiquaries of the age. It is much to be regretted that this relic is lost. Sir Richard Hoare and his indefatigable coadjutor, Mr. Cunningham, were found to contain, in some infancies, cills filled with burnt bones, and in others entire flcketons, with various relics of Britifh art. Some other objects here, however, beside the barrows, present themselves to our notice. The principal of these are the Avenue and the Curfus, the former of which has been previously noticed. It is a narrow strip of raised ground, bounded on each side by a flight bank of earth, and extending in a straight line from the entrance through the vallum of Stonehenge on the north-eall, to the distance of five hundred and ninety-four yards, at which spot it divides into two branches, one of which continues southward, and is seen between two rows of barrows, while the other proceeds northward, and approaches within a few yards of the curfus. The lait is a very curious and interesting appendage to Stonehenge, if such it can be properly considered, and certainly ranks among the most perfect velliges of this fort that are to be found in our country. It is a flat tract of land, bounded by two parallel banks and ditches, and is situated about half a mile N.E. of the temple; it measures one mile five furlongs and one hundred and seventy-five yards in length, and one hundred and ten yards in breadth. Its direction is from east to west, and at the former extremity is a mound of earth, resembling a long barrow, which stretches entirely across it. The western extremity is defitute of any mound like that at the extremiend; but there are two barrows, irregularly placed within the area of the curfus, a part of which appears also to be cut off by a flight bank. The original purpose of this it is difficult to determine, for we can scarcely suppose that if (as would seem most probable from the existence of the mound) the chariots started from the east end, they would drive over this bank to the termination of the course at the west end. We should therefore be inclined to think it had been raised at a later period for some object distinct from racing, did we not perceive that another similar bank is thrown across a second and smaller curfus, which is situated at the distance of nearly a mile from the

STONEHENGE.

larger one. From the near resemblance of the above work to the cursus of the Romans, it seems reasonable to suppose, that if these earth-works were not formed by that people, they were made in imitation of them, and by a class of people familiar with their manners and customs. Having thus given a full, and, it is hoped, clear account of what Stonehenge has been and is, it will be necessary to review the writings of those antiquaries who have published their opinions on the subject. See HIPPODROME.

Writers on Stonehenge.—The earliest account of Stonehenge occurs in the writings of Nennius, who lived in the eighth century. He narrates the story of the massacre of four hundred and sixty British nobles, at a conference between king Vortigern and Hengist, at or near the spot on which our monument is situated, and attributes its erection to the Britons, who thereupon endeavored to perpetuate the memory of this tragic event. The historical Trials of theWelsh also refer its origin to the same cause, and relate that it was constructed by Merlin, at the desire of Aurelius Ambrosius, the successor of Vortigern, after he had punished the perfidy of Hengist. This likewise is the account of Walter de Mapes, a Welsh chronicler, who is very circumstantial in his narrative.

Jeffery of Monmouth is another monkish historian, who gives, with some flight variation, a similar account of the origin of Stonehenge. The same story is also noticed by some other authors about the same era, and particularly by Giraldus Cambrensis, who farther relates that, during his tour through Ireland, he "saw with his own eyes" an immense monument of stones on the plains of Kildare, or Killraus, corresponding in appearance and construction with that of Stonehenge. Henry of Huntingdon calls this structure one of the wonders of Britain; but disbelieving the story of Merlin, candidly confesses that no one can devise by what means, or for what purpose, such a work could have been erected. Camden, the great antiquary and chorographer, characterizes this monument as an "infernall subterracel," or a wild structure. His description of it is so very erroneous and defective, that we doubt much if he ever saw it. On the question of its origin and uses he forbears to give any opinion.

Such is the scanty information which certain old writers, commonly called historians, furnish relative to this curious monument of ancient times. Modern authors on the subject have thrown aside every item of historical information, and have raised their theories concerning it solely on speculative foundations. Of these theories, that of Inigo Jones first demands attention. His essay was undertaken at the desire of King James I., who commanded the "author to produce of his own practice in architecture, and experience in antiquities abroad, what possibly he could discover concerning this monument of Stonehenge." Jones did not, however, live to complete the proposed work; but his son-in-law, John Webb, finished and laid it before the public in one small folio volume, with a portrait of the author, and several plates, A.D. 1655. In this work he endeavours to shew that Stonehenge was a temple of the Romans, dedicated to Celsus: but unfortunately for Jones's theory, he has committed palpable errors in the form and arrangement of the stones, and has thus rendered his deductions and allusions untenable and untrue.

Jones's work was succeeded, in 1663, by an answer and dissertation from the pen of Dr. Charleton, who contends that Stonehenge was an erection of the Danes; but, unfortunately for his theory, the monument existed long previous to the settlement of any Danes in Britain. Nennius, who first notices it, wrote anterior to the year 800, at which period people had not entered Wilthire.

Dr. Charleton's dissertation introduced a voluminous essay in support of Jones, by his editor, Mr. Webb, in folio, 1665. This volume abounds with dulness, sophistry, malversation, and profanity. It was followed by a volume from Aylett Sammes, who, after recapitulating the former suppositions respecting Stonehenge, remarks, "why may not these giants (alluding to the title of Chorea gigantium given to our monument) be the Phenicians; and the art of erecting these stones, amidst of the stones themselves, brought from the furthestm old parts of Africa, the known habitats of the Phenicians." This idea, however plausible it may seem, completely fails, from the want of evidence to prove the settlement of those people in England.

Bishop Gibson, in his edition of Camden's Britannia, 1694, after opposing the suppositions of Jones and Charleton, concludes with observing, that "one need make no scruple to affirm, that it (Stonehenge) is a British monument, since it does not appear that any other nation had so much footing in this kingdom, as to be authors of such a rude and yet magnificent pile." The learned prelate is followed in the same opinion by most succeeding writers, though they differ from each other in the period of its origin, and the purposes of its erection.

Dr. Stukeley, more fanciful than correct in his reasonings, published a folio volume in 1740 on the subject, containing several plates. In this volume he attributes the work to the Druids; but, instead of reeling his theory upon solid British ground, he takes up a large portion of his essay with irrelevant dilatation and speculation. Wood, an architect of Bath, devoted much time to make plans of this structure, which he published with an essay, in 1741. His opinion is, that it was a temple, erected by the British Druids about a hundred years before the Christian era.

William Cooke, M.A. in a treatise entitled "An Enquiry into the Patriarchal and Druidical Religion, Temples, &c." 1775, supposes Stonehenge to have been a place held sacred by the Druids, and appropriated to a meeting of great assemblies on civil or religious occasions; and adds, "the world does not afford a soberer spot. Its situation is upon a hill, in the middle of an extended plain in the southern part of the kingdom, covered with numerous herds and flocks of sheep, in which respect the employment and the plain itself are patriarchal: where the air is perfectly salubrious, and the yielding turf fine as the surface of a bowling-green."

Dr. Smith, whose work on Stonehenge, called "Choix Gaufr," appeared in 1779, after giving an account of the theories of Jones and others, with copious extracts, and a minute description of the monument itself, says that he considers it to have been of Druidical origin, and erected as well for the purposes of astronomic observation as of religious ceremonies.

King, in his "Monimenta Antiqua," conjectures that this monument was constructed in the very latest ages of Druidism, while that religion was struggling against the overwhelming tide of Christianity. This gentleman, however, had such strong prejudices and antipathies against every thing pagan, that he could not even mention this, or any other anti-christian temple, but in terms of repro-
STONEHENGE.

aliuded to in a Welsh Triad, as constituting the greatest labours of the island of Britain, i.e. "lifting the stone of Ketti;" "building the work of Emrys;" and "piling the mount of the allembles." That Stonehenge is really a Druidical structure, the fame learned writer farther remarks, "is evident from the language in which it was delivered, and the great veneration in which it was held by the primitive bards, those immediate descendants and avowed disciples of the British Druids. As the great sanctuary of the dominion or metropolitan temple of our heathen ancestors, so complex in its plan, and constructed upon such a multitude of astronomical calculations, we find it was not exclusively dedicated to the Sun, the Moon, Saturn, or any other individual object of superstition; but it was a kind of Pantheon, in which all the Arkite and Sabian divinities of British theology were supposed to have been present; for we perceive Noe and Ha, the deified patriarch; Elphin and Rheiddin, the Sun; Eleve, Iba; Ked, Ceres, with the cell of her sacred fire; Llywy, Proferpine; Gwyden, Hermes; Budd, Victory; and several others." As to the precise date of Stonehenge, Mr. Davies says nothing definitively, but remarks, that it was most likely of later origin than the introduction of the Helio-Arkithe superstition, which is traditionally said to have been of foreign origin, and to have come into England by the way of Cornwall, and, therefore, probably from the tin-mERCHANTs. He also remarks, that "it was a monument of venerable antiquity in the days of Hengist; and that its peculiar sanctuity influenced the selection of the spot for the place of conference between the British and Saxon princes." P. 385, &c.

Mr. Davies farther mentions a passage in the Greek historian Diodorus Siculus, describing a round temple dedicated to Apollo, which Mr. D. concludes to have been most likely our monument of Stonehenge. The fablance of the Grecian author is: Among the writers of antiquity, Hecateus and some others relate, that there is an island in the ocean, opposite to Celtic Gaul, and not inferior in fize to Sicily, lying towards the north, and inhabited by Hyperborei, who are so called because they live more remote from the north wind. The soil is excellent and fertile; and the harvellt is made twice in the same year. Tradition says that Latona was born here, and therefore Apollo is worshipped above any other deity; to him is also dedicated a remarkable temple of a round form, &c.

The Rev. James Ingram, in his "Inaugural Lecture on the Utility of the Saxon Literature," has suggested a new idea relative to Stonehenge: he considers it to have been defined "as an heathen burial-place, and the curvus-adjoining as the hippocorde on which the gods of the deceased were run for at the time of the burial." This opinion is entitled to some credit and consideration, from the vast number of barrows which abound in this part of the plain.

The late Mr. Cunningham, in the "History of Ancient Wiltshire," folio, 1812, grounds a novel supposition on the difference in quality and size between the stones of the great circle and interior row, and those of the smaller ones; and thence he supposes, that Stonehenge was erected at different periods. He also supposes, that the larger stones, with their impolts, constituted the old, or original work; and that the small stones of the second circle, and those of the inner range, were raised at a later period, as "they add nothing to the grandeur of the temple." To exemplify this opinion, sir Richard Hoare has given a bird's-eye view of the structure, thus divested of the smaller stones. Unfortunately for the theorist, this system is not warranted by any example among the numerous Druidical circles of Great Britain; but, on the contrary, it will be more consistent with theory, and with the practices of remote ages, to conclude, that the second circle of small, rough, unknown stones, with another circle immediately within the ditch, and some other members, now destroyed, formed the original, pristinely temple. Many arguments might be used to exemplify this opinion; and also to prove that the great circle of upright chiselled stones, with their impolts, and the third row of trihions, were posterior to the former, raised by another clafs of people, and executed at a time when their principles and arts had been considerably changed. Contemporary with which it is conjectured, that an avenue of stones was raised, extending from the temple towards the curits to the north-east; and also that those places for races and for other sports were formed at a time when the inhabitants of Britain had intercourse with the Greeks, or Romans.

A learned and eloquent writer in the "Edinburgh Review," for April 1806, in noticing Barry's account of the "Orkney Islands," remarks, that "these circles, besides being used as places of worship, and courts of justice, evidently served the purpose of rude astronomical observatories, by which the Druids could ascertain the rising and setting of the sun, moon, and stars; the feasons of the year; and even the hours of the day: and where they are tolerably entire, a slight degree of attention would enable any person to do so at this hour. The sun seems to have been a great object of veneration, as an emblem of the deity."

With the following extract from sir Richard Hoare's "Ancient Wiltshire," we shall conclude our account of Stonehenge.

"It may be naturally expected, that, after quoting the various descriptions of others respecting Stonehenge, I should give some opinions of my own. This I shall do with diffidence, and lament that the history of this celebrated wonder of the world will most probably ever remain unknown. I cannot for a moment hesitate in declaring it to be neither Roman, Saxon, nor Danish. We learn from the Holy Scriptures, that the earliest memorials were of stone; and we find to this day, single, double, and triple upright stones, as well as numerous circles dispursed about our dominions: we then find some attempts at architecture in the cromlech and kilwaen, in both of which we see immense stones laid incumblent upon others that are upright; whether these gave the idea of the impolts at Stonehenge, or vice versa, will be a difficult matter to determine; at all events, I consider Stonehenge of a much more modern date than Aubury, where there are no impolts, and no marks of working on the stones; but in the former we perceive a regular plan, a great deal of symmetry, and great knowledge in mathematics. We know, also, that many stone monuments exist on the continent, and in that part of it from whence our island probably received its earliest population, viz. Gallia-Celtica."

"The most remarkable of these monuments, and such as must excite curiosity in the highest degree, is situated in the hamlet of Carnac, near Vannes and Auray, on the western coast of Bretagne, and in the department of Morbihan, in France. M. Cambray, in his "Monuments Celtiques," has given a very detailed and animated description of this interesting relic of antiquity. He tells us, that some detached stones on the hillside and banks announce the approach to this grand theatre, which consists of an immense number of rude unhewn stones (amounting to four thousand, or more), standing in an upright position, on a sandy plain, near the sea-coast. They are ranged in eleven straight lines, which lines are separated from each other by a space of thirty or thirty-three feet, and the distance from one stone to another varies from twelve to fifteen feet. The height of these stones measures twenty-five feet."
twenty-two feet out of ground; the width varies; one of them is twenty-two feet high, twelve feet wide, and six feet thick; and many of them are movable; these stones present the most singular aspect: they stand alone on an extensive plain, attended only by the sand that supports them, and the vault of heaven that surrounds them; not an inscription to explain, nor an analogy to inform; the men whom you call, the traveller whom you interrogate, gaze at it, and either turn away their head, or recount follies. They recall to our memory those times which neither our calculation nor our history can ever attain.

I have before stated my opinion, that our earliest inhabitants were Celts, who naturally introduced with them their own buildings, customs, rites, and religious ceremonies; and to them I attribute the erection of Stonehenge, and the greater part of the sepulchral memorials that still continue to render its environs so truly interesting to the antiquary and historian.

"The general title of Druidical has been given to all these stone monuments, and some of my readers may be perplexed that I have not adopted it. That the Druids existed in our island at a very early period, and officiated as priests, there can be no doubt; but, as the learned Mr. Bryant, in his Mythology, observes, "under the function of their names, we shelter ourselves whenever we are ignorant and bewildered." And Mr. Borlase, with equal judgment, remarks, "that the work of Stonehenge must have been that of a great and powerful nation, not of a limited community of priests; the grandeur of the design, the distance of the materials, the tediousness with which all such massive works are necessarily attended, all these facts, which I have stated, were the fruits of peace and religion."

Besides the works already referred to, the preceding account has been chiefly derived from the Topographical History, &c. of Wiltshire, in vol. xv. of "The Beauties of England," by J. Britton, F.S.A. 1814. "The History of Ancient Wiltshire," folio, by Sir Richard Hoare, with numerous plates of Stonehenge, the barrows on Salisbury plain, and the discoveries made in opening them, is most curious and interesting; and truly honourable to the liberality and perseverance of the worthy barber, who has so laudably employed his time. One of the plates in this volume is more particularly interesting, as displaying a plan of the site of the temple, the avenue, the situation, and extent of the great curfus; also a smaller cursus, with numerous ditches, barrows, and encampments, in the vicinity of Stonehenge. Comte Alexander de la Borde, in an elegant work now publishing in Paris, entitled "Les Monumens de la France clasique chronologiquement," &c. has given views and accounts of some curious Celtic monuments in that kingdom.

STONEHOUSE. See Plymouth Dock.

STONESHATTER LAND, in Agriculture, a term applied to that part of land which is constituted of loofe, reduced, mixed, flomy materials, and which is of a light, dry quality, capable of being worn at almost any time. It is often good turnip land with but little cultivation and nurture. See Soil.

STONI, in Ancient Geography, a people of the Alps, according to Strabo, who join to the Lepantii and Tridentini. According to Livy, they were subjugated by the consul Q. Marcius.

STONINGTON, in Geography, a port-town and port of America, in New London county, Connecticut, 14 miles E. by S. from New London city, separated from Rhode Island by the E. line of the lute, settled in 1658, and containing six places of worship, and 3043 inhabitants, of whom nine are slaves.

STONING, North, a town of Connecticut, in New London county, containing 2524 inhabitants, of whom two are slaves.

STONO INLET, a channel on the coast of South Carolina, S. of the channel of Charleston, at the N.E. corner of John's island, which is bounded by Stono river on the west. N. lat. 38° 41'; E. long. 80° 3'.

STONY CREEK, a small stream of Upper Canada, which runs into Lake Erie, E. of Sangas creek, having a harbour for boats.

STONY HILL, situated in Baltimore county, Maryland, 5 or 6 miles N.W. of Whetstone Fort, at the mouth of Baltimore harbour, and two miles S.E. of Hock's Town.

STONY ISLAND, an island near the E. coast of Labrador. N. lat. 53° 4'. W. long. 55° 30'.—Alfo, a small island in the Spanish Main. N. lat. 14° 26'. W. long. 82° 45'.

STONY MOUNTAINS, mountains in the N.W. part of North America, extending from S. to N. in a W. direction, from N. lat. 48° to 68°. The north part of this range is called the Mountains of Bright Stones.

STONY POINTS, a small peninsula in Orange county, New York, projecting from the W. bank of Hudson's river into Haverstraw bay, about 40 miles N. of New York city. The population of Haverstraw in 1810 was 1816, including 36 slaves.

STONY RIVER, a river of West Florida, which runs into the gulf of Mexico. N. lat. 29° 55'. W. long. 84° 15'. See also Roche.

STONY STRATFORD. See Stratford.

STONY LANDS, in Agriculture, such as are full of flints, pebbles, or small fragments of free-stone. It is found that lands of this sort, in many places, yield good crops; and the general rule is, that in hilly and cold lands, the flones should be as carefully picked out as possible, but in light and dry grounds they should be left. These lands should, however, have the large stones removed as soon as possible. See Clearing of Land.

In some parts of Suffolk, the flinty flones, in cafes where they have not been picked off the land, lie so thick as effectually to cover the ground; and it is said to be curious and interesting to see how the vegetation flourishes and gets through such beds of stones. The common opinion there is, that if the farmers were to put themselves to the trouble and expense of picking them off the land, the soil would be most materially injured; and that some, indeed, who have tried this experiment, are thoroughly convinced of the loss thereby sustained, the land having never since produced such fine crops of corn as before; this, however, only applies, it is thought, to places where the flones are very numerous and closely befted upon the land. See Stone, in Agriculture.

STONYHARD, the name of a plant of the weed kind, common in arable lands, the corn gromwell.

STOOK, or Stud, the common name of a flod or houttack or corn or grain let up in the field. See Hat-tack.

In some districts, a distinction is made in this mode of putting up corn in the field; the flod or flouk, consisting of twelve wheats, while the houttack has only ten.

STOOKING, or Stouking, the operation of setting up the wheats of grain into flocks, flouts, or houttacks, in the field, to guard them from rain. It is sometimes written flocking. It was formerly the practice to let one flout up right, with the ears uppermost; and round that to place a circle of many other wheats, in the same direction, inclining on the first flout; then to lay an horizontal circle of wheats, with all the ears in the centre, and cover those ears with a loaf.
loose sheaves or two. And thus placed, they are faid to be
well protected from all wet. But a better mode is that
which is practiced in Yorkshire, as described by the Rev.
Mr. Comber; ten sheaves are disposed in two rows, each
row leaning against the other; then two sheaves are opened
at the ear-ends, and flipped on the top, so as to meet at the
centre with their tails, and to flipe downwards. In this
mode the air has a free course, whether it bears against one
or other end of the flipe, or even against either side of it.
Thus, two weighty sheaves afford a good cover, and con-
tinue to, being hardly to be blown off by any wind, if care-
fully laid on: at least not to be blown away but so as soon
as to be replaced. And the flipeing position of the cap-sheaves
never exposes them to receive directly, nor to retain or
transmit the rain to the corn below, but to throw it off,
especially as the tails of the sheaves, in which the straw
is thickift and strongest, receive the miff rain, which can do
them little or no harm, and especially if they be thrust
clofely together. See Harvesting and Hattock.
STOOL, Alves, in Medicine. A thing is faid to be
voided by flipe, when it is discharged by the anus, or fum-
dament. In the Philosophical Transafions, we have in-
stances of fick persons voiding facitious flones, balls, &c.
by flipe. See Alves and Defecfion.
Stools, Bloody, in Medicine. The spirit of vitrif, mixed
with the patient’s drink, has often been found beneficial in
cures of bloody flipes. See Dysentery and Flux.
Stools, Retention of the fift, in infants. See Infant.
Stool, in Mining, is used when the miners leave digging
deeper, and work in the ends forward. The end before
them is called the falled.
Stools, in Ship-Building, pieces of plank bolted to the
quarters, for the purpose of forming and creafing the quar-
ter-galleries, and fometimes to the flipe’s fides abait the mafs
for the backflays. Also ornamented blocks of wood for the
poops and top-lanterns to fland on.
Stool, Cucking. See Cucking.
Stool, in Agriculture, a term used pro vincially to fignify,
to ramify or tiller, as grain.
Stools, in Gardening, fuch headed-down young trees
and shrubs in the nurfery-ground, or other places, as are
appropriated for the production of an annual fupply of
lower shoots or branches near the ground, properly fituated
for layering. See Laying.
Stools, Hop, in Rural Economy, the small contrivances
of this kind which are made ufe of in hop-gardens, in pick-
ing the produce from off the hinds, in some districts. They
are thought ufeful and improper in some hop plantations in
different districts, and of course never employed; but in
others they are still continued, and fuppoled to be of con-
fiderable utility and benefit in the execution of the above
fort of work.
Stooming of Wine, a term ufed to fignify the putting
of bags of herbs or other ingredients into it to pre-
vent fermentation.
Stoop, in Commerce, a liquid meafure in Holland and
Flanders. See Tab. XXXI. under Measures.
Stoop, in Rural Economy, a pole fixed in the earth, as a
gate-polt, &c. and many other forts.
Stooping, in Falconry, is when a hawk, being upon
her wings at the height of her pitch, bends down violently
to take the fowl.
STOOKER, in Coinage, a small Dutch filver coin, valued
at 2½ fivers.
STOP, in the Mange, is a paine, or difcontinuation of
go. In order to flop a horfe, the rider fhould, in the
fift place, quicken him a little, and at the infant when
he begins to go faifer than the usual cadence, or time of his
pace, bring to the calves of his legs, to animate the horfe,
and to make him bend and play his haunches; then flinging
his shoulders backwards, hold the bridle more and more
tight, till the flop is made; then vigorously extend the
hams, and reit upon the ftrump to make him form the
times or motions of his flop, in falcading with his haunches
three or four times. You fhould not form the flops of
your horfe fhort and precipitate, let you spoil his hams and
mouth. After flapping, a horfe fhould be made to make
two or three corverts.
With a raw and young horfe very few flops fhould be
made; and when they are made, they fhould be performed
by degrees, very gently, and not all at once; because nothing
so much hirmains and weakens the hocks of a fliff and awkward
horfe as to be a sudden and rude flop. It is an universally agreed
point, that nothing hews to much the vigour and obedience
of a horfe, as his making a beautiful and firm flop at the
end of a fliff and violent career. The facility of flapping,
however, depends upon the natural aptnefs and content of
the horfe, and also upon his form and the proportions which
the different parts of his body bear to each other. The
merit of a flop mutt, therefore, be cparated by the strength
and temper of the horfe, by the fteadinefs of his head and neck,
and the condition of his moutb and haunches. If your
horfe has not readily obeyed in making his flop, make him
go backwards, by way of punishing his fault. If in flapping
he fupplies up his nofe, or forces the hand, keep your
bride-hand low and firm, and your reins quite equal; give
him no Libertv, prefs upon his neck with your right hand,
till he has brought down his nofe, and then immediately
give him all his bridle: this is the furest method to bring
him into the hand. To compel a horfe to flop upon his
haunches, nothing is fo efficacious as a little flapping ground:
nevertheless you muft examine, previously to this kind of
exerife, if his feet, reins, shoulders, and legs, are able to
bear it; for otherwise your horfe would soon be fpooled.
In this cafe the rider fhould put the fires of his aids rather
in his thighs and knees than in the ftrump. One of the
moft trying leffions to which a horfe can be put is to flop
him, and make him go backwards up hill; and therefore, on
these occasions, you muft fabe the fore-parts of the horfe as
much as poifible, and throw your whole weight upon the
hinder. As there are fome horfes which, from weaknefs in
their make, can never be brought to form a jull and beauti-
ful flop, there are others which are apt to flop too fuddently
and fhort upon their shoulders, though otherwife too much
raised before and too light. These employ all their powers
in order to flop all at once: these horfes fhould never be
made to go backwards; but, on the contrary, fhould be
fopped flowly and by degrees, that they may be embold-
ned; but they fhould never be forced or kept in too great
a degree of fubjeftion. The leffon of making a horfe to flop
upon his haunches is admirable, if it be practiced with
horfes which have been fuppled and prepared; but it fhould
never be ufed to colts or raw horfes, whose joints are fliff.
The moft certain method, fays Mr. Berenger, to unite and
affemble together the strength of a horfe, in order to give
him a good mouth, to fix and place his head, as well as to
regulate his shoulders, to make him light in the hand, and
capable of performing all forts of airs, depends entirely
upon the perfection and exactnefs of the flop. The qualities
above
above enumerated are essential to the top, and the top must be considered as the eff-ct, and not as the cause of the good qualities. Berenger's Hist. and Art of Horsemanship, vol. ii. chap. 5. The opposite term to top is porting. In former times, the top of a horse was called parade. See NAIL.

STOP, Half a, is a top not finished by a pesade; so that the horse, after faiding three or four times upon the haunches, returns and continues his gallop, without making pesades or corvetts; which fee.

STOP, at Sea, a word used by him that holds the half-minute gahs, in heaving the log; for immediately when the glass is out, he calls stop to them that let run the line. See STOPPING.

STOP, in the Practice of Rigging, is a temporary feizing. When used to stop warming, it is faked. This is a name given to several turns of tumps-yarn taken round the end of a rope, similar to a feizing, to faid it to another rope. Also, a projection left on the upper part of top-gallant masts, &c. to prevent the rigging from riding down. See STOPPING.

STOP, Saturday. See Saturday.

STOP is a floating beam, used to top and detain barges at the toll-houses, when neceffary, and during the night. Stop-Gates are similar to Safety-gates; but they require to be lifted up, instead of acting of themselves.

STOP-Planks are planks put into a grove, and serving the fame purpofe with top-gates.

STOPCOCKS, in Hydraulics, are appendages to pipes conftiuted for the conveyance of fluids; and thefe, as well as valves, differ in their form and construction according to their various situations and ufe. Stopcocks ufuall confift of a cylindrical or conical part, perforated in a particular dire&ion, and capable of being turned in a focket formed in the pipe, fo as to open or shut the passage of the fluid, and sometimes to form a communication with either of two or more vessels at pleasure. A valve is employed where the fluid is allowed to pass in one dire&ion only, and not to return. See VALVE.

STOP, or Step, in Mining. When a funph or pit is sunk down in a lode, they break and work it away in flairs or fteps, which method of working is called topping; and the height or ftep which each man breaks, is called a ftep.

STOPIN, a term in ufe at the military laboratory, de-erived from the French word eflamm, and figurating a wad, lump, clew or hard of hemp, tow, rope-yarn, &c.

STOPPAROLA, in Ornithology, the name of a bird of the lark kind, defcribed by Aldrovanus, and supposed by Mr. Ray to be the fame with the flaptulata, or the tordino of the Venetians; but the muscipula grifola of Linnaeus. See Fly-catcher.

STOPPEL, in Geography, a town of Flandres; 5 miles N.W. of Hull.

STOPPERS, in a Ship, certain fhort pieces of rope, which are ufually knotted at one or both ends, according to the purpofe for which they are defigned. They are either ufed to fpind or any heavy body, or to retain a cable, shroud, &c. in a fixed position. Thus, the anchors, when fift hoifted up from the ground, are hung to the cat-head, by a flopper, called "anchor-slopper," attached to the latter, which falling through the anchor-ring, is afterwards falfened to the timber-head; and the fame rope ferves to fallen it on the bow at fes; or to fpind it by the ring which is to be funk from the flip to the bottom. The floppers of the cable have a large knot and a lainiard at one end, and are falfened to a ring-bolt in the deck by the other. They are attached to the cable by the lainiard, which is falfened

freely round both by feveral turns pafted behind the knot, or about the neck of the flopper; by which means, the cable is reftrained from running out of the flip, when the rides at anchor.

Thofe that are ufed to check the cable are called "bit-floppers;" and the latter are denominated "deck-floppers." "Dog-floppers" are ufed as additional fecurities when the flip is riding in heavy gales, or bringing up a flip with much fenm-way, to prevent the cable from flapping at the bits, and to fave the deck-floppers. "Wing-floppers" are ufed for the fame purpofe as dog-floppers.

The floppers of the fhrouds, called "frhood-floppers," have a knot and a lainiard at each end. They are only ufed when the fhrouds are cut afunder in battle, or difabled by tempeftuous weather; at which time they are lafed, in the fame manner as ftofe of the cables, to the separated parts of the fhroud, which are thereby reunited, fo as to be fit for immediate service. This, however, is only a temporary expedient.

"Fore-tack" and "fleet-floppers" are ufed for fecuring the tacks and fheets, till fayed. Falconer.

STOPPER-BOLTS, in Ship-Building, large ring-bolts driven through the deck and beams, before the main hatchway, for the floppers to be attached to. They are carefully chenched on iron plates beneath.

STOPPING, in Grammar. See POINT and PUNCTUA-

TION.

STOPPING, among Horfes, the practive of filling the hollow of a horfe's foot with poultice, cow-dung, or any other moit application. It has the effed of softening the fole, and, on some occasions, may be advantages, though it is frequently misapplied, and of course does injury. It is not ufually employed for the feet of team-horfes, especiffy thofe of the plough kind, as travelling too much amidst the mould renders them hard, brittle, and unceafy.

STOPPING a Leak, at Sea. See LEAK.

STOPPING a Ship. When a ship comes to an anchor, and the cable is veered out by degrees till the flip is found to ride well, and then flopped, it is called fopping the flip.

STOPPERS, up, in Ship-Building; the poppets, timber, &c. ufed to fill up the vacancy between the upper fide of the bilge-ways and the flip's bottom, for supporting her when launching.

STOPS, in Grammar. See POINT.

STOPs of an Organ. See ORGAN.

STOPs, or Stoops, in Rural Economy, a term provisionally applied to small well-buckets, and thofe of some other kinds.

STOR, in Geography, a lake of Sweden, in the province of Vefjarla; 6 miles S.W. of Gefle. —Also, a lake of Norway, in the province of Aggerbuu; 40 miles N.E. of Chrifhania. —Also, a river of Mecklenburg, which runs from lake Schwerin to the Elbe. STORA, a town of Sweden, in the government of Vafu; 20 miles S.E. of Chrifhianfand. STORA. See SGIOTA.

STORAX-Tree, in Botany. See STYRAX.

STORAX, official, in the Materia Medica, is the rufinous drug, obtained in perfection only from thofe trees that grow in Aftratic Turkey, which influes in a fluid flate from incifions made in the bark of the trunk, or branches, of the florax-tree. It is brought from Turkey, but is fo adul-
terated, that it is very difficult to meet with any that is pure. It has a moll pleasing fragrant odour, and is called fylax colatim, because it is said to be transported in hollow canes; or, according to others, because it exudated from the tender twigs and young shoots of the tree, and coated them.
them over to a reed or other hollow cylindrical body drawn over the twigs. Two kinds of this reed have been commonly distinguished in the flouses: viz. the pure and the common floras; the first, or pure, is usually obtained in irregular compact masses, free from impurities, of a yellowish or reddish-brown appearance, and intermixed with whitish tears, somewhat like gum ammoniac or benzoin; it is extremely fragrant, and upon the application of heat readily melts. This has been called "flora in the lump," "red floras," and the separate tears, "flora in the tear." The common floras is found in large masses, very light, and bears no kind of external resemblance to the former floras, as it seems to be almost wholly composed of dirty saw-dust, merely caked together by the resinous matter; and though much less esteemed than the pure kinds of floras, yet when freed from the woody part, it is paid to polishes more fragrance, and to be superior to the other kind. Rectified spirit, the common menstruum of floras, readily dissolves the floras, which may be impregnated to a solid confidence in the manner directed for the "flyras purificato" in the London Pharmacopæa, without substantiating any considerable loss of its sensible qualities.

Common floras, infused in water, imports to the menstruum a good yellow colour, some trace of its smell, and a slight balsamic taste. It gives a considerable impregnation to water by distillation, and strongly diffuses its fragrance when heated, though it scarcely yields any essential oil. The spirituous solution, gently diffused off from the filtered reddish liquor, brings over with it very little of the fragrance of the floras; and the remaining infusion is more fragrant than the finest floras in the tear, which Dr. Lewis says with.

The pure resin diffused without addition yields, along with an empyreumatic oil, a portion of saline matter, similar to the flowers of benzoin; and Dr. Lewis says, that he has also sometimes extracted from it, a distillation of the same nature by coction in water.

Among some of the ancients, floras was a familiar remedy as a solvent, and particularly used in catarrhal complaints, coughs, asthma, menstrual obstructions, &c., and from its affinity to the balsams, it was also preferred in ulcerations of the lungs, and other states of pulmonary consumption. And our Pharmacopæas formerly directed the "pluâ e floras" (see Storax Pills); but this odorous soup has now no place in any of the official compounds; and though it be a medicine which might seem to promise some efficacy in nervous debilities, yet it is almost totally disregarded by modern practitioners. Lewis's Med. Med. Med. Woodville's Med. Bot.

Storan, Liquid, is a resinous juice, obtained from a large tree, with leaves like those of the maple, called by Ray "floras ascrius folio," by Linnæus "liquidambar florasiflua," a native of Virginia and Mexico, and lately naturalized to our own climate. The juice called liquidambar, is said to exude from incisions made in the trunk of this tree, and the liquid floras to be obtained by boiling the bark or branches in water. See Liquidambar.

Two sorts of liquid floras are distinguished by authors: one, the purer part of the resinous matter that rises to the surface in boiling, separated by a strainer, of the consistence of honey, tenacious like turpentine, of a reddish or ash-brown colour, moderately transparent, of an acrid unctuous taste, and a fragrant smell, resembling that of the solid floras, but somewhat disagreeable; the other, the more impure part, which remains on the strainer, untransparent, in smell and taste much weaker, and much more commonly confused with the substance of the bark. That which is commonly met with in the flouses under this name, Vol. XXXIV.

is of a weak smell and a grey colour, and is supposed to be an artificial composition. Liquid floras has been chiefly used in external applications. Among us, it is at present almost wholly in difuse. Lewis's Med. Med.

Storax, White. See Balsamum Peruicinum, under Balsam.

STORICA, in Geography, a town of Poland, in the pralatinate of Kiev; 24 miles S.S.W. of Bialacevick.

STORCK, Anthony, in Biography, a medical professor of considerable note at Vienna, succeeded the celebrated Van Swieten in the office of physician and director of the college of medicine in the university of that metropolis, and was also honoured with the appointment of principal consulting physician to the empress Maria Theresa. He distinguished himself chiefly by a long and studious course of experiments relative to the operation of various narcotic vegetables, and to the bel mode of preparing and administering them. The vegetables of which he has treated in various tracts, are the hemlock, henbane, farronum,acenit, meadow-saffron, and pulsatilla nigrae; and although he was disposed to over-rate the efficacy of some of these substanices, and has ascribed to them virtues which sublimate experience has not always confirmed, he had the merit of calling the attention of the medical world to a class of active remedies, which, under proper management, are productive of much benefit, and constitute a valuable addition to the materia medica. Between the years 1760 and 1771, his various tracts upon these subjects were printed at Vienna, and they have sublimately undergone several editions and translations in other countries. He was also author of a collection of cards which occurred under his observation in the hospital at Vienna, entitled "Annum Medicus, quo MS. luptant Obserbationes circa Morbos acutus et chronicus," 1759; of which he published another "Annum Secundum" in 1761. This work was afterwards continued by his successor, Dr. Colin. In 1775, he published a volume, entitled "Institutn Facultatis Medicæ Vindobonensis," Eley Dict. Hist. de la Méd.

STORDALEN, in Geography, a town of Norway; 28 miles N.E. of Drosthen.

STORE, a town of America, in North Carolina; 30 miles W. of Exeter.

STORE. Bill of Store. See BILL.

STORE, Naval. See NAVAL.

STORE-House. in Agriculture, that sort of house or building which is constructed for the purpose of storing up and preserving some sort of farm produce, which should be constructed suitably to the particular kinds of products they are to contain, and to the uses to which they are to be applied.

Houses of this kind are sometimes also employed for storing and laying up different sorts of tools and implements, and many other things which are necessary in farming, in order to keep them safe and dry.

They are seldom used for any sort of grain, especially for any length of time, as that requires a particular sort of building. See Granary.

The store-houses of a fortres are constructed for the preservation of all sorts of artillery and ammunition; those of a dock-yard, or of a maritime town, for cables, anchors, timber, and other necessaries, to repair and furnish ships. And they are of different forms and sizes, according to the purposes for which they are intended.

STORE-Room, in Rural Economy, a room or place in a house or other building, in which are kept different sorts of farm articles. These rooms should be as dry as possible, and perfectly secure from vermin. An upper floor is the
belts for the first purpose; but for the latter, vaults or cellars under ground are the most suitable.

Store-Room, in a Ship, an apartment or place of reserve, of which there are several, to contain the provisions or stores of a ship, together with those of her officers, during a sea-voyage.

Store-keeper, an officer in the royal dock-yards, who is invested with the charge of the principal naval stores: as the fials, anchors, cordage, & c.

Store-Magier, in Agriculture, a term applied to that kind of farmer who is, in a great measure, in the live-stock kind of farming in some way or other, as either by means of sheep, neat cattle, or some other sort of domestic animals.

Store-Ship. See Store-Ship.

STOREA, among the Romans, a kind of basked made of ropes or rushes, for gathering flowers or garden-fruits.

Storea was likewise a kind of defence, made of large cables fashioned into a fort of netting; which was so strong, that no weapon, though thrown out of an engine, could penetrate it.

STOREGE, Στοργη, a Greek term, frequently used by naturalists to signify that parental instinct, or natural affection, which animals bear toward their young.

The storege is an admirable principle implanted by the all-wise Creator throughout the animal world, for the preservation of it; and is governed by such rules as make it best contribute thereto. By means of this, with what care and acuteness do animals nurse their young? and what dangers will they brave for their security? even the most timorous creatures, which at other times fly the face of men, dogs, &c. will, for the sake of their young, expose themselves. Thus hens, instead of flying from, will assault such as meddle with their brood; and partridges, before their young can fly, will frequently drop down before the dogs, first at left then at greater distances, to dodge and draw them off from pursuing their young.

With what concern do others look about their young in places of safety? and some even admit them for shelter into their bodies. Thus the opossum, Dr. Tyfon observes, has a curious bag on purpose for securing and carrying about her young. The same author adds, from Oppian, that the dogfish, upon any storm or danger, receives her young into her belly, which comes out again when the fright is over. And it is said that the squinna and glaucus do like.

With what tenderness do others seek and prepare the food for their young, teach them to suck, cherish, or lull them to rest, &c. like so many nurses, deputed by the Creator to take care of their creatures? and still in proportion, as they grow up, and become fit to look to themselves, this storege abates; and at length, when no longer needed, becomes extinct. Mr. Ray observes, that young doves are fed with meat first eat by the dam, and fodder awhile in her prolapse. And Clufius observes, that the old female Ethiopian takes no food but from the male, after this manner.

The returns made by the young to the parent animal, when grown old, are not less considerable. Pliny fays of rats, that they nourish their aged parents with eminent piety.

St. Ambrose, and after him Olaus Magnus, observe of the crane, that when the parents, through old age, are bereft of their feathers, and left half naked, their offspring flit around them, and cherish them with their own feathers; that they seek food for them; and when nature, as it often happens, repairs their decays, and restores them to strength again, they take them up, by turns, on their wings, and inhabituate their unplummed limbs to their ancient art of flying. See Instinct.

STORHAMNEN, in Geography, a small island on the W. side of the gulf of Bothnia. N. lat. 62° 32'. E. long. 17° 13'.

STORHOLMEN, a small island on the W. side of the gulf of Bothnia. N. lat. 62° 33'. E. long. 17° 42'.

STORING Substances of the Corn, Fruit, and other Kinds, in Agriculture and Gardening, the means of advantageously and properly laying them up and securing them for future use.

In the storing of grain, as there is a constant decrease and loss in the weight of the corn from the moment of its being laid up, to that in which it is disposed of, (though this is considerably more at first than afterwards,) it is obviously a practice that should be carried to as little extent as possible in all cases. The common lofs in this way has been found to be from one-twelfth to one-tenth of the whole in different sorts of corn, according to circumstances, and the length of time it has been stored up.

The storing of all articles of this kind should always be performed at dry times, and in dry well- aired places, and not laid in too large quantities together, but so that they may be capable of being readily turned over, and have new surfaces frequently exposed to the action of the atmosphere. Corn is often not only injured, but rendered improper for storing up, by being suffered to remain too long on moist damp floors, in barns and other places.

The storing of fruits, vegetables, and roots, has been performed in various ways, which are well known already; but lately some better modes have been suggested for this purpose.

For apples and pears, it has been stated in the "Memoirs of the Caledonian Horticultural Society," that after they have been carefully gathered from the trees, and laid in heaps covered with clean cloths or mats for sweating, which is effected in three or four days, they remaining for that length of time afterwards, they are to be wiped separately with clean cloths; when some glazed earthen jars are to be provided with tops and covers, and likewise a quantity of pure pit-fand, which is quite free from any mixture. This is to be thoroughly dried upon a flue. Then put a layer of this sand an inch thick on the bottoms of the jars; above this a layer of fruit, a quarter of an inch free of each other; covering the whole with sand to the depth of an inch; then a second course of fruit is to be laid in, and again covered with an inch of sand, proceeding in the same way until the whole be finished and completed. An inch and a half in depth of sand may be laid over the lat or uppermost layer of fruit; when the jars are to be closed and placed in some dry situation, as cool as possible, but entirely out of the way of frost.

The usual time at which each kind of such fruits should be ready and fit for the table being known, the jars containing such fruit may, it is said, be examined, by turning out the sand and fruit together cautiously into a flue. The ripe fruit may then be laid upon the shelves of the fruit-room for use, and the unripe be carefully replaced in the jars as before, but with fresh dry sand.

Some kinds of apples managed in this way, will, it is said, keep a great while, as till July; and pears until April, and in some forts till June. It is not improbable but that many other sorts of fruit might be stored and preserved in somewhat the same way.

Vegetables of the cauliflower kind have been stored and kept well through a great part of the winter, it is said, in the same work, by putting them, when in full head,
on a dry day, into pits about eighteen inches in depth, and much the same breadth, in a perfectly dry soil, with the stalks and leaves to them, the latter being carefully doubled over and lapped round the heads, instead of hanging them up in fields or other places, as is the usual practice in preparing them. In performing the work, it is begun at one end of the pits, laying the heads in with the root-stalks upermost, so as that the former may incline downward, the roots of the one layer covering the tops or heads of the other, until the whole is completed. The pits are then to be closely covered up with the earth into a fort of ridge, and beaten quite smooth with the back of the fpade, in order that the rain-water may be fully thrown off. Fine cauliflowers have been thus stored and kept for the occasional supply of the table until the middle of the following January.

For storing and preserving different kinds of roots for common summer use, until the coming in or return of the natural crops, the following method has likewise been proposed. As the ice in ice-houses has commonly sub-fledged some feet, as four, five, or more, by the beginning of the spring, it is proposed to deposit in the rooms or vacancies so left empty, the roots that are to be preserved. As soon as any openings in the places have been well fluffed with straw, and the surfaces of the ice covered with the fort of material, cave-boxes, dry ware, cauls, balkets, or any other such vessels, are to be placed upon it, which are then to be filled with the roots, such as turmips, carrots, beets, celery, potatoes in particular, and some others.

In cales where there are not ice-houses, vegetation may be greatly retarded, and the roots preferred by storing them in deep vaulted cellars, caves, coal-pits, mines, or in any place heated deep in the earth. Potatoes have also been well flored and preserved, it is said, by earthing them in small parcels, as about two holls each, heaped up, and covered in the usual way with straw and earth; which are turned over into other pits in the early spring, first rubbing off all the sprouts or shoots, and having the roots well watered in small quantities as they are put into the other pits, the whole earthy covering being also well watered and beaten together at the time with the back part of the fpade. This covering is to be made to the thickness of about two feet. The same practice or process is to be repeated every time the potatoes are turned over, which should be about once in three weeks, as the flate of the weather may be. And where the pits or heaps are not in the shade, it is sometimes proper, when the seedon is very hot, to cover them with mats supported on sticks, so as to permit a free current of air between the mats and the heaps.

In this way, it is stated that these roots have been preserved quite plump and entire in the tabile until the end of September, or till the succeeding crop becomes perfectly ripe, so as to be used without loss, as that must always be the case where the roots are largely employed before they are in a flate of mature growth. It is affited, too, that in this manner potatoes are even capable of recovering in plumpness and talt, where they have been suffered, by improper exposure to air or heat, to become deficient in these qualities.

STORK, Ciconia, in Ornithology, a family of the Ardea or Heron clas. See HERON.

Naturalists have been much puzzled in ascribing the winter abode of storks. Many authors have supposed that they go to the Nile at this season in quest of food; to which purpose Dr. Shaw observes, that in the middle of April he saw three flights of these birds, each of which took up more than three hours in passing by him, extending itself more than half a mile in breadth. These, he says, were then leaving Egypt, where the canals and the ponds that are annually left by the Nile were become dry, and directing themselves towards the north-east. He adds, that they return again a little after the autumn equinox, when the waters of the Nile returning within the banks, leave the country in a fit state to supply them with nourishment. But M. Klein controverts the opinion, that storks visit Egypt in the winter in search of food; observing, that if this were the case, they would not go in the winter, and remain till April, but in the summer; for the inundation of the Nile begins towards the end of April, and about the month of September the waters diminish, and about the 7th or 8th of October quite retire into their channel, so that in the winter this river is extremely small; and he apprehends that they take up their winter-quarters under water.

It is observed of the storks, says Dr. Shaw, that for the space of about a fortnight before they pass from one country into another, they constantly resort together from all the circumjacent parts in a certain plain, and there forming themselves every day into a dou-wanne (according to the phrase of the people), are said to determine the exact time of their departure, and the places of their future abodes. See Jer. chap. viii. ver. 7.

The stork is held in the highest esteem and veneration among the Mahometans, with whom it is no less favored than the ibis was among the Egyptians; and no less profane would that perfon be deemed, who attempted to kill or molest it. The regard paid to these birds, Dr. Shaw imagines, may probably have arisen, not so much from the service they perform to a moit fenny country, in clearing it of useless reptiles and insects, as from the solemn geometrical calculations they are observed to make as often as they rest upon the ground, or return to their nects. Shaw's Travels, p. 428, fol.

STORKAGAT, in Geography, a town of Sweden, in the county Bothnia; 25 miles S. of Pitea.

STORCO, a small island on the E. side of the gulf of Bothnia. N. lat. 63° 52'. E. long. 22° 39'.—Als, an island in the Baltic, near the S. coast of Sweden. N. lat. 58° 15'. E. long. 15° 34'.

STORKOW, a town of Brandenburg, in the Ucker Mark; 26 miles W.S.W. of Francfort on the Oder. N. lat. 52° 15'. E. long. 14° 55'.

STORKYRO, a town of Sweden, in the government of Wasta; 17 miles E. of Wasta.

STORM, in the Military Art. See Assault.

Storm, in Rural Economy, a term signifying a fall of snow, hail, &c. which is injurious either to animals or plants.

In some districts, storks of these kinds are very prevalent, and highly hurtful in different ways. In the sheep farms in the northern parts of the island, storks are often extremely hurtful and destructive to the sheep. They are the most fatal to these animals, it is said, when the frost is keen, the wind strong, and the snow light and mobile; as then the defecated flocks move before the blast, into some hollow part or place, where they find a little relief from the piercing storm, but are soon covered up deep with drifted snow; and when long confined beneath it, many of them perish, and those which survive are often much reduced in condition, and sometimes have lost part of their wool. And should this place of retreat be near a rivulet, as often happens, and a sudden thaw come on, the melted snow brings down a torrent of water on them, and they all perish.

Smooth
Smooth green hills, that are defluent of rocks, woods, or other shelter, are, it is thought, the most in danger for the sheep on them, from the drifting snow. The sheep, in these cases, are to be collected, and kept moving, in order to prevent their being consumed with the cold, and over- blown by the drifting snow. Stone boulders are also useful; but the true and effectual shelters are, it is said, plantations of forell trees, to which the sheep naturally fly on the approach of storms. See Sheep.

STORMAY, in Geography, a bay on the south coast of New Holland, between South Cape and Taffman's Head.

STORMCAPE, is the northern limit of the mouth of Bay Verte, and forms the fourth-calf corner of the province of New Brunswick.

STORM-FINK, or Storm-Finch, in Ornithology. See Procellaria Pelagica.

STORMAR, or STORMARIA, in Geography, a district of the duchy of Holllin, of which Hamburg is the capital. The Stoor, whence it derives its name, confines this district on the north, and separated it from Ditmarfia: the Sunla, Trave, and Billa, determined the rest of its extent. It was formerly almost one slimy marsh. The wet and low situation of Stormaria and Ditmarfia exactly corresponds with the Roman account of the Saxons living in inaccessible marshes. Stormaria is somewhat quadrangular, and its sides may be estimated at 33 miles. Adam Bremen derives the name from forum, a metaphor expressive of the feditions of its inhabitants; but Stoor, the river, and Marf, the residents in marshes, seem to compose a jufter etymology. Adam distinguishes the Stormarii by the epithet "nobiliores." Their banner, in ancient times, was a white swan with a golden collar. Hamburg, their metropolis, had been, before the eleventh century, "viris et armis potens," but in Adam's time it was "in folitudinem reducata." Stormaria was one of the three districts which anciently divided Norderland, or Eald-Saxon; Ditmarfia and Holllin being the two other districts. These were the countries in which our Saxons ascended, when the Roman geographer (Ptolemy) first noticed them; and from these they spread terror throughout Europe, when their attention became directed to maritime depredations.

STORMONT, a district of Scotland, in Perthshire, on the left side of the Tay. Dunkeld is the chief town.

STORMONT, a county of Upper Canada, bounded east by the county of Glengary, south by the river St. Lawrence, the west boundary of the township of Osnabruck, and west by the late township of Williamshurg, running N. 24° 11' W., until it intersects the Ottawa or Grand river; thence descending that river, until it meets the north-west boundary of the county of Glengary. The county of Stormont comprehends all the islands in the river St. Lawrence near it, and the greater part of the county lies fronting the St. Lawrence.

STORNIA, in Ancient Geography, a town of India, on the other side of the Ganges, belonging to the people called Tangani, according to Ptolemy.

STORNARA, L.A., in Geography, a town of Capitanata; 9 miles N.E. of Acoli.

STORNAWAY, a parochial town on the eastern side of the isle of Lewis, and shire of Ross, Scotland. It contains a good and well-frequented harbour. The parish is of great extent, and stretches about ten miles north-west, along the north side of an arm of the sea, called the Broad Bay. In this, ships of large burthen have good anchorage, and can ride with safety, as no heavy sea can come into it. The town of Stornaway is situated at the extremity of both Stornaway; and, from a small origin, has of late attained considerable size and opulence, by the patriotic exertions of lord Seaforth. The principal employment of the inhabitants of Stornaway is the prosecution of the white and herring fisheries. It is a port of the customs, and has a post-office, and regular packet, which sails weekly with the mail and passengers. The houses of the town are generally well built, and, in 1811, amounted to 698, with 3300 inhabitants. Here are a neat and commodious custom-house, a town-house, assembly-room, and a church, also two free-schools, and one instituted and patronized by lady Seaforth, for the introduction and promotion of the spinning of yarn in the island of Lewis. In Stornaway is also situated Seaforth Lodge, the residence of lord Seaforth, baron Mackenzie of Kintail, and lord lieutenant of the shire.—Carlilie's Dictionary of Scotland, vol. ii. Beauties of Scotland, vol. v.

STORO, a small island on the east side of the gulf of Bothnia. N. lat. 63° 24'. E. long. 22° 3'.

STOROHAMN, a small island on the west side of the gulf of Bothnia. N. lat. 62° 45'. E. long. 17° 58'.

STOROZEVOI, a cape on the north coast of Russia, in the fritis of Vaigatkoii. N. lat. 69° 25'. E. long. 86°.

STORSIO, a large lake of Sweden, in the province of Jamland; containing several islands, on which is the town of Profon, and on another the town of Nordter. It has a communication with many other lakes and rivers, and by means of these with the gulf of Bothnia. N. lat. 63° 16'. E. long. 14° 10'.

STORSKAR, two small islands on the east side of the gulf of Bothnia. N. lat. 63° 17'. E. long. 20° 32'.

STORT, a river of England, which falls by Bishop's Stortford, &c. and runs into the Lea, 2 miles N.E. of Hoddesdon.

STORTA, LA, a town of the Patrimon, near the ruins of the ancient Veii; 6 miles N.W. of Rome.

STORTFORD, Bishop's. See Bishop's Stortford.

STORNIA, the name of an instrument used by the ancients for drawing blood from the nofe; but we are not perfectly informed of its shape or structure.

STOSSEN, in Geography, a town of Saxony, in Thueringia; 6 miles S.E. of Naumburg.

STOT, in Rural Economy, a provincial term applied to a feer, or young growing bullock.

STOTTFIELD HEAD, in Geography, a cape of Scotland, on the coast of Murray. N. lat. 57° 42'. W. long. 3° 10'.

STOTTER SEE, a lake of Bavaria, in the bishopric of Augsburg; 10 miles N.N.W. of Fuellen.

STOTTLEDORF, a town of Austria; 6 miles S. of Sonneberg.

STOVE, in Building, a hot-house or room. The term stove is also used more particularly for a place in which fire is made, and by means of which heat is communicated to a room or building. See CHIMNEY.

Stoves should, in propriety, be distinguished from fire-places, from the fire being included within the stove, and giving out its heat through the sublance of the materials of which the stove is composed, to the air in the apartment; and in many stoves there are ingenious contrivances, to make a great quantity of air pass in contact with the heated surface of the stove, and be thus heated before passing off into the apartment. Fire-places, on the contrary, have the fire as open and as much exposed as possible, conveniently with the carrying off of the smoke, in order that it may throw out radiant heat into the apartment. This distinction is not sufficiently attended to in common language.
STOVE.

In modern fire-places, every care is taken that the air of the room may be heated; but it does not appear, from the contruction of their fire-hearths, that our forefathers had any idea of warming the air of a room to fit in. All they proposed was to have a place to make a fire in, by the radiating heat of which they could warm themselves when cold.

The ancients are supposed to have used flaves, in which the fire was not seen; but on inquiring into the progress of the art of warming apartments economically, few traces remain of the manner in which the ancients warmed their habitation. It is imagined they lighted the fire in a large tube in the middle of a room, of which the roof was open, and that the other apartments were warmed by portable braziers. In Seneca's time, they began to construct tubes in the walls, to convey the heat into the upper apartments; the fire-places being still placed below. It appears, however, that this was the origin of flues for smoke, and even of flaves; the situation and proportions of which have successively undergone an infinity of changes, according to the localities, the wants of the inhabitants, and the fashion of the decorations.

The ancients had the custom of heating apartments by fire plaques under arches or vaults; but this was confined to palaces, and other edifices, where magnificence was augmented by prodigality; and the vestiges that have been discovered among ancient ruins, sufficiently point out this as their definition. In digging, some years ago, for foundations in the city of Autun, one of these ovens was discovered under a mosaic pavement, with chimney at each extremity.

The northern Chinese have a method of warming their ground-floor, which resembles the ancient plan just mentioned. The floors are made of tiles a foot square, and two inches thick; their corners being supported by bricks set on end, that are a foot long, and four inches square: the tiles, too, join into each other, by ridges and hollows along their sides. This forms a hollow under the whole floor, which on one side of the house has an opening into the air, where a fire is made; and it has a funnel rising from the other side to carry off the smoke. The fuel is a sulphurous bit-coal, the smell of which in the room is thus avoided, while the floor, and of course the room, are well warmed.

But as the under-side of the floor must grow foul with foot, (and a thick coat of foot prevents much of the direct application of the hot air to the tiles,) Dr. Franklin suggests that burning the smoke, by obliging it to descend through the red coals, would, in this construction, be very advantageous; as more heat would be given by the flame than by the smoke, and the floor, thereby being kept free from foot, would be more heated with less fire. A different kind of flave used in China, and called hang, is briefly described under that article.

Francis Keßlar of Frankfort, whose work, entitled "Épargne-bois," &c. (the Wood-saver, &c.), appeared, in French, in 1619, is the oldest writer who deprivers to be quoted, as having proposed any useful ideas on the subject of flaves. He formed eight chambers, one above another, through which the smoke was to pass before it entered the chimney. He also brought air directly from without into the aërical, to feed the fire; and there was another aperture to draw air from the apartment for the same purpose.

Savot, in his "Architecture Française des Bâtiments particuliers," i.e. Architecture of private Houses, printed in 1625, gave some advice relative to the belt method of constructing chimneys, but with scarcely any object than to prevent their smoking.

M. Daleime, in 1686, suggested the first idea of a flave without smoke, which he called furnus aequos. Here the smoke is forced to descend into the fire-place, where it is consumed. Dr. Franklin, who afterwards executed a very complete flave on that principle, still spoke of it, in 1773, as a mere-curiosity or philosophical experiment, as it required too much attention to be managed by common servants.

This machine consisted of a tube of iron-plate, such as is used for the flue of a German flave. This tube was bent at right angles, and the part which was horizontal was about two feet in length, and joined to the side of the tube, which ascended vertically. At the opposite end of the horizontal tube the furnace was made: it consisted of a cylindrical tube of plate-iron erected upon the horizontal tube near the end, and provided with a grating, upon which the fuel was placed; and the grate prevented the fuel falling down into the horizontal tube. To light this flave, some clear burning charcoal was put into the large short tube or furnace, and supported on the grate. As soon as the tubes grew warm, the air within them would ascend in the perpendicular tube or chimney, and go out at the top of it; fresh air must enter into the horizontal tube through the furnace. In this course it must descend through the burning fuel, and becoming heated by the burning coals, which had been thrown into flame, which, after destroying the offensive smell, comes out at the end of the longer tube, as more heated transparent gas or vapour.

Whoever would repeat this experiment with succefs, must take care that the part of the shorter tube is quite full of burning coals, so that no part of the smoke may descend and pass by them, without going through them, and being converted into flame; and that the longer tube is so heated, that the current of ascending hot air will be established in it, before the things to be burnt are laid on the coals; otherwise there will be disappointment.

It does not appear, either in the Memoirs of the Academy of Sciences, or Philosophical Transctions of the English Royal Society, that any improvement was ever made of this ingenious experiment, by applying it to useful purposes; but there is a German book, entitled "Vulcanus Famulans," by Joh. George Leutmann, P.D., printed at Wurttemburg in 1723, which describes, among a great variety of other flaves for warming of rooms, one which seems to have been formed on the same principle. It was probably taken from the hint thereby given, though M. Daleime's experiment is not mentioned; for the construction is as nearly as possible the same, except in the proportions of the parts; the furnace being made in the form of a basin or vase, having the grate in the bottom of it.

Gauger, author of "La Mecanique du Feu," &c. printed at Paris in 1709, was the person to whom we are indebted for the first and most complete syllabus of experiments on the circulation of heat, by means of air-holes affording warm air; as also the manner of making one fire warm several rooms, and to fend off the heat in elliptic curves.
curves. We there find a description of a chimney, with
the back, the larch, and the jambs, of hollow iron, to
beat the air that is to enter the room. But it does not ap-
tear that this work produced much effect at the time; the
most important truths lie concealed in books, till some
preventing interest awakens the attention of mankind to their
utility.

Dr. Franklin, in 1745, published an account of the new
floes of Pennsylvania; the advantages of which he com-
pares with those of the floes of Germany and Holland,
and the chimney of Ganger. A description and drawing
of this floe are given in our article Fire-Place.

In 1785, Dr. Franklin published the description of an-
other floe, which has the flame reveried; that is, it
palies downwards through the fuel. The appearance of
this floe is that of a vase of cast-iron, with its pedestal;
and this is mounted upon the top or lid of an air-box, fit-
ting upon the hearth of the fire-place, and built close in
niches in the stone-work: but the vase being wholly de-
tached from the back of the niche, has a very neat ap-
pearance. The top of the vase turns back upon a hinge, so as
to open like a lid, to put in the fuel; and the opening is
covered by a brass frame, which allows the air to enter.
The bottom of the vase has in it an opening, of about two
inches diameter, which leads through the ilam or foot of
the vase into a hollow iron box, forming the pedestal. At
the bottom of this pedestal is a grate in the lid or top of
the air-box, upon which the vase stands. The air-box is di-
vided by four partitions, between which the smoke palies and
repalies horizontally in a waving direction, until it escalate
into the chimney. Thus the smoke and flame, immediately
after it has defended through the grate in the top of the air-
box, palies backwards towards the chimney between the two
middle partitions; but as it cannot enter into the chimney at
that part, it turns round the ends of those partitions, and
returns in two currents towards the front of the box; then
returns again round the end of other partitions, and goes
back into the chimney, which is behind, or rather at the sides
of the niche in which the vase stands. The front plate of
the air-box is made to slide in a groove, in two pieces, which
meet together in the front like folding-doors; and these
pieces being flided back, expose the spaces between the par-
titions, which, as before mentioned, act as winding flues
for the smoke to circulate in, and give out its heat through
the metal of the air-box. In the space between the two
middle partitions, and into which the smoke first descends,
a drawer is fitted to receive the ashes or cinders, which may
fall through the grate in the top of the air-box; and it can
be readily withdrawn, to clear it out.

There is likewise a small grate at the lower part of the
vafe, upon which the fuel contained in the vafe will rest.
When this fuel is lighted, the flame and smoke will draw
downward, and, descending through the grate, will pass
through the hole in the bottom of the vafe into the hollow
pedestal, and through the grate in the top of the air-box;
it then palies horizontally in the space between the two
middle partitions of the air-box, and proceeds in the same
direction towards the back of the chimney; there dividing,
each part of it turns to the right, and palies round the farther
end of the middle partition; then coming forwards, it turns
round the near end of the outside partition; then moving
backwards, it arrives at the opening into the bottom of one
of the upright corner furnaces behind the niche, through
which it ascends into the chimney, thus heating that half
of the box and that side of the niche. The other part of
the divided flame palies to the left, round the far end of the
middle partition, round the near end of the outside partition,
STOVE.

dust be suffered to lie upon them. But as the greatest care will not always prevent these things, it is well once a week to wash the floor with soap-les and a brush, rinsing it with clean water.

The advantages of this reversed flame in stoves are very considerable. The chimney does not grow foul, nor ever need sweeping; for as no smoke enters it, so no foot can form in it.

The air heated over common fires instantly quits the room, and goes up the chimney with the smoke; but, in the stove, it is obliged to descend in flame, and pass through the long winding horizontal passages, communicating its heat to a body of iron-plate, which, having thus time to receive the heat, communicates the flame to the air of the room, and thereby warms it to a greater degree.

The whole of the fuel is consumed by being turned into flame, and the benefit of its heat is obtained; whereas, in common chimneys, a great part goes away in smoke, which may be seen as it flies, but it affords no rays of warmth.

Some idea may be formed of the quantity of fuel thus wasted in smoke, by reflecting on the masts of foot that a few weeks' firing will lodge against the sides of the chimney; and yet this is formed only of those particles of the column of smoke which happen to touch the sides in its ascent. How much more must have palled off in the air? And we know now that this foot is fill fuel, for it will burn and flame as fresh; and, when hard caked together, is indeed very like and almost as solid as the coal from which it proceeds.

The destruction of fuel goes on nearly in the same quantity in smoke as in flame, but there is no comparison in the difference of heat given. When fresh coals are first put on a fire, a considerable body of smoke arises. This smoke is, for a long time, too cold to take flame; but if a burning candle is plunged into it, the candle, instead of inflaming the smoke, will instantly be extinguished. Smoke must have a certain degree of heat to be inflammable. As soon as it has acquired that degree, the approach of a candle will inflame the whole body, and the difference of the heat which it gives will be very sensible. A still easier experiment may be made with a candle itself. Hold your hand near the side of its flame, and observe the heat it gives: then blow it out, the hand remaining in the same place, and observe what heat may be given by the smoke that rises from the still burning funnel; you will find it very little: and yet that smoke has in it the substance of so much flame, and will instantly produce it, if you hold another candle above it so as to kindle it. Now the smoke from the fresh coals, laid on this stove, instead of ascending and leaving the fire, while too cold to burn, being obliged to descend through the burning coals, receives among them that degree of heat which converts it into flame; and the heat of that flame is communicated to the air of the room, as we explained.

The flame from the fresh coals laid on in this stove, descending through the coals already ignited, preserves them long from consuming, and continues them in the state of red coals, as long as the flame continues that surrounds them, by which means the fires made in this stove are of much longer duration than in any other, and fewer coals are therefore necessary for the day. This is a very material advantage indeed. That flame should be a kind of pickle to preserve burning coals from consuming, may seem a paradox to many, and very unlikely to be true, as the doctor tells us; it appeared to himself the first time he observed the fact; but therefore relates the circumstances, and mentions an easy experiment, by which his reader may be in possession of every thing necessary to the understanding of it. In the first trial he made of this kind of stove, which was constructed of thin iron plate, he had, instead of the vane, a kind of inverted pyramid, like a miller's pepper; and fearing at first that the small grate contained in it might be clogged by cinders, and the passage of the flame sometimes obstructed, he ordered a little door near the grate, by means of which he could occasionally clear it; though after the stove was made, and before he had tried it, he began to think this precaution superfluous, from an imagination that the flame, being contracted in the narrow part where the grate was placed, would be more powerful in consuming what it should there meet with, and that any cinders between or near the bars would be presently destroyed and the passage opened. After the stove was fixed and in action, he had a pleasure now and then in opening that door a little, to see through the crevice how the flame descended among the red coals, and observing once a single coal lodged on the bars in the middle of the focus, he observed by a watch in what time it would be consumed; he looked at it long without perceiving it to be at all diminished, which surprised him greatly. At length it occurred to him, that he had seen the same thing a thousand times, in the conversion of the red coal formed in the funnied of a burning candle, which, while enveloped in flame, and thereby prevented from the contact of the palling air, is long continued, and augments instead of diminishing, so that we are often obliged to remove it by the funnied, or bend it out of the flame into the air, where it pretently consumes to affection. He then supposed, that to consume a body of fire, palling air was necessary to receive and carry off the separated particles of the body: and that the air palling in the flame of the stove, and in the flame of a candle, being already saturated with such particles, could not receive more, and therefore left the coal undiminished as long as the outward air was prevented from coming to it by the surrounding flame, which kept in a situation somewhat like that of charcoal in a well-luted crucible, which, though long kept in a strong fire, comes out unconfused.

This stove of Dr. Franklin is very ingenious, and has been much used in France, where the management of coal-fires is but little understood, and they are therefore induced to use floves in preference to open fires, when they burn pit-coals. Dr. Franklin completed the stove just described in 1771, and used it in London during three winters. While he was in France, he contrived another grate for burning pit-coals, which has the same property of burning the smoke, and at the same time the fire is exposed in a grate. The grate is a short cylinder, with its axis placed horizontally, and the end turned towards the apartment; one of its circular ends being made with bars, and the other is a back-plate: it is one foot (French) in diameter, and eight inches deep or long between the bars and the back: the sides and back are of plate-iron, the sides having holes of half an inch diameter, and three or four inches distant from each other, to let in air for enlivening the fire: the back is without holes, and the sides do not meet at either the top or bottom by eight inches: and this square space is filled with grates of small bars, crossing from front to back to let in air below, and let out the smoke or flame above. The three middle bars of the front grate, that is, the circular end, are fixed: the upper and lower may be taken out and put in at pleasure, when hot, with a pair of pincers. The whole of this cylindrical grate turns upon pivots fixed in the opposite sides, across the centre of it: the pivots are supported by a crotchet, the item of which is an inverted conical tube five inches deep, which fits as many inches upon a pin, which is fixed upright in a cast-iron plate that lies upon the hearth. In the middle of the top and bottom grates are
are fixed small upright pieces, about an inch high, which, as the whole is turned on its pivots, flop it when the grate is perpendicular. By this means the grate can be inverted by turning it over upon its pivots, but as that will 'prevent the back-plate to the apartment, it requires to be turned half round horizontally upon the conical pin to bring the front bars to the room.

In making the first fire in the morning with this grate, there is nothing particular to be observed: it is made as in other grates, the coals being put into the cylindrical grate above, after taking out the upper bar, which must be replaced when they are in.

The round figure of the front bars filled with fire, when thoroughly kindled, is agreeable: it represents the giver of warmth to our fires. As it burns down, it leaves a vacancy above, which must be filled with fresh coals, the upper bar is to be taken out, and fresh coals thrown in, the bar being afterwards replaced. The fresh coals, while the grate continues in the same position, will throw up, as usual, a body of thick smoke; but every one accustomed to coal-fires in common grates must have observed, that pieces of fresh coal stuck in below among the red coals, have their smoke fo heated, as that it becomes flame as fast as it is produced, which flame rises among the coals, and enlivens the appearance of the fire. Here, then, is the use of this tivel-grate: by a push with the tongs or poker, it can be turned over on its pivots till it is inverted, and the front bars face the back of the chimney; then turn it gently round on its vertical socket or axis, till it again faces the room, whereby all the fresh coals will be found under the live ones, and the greater part of the smoke arising from the fresh coals will, in its passage through the live ones, be heated so as to be converted into flame. By this means much more heat is obtained from them, and the red coals are longer preferred from consuming. This construction, though not to complete a consumer of all the smoke as the vale, is yet fitter for common use, and very advantageous; it gives also a full light of the fire always, a pleasing object which we have not in the other. It may with a touch be turned more or less from any one of the company that desires to have less of its heat, or preferred full to one jall come out of the cold; and when the front bars of the grate are supported in a horizontal position, a tea-kettle may be boiled on them.

Notwithstanding the acknowledged advantages of Dr. Franklin's construction of a stove, the expense and trouble of it, and the difficulty of procuring workmen who understood the manner of executing it, have prevented the general use of his stoves. Mr. James Sharp, with a view of obviating these objections and difficulties, has proposed several improvements, for which he has obtained his majesty's patent. According to the method which he proposes, they are easily accommodated to any rooms, where communication can be had with the external air; both to those which have, and those which have not chimneys: so that not only small rooms, but the largest halls, libraries, or churches, may be warmed in a more effectual manner than had ever been done before, and the greatest degree of heat produced from a given quantity of fuel. Mr. Sharp, by adding funnels to the top, renders these stoves fit for any chimney, and by lengthening the funnel, to any place without a chimney at all. By the hollow base with which his stove-grates are furnished, he is able to apply them with much greater effect to the external air, without any addition of brickwork; and by the alterations in the air-box, a much greater quantity of warm air is introduced than it was possible to introduce in their former state. If a stove of this kind is to be placed in a common fire-place, a hole must be made through the back of the chimney or through the hearth, to communicate with the external air; and this hole should be made as large as possible, and in a defending position, so that the outward air may ascend towards the stove. The hollow base of the stove must be placed against this hole, so as to cover it completely; and the bottom of the base must be fitted so close to the earth, and pointed with lime or putty, that the air may not pass. Upon the stove there must be put a few feet of iron funnel to reach above the breadth of the chimney; and the chimney inclosed by iron plates, so constructed and placed in a square or oblong iron frame, that they may be easily removed when the chimney wants sweeping. By this construction, the warm air, introduced by the stove, will be carried into the room, which would otherwise pass up the chimney, and be lost. But if the stove is to be fixed in a room where there is no chimney, it may be placed in any part of it, where communication may be had with the outward air; and nothing more is necessary than a sufficient length of funnel to carry it through the roof, or wall, or window, or into any other chimney that may be convenient. If the fire-place be too small for the stove, the chimney may be cloyed by the aforementioned frame and plates, and the stove stand before the fire-place, and the smoke be carried off, by the help of a circular elbow, into the chimney above the mantle-piece. Many of these stoves, it is said, have been lately put up, in order to cure smoky chimneys, and have always succeeded. For farther particulars, see Sharp's Account of the Air-Stove Grates, &c.

The inhabitants of the northern parts of Europe have long been accustomed to the use of stoves in which the fire is shut up, and gives out its heat to a draught or current of air, which is made to pass through proper openings in the stove, and when sufficiently warmed, enters into the apartment. The smoke arising from the fuel is made to pass through a circumstantial passage of flues, by which means the greatest part of the heat is absorbed. Stoves on this principle are known in England, but are very seldom used, except for warming of halls, libraries, and passages, in grand houses, as the English are not contented to feel the air warm, unless they see the fire. In Russia, Sweden, and other northern countries, they are indispensably necessary, as without them, it would be impossible to keep the rooms tolerably warm. A common fire-place has too large an opening, and it can be not taken to supply it continually with wood, &c. the heat it produces is hardly sufficient, because it follows the current of the air, and is carried off by the smoke. These stoves, on the contrary, retain the heat a much longer time; and as their external parts, and also their flues, are very thin, they communicate their heat very readily, so that with a small quantity of wood, they warm an apartment much more than the fire of a common fire-place would do, with fix times the quantity. For it was not sufficient that the inhabitants of these severe climates should discover the most simple means of keeping up in their houses a comfortable degree of heat, it was also necessary that this should be done with the least possible expense of fuel.

The stoves which they employ perfectly fulfil the above-mentioned intentions; they are also susceptible of every kind of ornament. The more surface we give to a stove constructed in this manner, the more the heat is increased, consequently we must not be surprised to find that this kind of stove sometimes occupies the whole height of an apartment, its width and depth being proportioned to its height.

The construction of these stoves is simple: they consist of four,
four, five, or more small chambers, built one above another: the lower one is for the fire which burns in it, and the smoke rising from it enters into the chamber immediately above, then into the third, and from that to the fourth. The passageways or holes through which the smoke enters into one chamber from that beneath, are, in all cafes, made at the corner of the chamber, opposite to the passageway at which the smoke will pass out from the same chamber to the next above it. By this means the smoke is obliged to pass through the whole of the chamber, and has the greatest chance of transmitting its heat. A fire lighted in one of these stoves early in the morning, and with a small quantity of fuel, retains a strong heat during the whole day. The door of the fire-place is only opened to put in wood, and remains afterwards constantly shut. The wood lies upon a grate, consequently it is not buried in and diffused by the ashes. The ash-hole is spacious, and one or two feet in height, according to the capacity of the stove. Two doors are placed at the extremities of the ash-hole, and the current of air is very considerable, by which the smoke is carried up with great force, and the wood burns very briskly.

Stoves of this kind may be advantageously placed in halls, at the bottom of stairs, in the anti-chambers of great houses; they may also, by proportioning their size to that of the rooms for which they are intended, be made use of in the houses of private persons. To this it may perhaps be objected, that the heat produced from these stoves is unhealthy, because they deprive the air of its moisture; and that the air, by being made too dry, loses its elasticity, in consequence of which, respiration becomes difficult and laborious. These objections would appear of great weight, if we had not the example of the Russians, the Swedes, the Danes, the Germans, and in short of all the inhabitants of the north of Europe, to shew that those who are habituated to such stoves, do not find them unhealthy. If others should be sensible of inconveniences from the dryness of the air in the apartment, it may be easily removed by the very simple expedient of placing upon the stove a vessel of glass or earthen-ware, which has a large surface, and is very shallow: this being filled with water, will infensibly evaporate, and restore to the air that moisture of which the heat of the stove has deprived it: the air will then recover its elasticity. If orange-trees are exposed to the heat of such a stove, and the fire is not properly regulated, the plants grow yellow and lose their leaves, especially if the air is not changed, which in winter is not very conveniently done; but if a vessel of water be placed upon the stove, the evaporation of the water will preserve the trees.

In a memoir published by M. Guyton in the Annales de Chimie, he has explained the construction of the stoves employed in Sweden, and recommends the adoption of one constructed on the same principle for general use in France.

The memoir is translated in the Repository of Arts, 1th Series, vol. xvi. The construction of the stove which is there recommended may be improved, to adapt it to our use in England, where pit-coal is used; but the following principles, which the author lays down, are very useful as guides in making all kinds of stoves for warming apartments.

1. Heat is produced only in proportion to the volume of air consumed by the fuel.

2. The quantity of heat produced is greatest, (the quantity and quality of the fuel being the same,) when the combustion is complete.

3. The combustion is the more complete, in proportion as the fuliginous part is longer retained in channels where it may undergo a second combustion.

4. The only useful heat is that sent out into, and retained in the space intended to be heated. The temperature of that space will be higher in proportion, as the current which must be renewed from without to support the combustion, is less enabled to take up in its passageway the heat produced.

Hence the following inferences evidently arise:

1. The fire-place ought to be insulated from all bodies that are rapid conductors of heat. All the heat that goes out of the apartment is absolutely lost, unless intentionally directed into another apartment.

2. Heat being produced only by combustion, and combustion being sustained only by a current of air, the current should be brought in by channels, where the needful rapidity may be preserved without being too diffused from the space to be warmed, so that the heat it there deposits, may be gradually accumulated in the whole of the insulated furnace, in order afterwards to flow out of it slowly, according to the laws of the equilibrium of that fluid.

3. The wood being so far confirmed as to give no more smoke, it is advantageous to close the mouth of these chambers, in order to retain there the heat, that would otherwise be carried off through the upper flue, by the continuance of a current of fresh air, necessarily of a low temperature.

4. Lastly; it follows from these maxims, that all things being equal, a higher temperature will be obtained, and supported during a much longer time, by forming in the internal parts of the stove, or under the hearth of a chimney, and in their vicinity, tubes in which the air that comes from without may be warmed before it enters the apartment, to serve the purpose of combustion, or replace that which has been consumed. These have been called bouclés de chaleur (mouths or apertures of heat); because, instead of contemplating their principal use and intention, it is commonly imagined they are only made in order to give by their inflows a more rapid current to the heat produced. Nor is this idea absolutely devoid of foundation, since the air that inflows from them has only changed its temperature, by carrying off a portion of the heat that would have remained in the interior. Those, however, who would proscribe them, as opposing the most important object, which is the retaining of the heat as long as possible, do not consider that they may be closed, and all communication with the external air cut off by a simple flue, and, therefore, it is easy to derive from them every possible advantage without any inconvenience. And we may add, that in small apartments, or such as are accurately closed, they are often indisputably requisite, if we could avoid being exposed to currents of cold air. Dr. Franklin very justly quotes a Chinese proverb to this effect: “Shun a current of air from a narrow passageway as you would the point of an arrow.”

The Swedish or Russian stoves, which have chambers for the reception of the flame and smoke, are little known in this country: but those which are in common use in the halls and cellars of our great houses are French stoves. They differ from the others in having a very great length of small flues or windling passageways, through which the smoke passes, and communicates its heat to the air, which circulates in similar passages, until it becomes warmed, and makes its exit through the mouths into the apartment. This method is not so simple as the small chambers or apartments of the Russian stoves, nor is it so good in the long run; because the passageways are very liable to become clogged with foot; and
and even before they are so clogged as to intercept the passage of the smoke, the transmission of the heat is much impaired, because the interior surfaces of the flues become coated with soot, do not conduct the heat so rapidly, and in consequence, a great part will chill pass out into the chimney. Also, these flues with small passages require a stronger draught in the chimney, to make the air pass through the passages, than when chambers are used.

The Holland iron stove, which has a flue proceeding from the top, the fire-place and all-pit being closed by small iron doors opening into the room, comes next to be considered. It is frequently made of iron-plate, and is most commonly called a German stove. Its conveniences are, that it makes a room warm all over, for the chimney being wholly closed, except the flue of the stove, very little air is required to supply that, and therefore not much rubbish in at crevices, or at the door when it is opened. Little fuel serves, the heat being nearly all saved; for it radiates almost equally from the four sides, and the bottom and top, into the room, and presently warms the air around it, which being rarefied rises to the ceiling, and its place is supplied by the lower air of the room, which flows gradually towards the stove, and is there warmed and rises in its turn, so that there is a continual circulation, till all the air in the room is warmed. The air, too, is gradually changed by the flue-doors being in the room, through which part of it is constantly passing, and that makes these flues more wholesome, or at least more pleasant, than the German flues, next to be spoken of. But they have the inconvenience that there is no night-of the fire, which is in itself a pleasant thing, nor can any other use be conveniently made of the fire but that of warming the room.

When the room is warm, people not seeing the fire are apt to forget supplying it with fuel till it is almost out, then growing cold, a great deal of wood is put in, which soon makes it too hot. The changes of air are not carried on quick enough, so that if any smoke or ill smell happen in the room, it remains a long time before it is discharged. For these reasons, the Holland flues have not been much introduced among the English (who love the fight of the fire), unless in some workshops, where people are obliged to fit near the windows for light, and in such places they have been found of great use.

The real German flue is made like a box, one side wanting, and that side is built against the wall of the room. It is composed of five iron-plates screwed together, and fixed so as that the fuel can be put into it from another room, or from the outside of the house. It is a kind of oven reversed, its mouth being without and body within the room that is to be warmed by it. This invention certainly warms a room very speedily and thoroughly with little fuel; no quantity of cold air comes in at the crevices, because there is no discharge of air which it might supply, there being no passage from the flue from the room. These are its conveniences. Its inconveniences are, that people have not to much fight or ufe of the fire as in the Holland flues, and are moreover obliged to breathe the same unwarmed air continually, mixed with the breath and respiration from one another's bodies, which is very disagreeable to those who have not been accustomed to it.

This may be remedied by making a small aperture into the flue, with a register to draw off the air. This kind of flue is still left in use in England than that which we have before decribed, and which is generally called the German flue, although it is used by the Dutch instead of the Germans.

Mr. Strutt, in their extensive cotton-mills at Belper, in Derbyshire, have employed a kind of floor which is found to answer extremely well; it consists of what is called a cockle, that is, a square chest or vessel of iron-plate, riveted together in the manner of a boiler, and let in a furnace, so that a fire can be made withinside of it upon a grate, and the smoke will pass off through a small passage into the flue which conducts to the chimney, the passage of which is regulated by a sliding damper. The cockle is of considerable dimensions, as much as four feet square and five feet in height, and the fire is made at the bottom of it, upon a grate of about fourteen inches by eighteen, so that the fire does not any where touch the inside of the cockle, but the heat rising up therein gives a considerable and equal heat, without rendering it so hot as to burn the air which it is intended to warm, for if that is once done the air will be rendered unpleasant.

The cockle is inclosed in a casing of brick-work, which is of the same shape as the cockle, and leaves a space all round between of a few inches. This space of brick-work is again surrounded by walls of brick-work, leaving a space of about eighteen inches all round; and these walls are carried up above, to form the chimney or funnel to convey the warmed air up to the several apartments of the mill. This chimney is divided, by thin brick partitions, into as many different flues as there are floors to be warmed; and a small opening is made, with a register, from each flue into the apartment it is intended to supply. This opening is made close to the floor; and in order to make a change of the air, ventilators are placed high up in the apartment, so as to be near the ceiling.

This division of the chimney into several different flues is intended to equalize the supply of air to the several apartments, and by this means the upper apartments are equally well supplied with warm air as those below.

In order to make the air pass in contact with the surface of the heated cockle, a horizontal partition is built in the space between the chimney and the brick-casing of the cockle. The level of this partition is at about one half the height of the cockle, and its effect is to divide the brick-casing of the cockle into two halves, one above the partition and the other below. The cold air is freely admitted into the lower part of the chimney beneath the partition, but cannot escape into the chimney above it, without entering into the space between the cockle and its brick-casing, through a number of small openings made in it beneath the horizontal partition; and in thus passing in contact with the surface of the cockle the air becomes heated, and passes out again, through openings in the brick-casing, into the chimney above the partition. In order to make the cold air strike more forcibly against the heated surface of the cockle, a small iron tube is fitted through each of the openings in the lower part of the casing, and the ends of these tubes approach very near to the surface of the cockle. Mr. Strutt has introduced this kind of flue into the new Infirmary at Derby, and in several other similar institutions it has been adopted with great success.

In 1799, Mr. James Burns of Glasgow took out a patent for an improved stove, or fire-grate, to burn with an open fire: his flue has a very elegant appearance, and several advantages. The object of the improvement was to prevent the heat generated by combustion, and thrown out into the apartment by radiation, from being unnecessarily wafted by the draught of air for the support of the fire, as is usual in stoves or grates of the common construction; where all the air that goes to maintain the combustion is furnished from the warm air in the room, the waft of which is supplied by the exterior cold air, which comes pouring into the room at the
bottoms of the doors, or by the sides of the windows, and thereby undeal a great part of the effect that otherwise would be produced by the fire. To accomplish this intention, the air that maintains the fire in the improved flues is brought through a tube, which is called the air-tube, from the outside of the house, and may be made to pass between two of the joints, (where the floors and ceilings are close enough to allow this,) so as to be brought to the bottom bars of the grate, without having any communication with the interior air of the room; while, at the same time, the grate and parts connected with it are so constructed, that when the fire is not wished to be supplied with cold air from the outside of the house, the palling may be shut more or less perfectly by means of a valve, a small door, a cock, or any similar contrivance. When convenience does not admit of the air-tube being carried to the outside of the house, it may be carried to a cellar, lardar, or stair-case, and the flame end will be gained, with this farther advantage, that such cellar, or other apartment, will be always well ventilated, and prevented from acquiring or retaining any unhealthy or disagreeable smells.

The principle is to supply the fire with air from without the room or apartment, so as to prevent the warm air of the room from being drawn to the fire-place and hurried up the chimney, while, at the same time, all the advantages of open grates may be enjoyed.

The form of Mr. Burns' flue is that of a vase or urn placed in the chimney-place, which is made circular, to form a niche for its reception. The urn is open at top, and the sides are formed of open work or grating, with a grated bottom, forming a sufficient space to contain the fire; but the pedestal and lower part of the vase are made close, to prevent the entrance of air to the fire, except that which palls up from the air-tube through the hollow pedestal; and within this pedestal is an air-valve, which opens and shuts by a regitler, to regulate the entrance of the current from the open air. In the pedestal of the vase is a drawer, to receive the ashes. The niche or chimney in which the vase is placed, has the usual opening at top to carry off the smoke. The air for the support of the fire enters from the external air, through the tube or air-pipe before described, and palls into the hollow pedestal of the vase; and having passed through the hollow neck or stem of the vase, it finds no difficulty in palling up through the bottom of the grate, the back or side of the ash-drawer next which the aperture is being made low, to allow it to flow in freely. The grate and its internal cavity may be of any convenient form, but circular or elliptical will answer best, especially when another improvement is applied. This is a glas taic or iron-work fence or fencce, to prevent those dreadful accidents which frequently occur of ladies' or children's clothes being set on fire by sparks from the grate. Where this safe-guard fence or fencce is wished to be applied, the inside of the chimney where the grate is to stand must be a semi-cylinder, or nearly so, with a lining or cover, made of metal, at such a distance from the semi-cylindrical wall or niche in which the flue is placed, as to give sufficient room for allowing the safe-guard or fence to be slid round into it, when the fire is wished to be left open to introduce fresh fuel, or when the drawer with the ashes is to be removed. The fence is a framework of metal, which, when filled up with glass, or with wire-work, forms a portion of a cylinder, answerable to the curvature of the space between the back of the chimney and the lining above-mentioned, made in one or two pieces, and moving in a circular groove in the hearth, which leaves to conduct it into its place behind the grate, when the fire-place is wanted to be left open, as before mentioned. The top of the front of the opening (the chimney-piece) projects in a circular form, or is furnished with an added projection, made of metal, and furnished with a circular groove on its under surface, of the same radius as the groove in the hearth, for the purpofe of guiding the upper part of the frame of the guard. The glas with which the frame of the guard is lined may be flamed or painted; complete safety is thus obtained, and, at the same time, the comfort arising from the view of a cheerful fire is not prevented by the interposition of any opaque body. But for nurseries or the like, where convenience and safety are more the objects than elegance or luxury, the frame-work may be filled up with wire-work.

Instead of such grooves at top and bottom for the fence to move in, the fence itself may be furnished with a groove at its top and one at its bottom, to receive any projecting piece of metal, or other substance of a proper curvature; or its bottom groove may receive the upper edge of the fender, which, being made to a proper curve, and properly adjusted and kept in its place, will answer the purpose. But whichever of these ways be followed, or whatever other method of construction (for it may easily be varied to answer circumstances), rollers or catthers should be provided at the lower part of the fence, to make it move with greater ease, either to the front of the grate, or into the space between the back of the chimney and the liang above-mentioned. Where either the glas or the wire-work frame, or both of them, are meant to be applied to square or rectangular chimneys, without the trouble of giving them a semi-cylindrical form, the lining to receive the fence or fences may be introduced at the sides, or jams, of such chimneys; or the fence may be made to ride, by means of pulleys, into the wall above the opening, or be slid sideways into the walls at the fides of the openings.

Besides the advantages already pointed out as connected with them, these flues posses all the following; any room or apartment may be heated by their means with a much smaller quantity of fuel than by common open fires; at the same time, the advantage of seeing the fire is not lost, as in close flues, for these grates have slide as well as bottom bars, which allow the radiant heat and light to be thrown out into the room, without any impediment; and, in fact, large rooms, halls, and the like, which by the usual methods can hardly be warmed, or made at all comfortable in cold weather, may, by means of these improvements, be heated as effectually as the smalleft apartment; for when their full effect is wanted to be procured, it is only necessary to keep the fence in its receds, that even that portion of heat which would be kept back by the interposed glas or wire-work, may be thrown out into the room, and perform its office.

In 1804, Mr. Joshua Jowett of London obtained a patent for a very similar contrivance, which he called a fire-guard flue, which is intended to prevent accidents from sparks of fire flying out. The flue itself is an open fire, and is usually made of a cylindrical form, the axis of the cylinder being vertical. One half of the cylinder which faces the apartment is made with bars at the lower part, to contain the fire, and an opening over them to feed it. The back part of the cylinder is made of cast-iron plate; but, instead of the brick-work being built up close round the back, a small space is left to receive the guard. The weight of the flue or grate is supported upon a vertical iron bar, which is in the centre, or axis of the cylinder, which forms the flue, and the guard swings round upon this bar as a centre, and being a half-cylinder of wire-work, can be brought in front to include the
STOVE.

the fire, or it can be turned round behind the flue out of sight.

The fire-guard may be fixed to any flue which will admit of two centres or pivots being placed in a perpendicular line in the back of the flue, to support the fire-guard, and guide its motion; and the flue must admit of grooves on either side, for the guard to pass through, as the levers will direct. The principle of the action of the fire-guard, is that of being united to two centres or pivots, placed perpendicular one to the other; and it is connected to the two centres fixed to the flue by means of two lever-cranes, one end of which is fixed to the guard, and the other end of each to the centres or pivots, by which the guard sways in a rotary motion, passing through a groove formed in the flue on either side, to swing from the fire when required, and is brought into use by means of a handle or nob, fastened to the front edge of the frame of the guard for that purpose; or, instead of drawing it out with the hand, as before described, it may be brought into use by means of a spring fastened to the crank, and pressing against the check or back of the flue, to throw the guard forward. The same effect may be produced by means of a balance fastened to any part of the fire-guard, and working with a line or chain over pulleys fixed to the flue, or by means of the combined force of the spring and balance.

Mr. Allan Pollock took out a patent, in 1807, for a flue which is very similar to the Swedifh flues, having chambers through which the smoke is facel'v conveyed, and gives out its heat to the air of the apartment in which it is placed: in addition to this, the flue is made to give a constant current of warmed air; for this purpose, the cold air is made to enter and circulate through winding passages, situated in the back of the fire-plate, or space in which the fire burns, and the fume passage is continued, by an iron tube, through the smoke-chambers up to an air-chamber situated in the top, from which it passes into the apartment. These flues are made of cast-iron; but, to prevent the air receiving any taint from passing in contact with the hot iron, Mr. Pollock proposed to apply a composition to the cores of the moulds in which the pipes are to be cast, which composition will become vitrified by the heat of the melted iron, when the fume is poured into the mould, and will form a glassy or vitrified lining to the tube, and prevent the actual contact of the air with the iron. These flues answer very well.

A very important improvement in those flues-places for burning coal, which are generally called bell-stove flues, has been lately made by Mr. John Cutler of London, for which he had a patent in 1815. The flues constructed by him are nearly such as are known by the name of register-flues, being made of cast-iron plate to incline the fire-place at the back and sides, but open in front to the apartment; leaving only a passage for the smoke through a regiler, at the upper part of theinclined space. Mr. Cutler's improvement consists in applying to such grates or flues a chamber, or magazine, situated beneath the grate (or the space inclined by grating) in which the fire is to burn. This chamber is to contain a magazine of fuel sufficient to supply the combustion for a whole day, or other required space of time; the bottom plate of the chamber is moveable; and by means of a wheel and axle, the fuel contained in the magazine can be elevated, so as to introduce a portion of the fuel into the grate at the lower part, or from beneath; and thus, from time to time, replace the fuel which is consumed, without the trouble of occasionally throwing on coals.

In order to make the fire burn, the flue or entrance to

the chimney must be of such a construction, as will produce the most efficient draught or current of air to pass through and across the top of the fire. This improvement of introducing a supply of fuel into the grate from beneath, causes the fire to burn clear and with little smoke; because the smoke, or gas, which issues from the newly introduced fuel, when it is first heated, must of necessity ascend through the burning fuel, and be thereby consumed. Another improvement is to reduce the fire, or extinguish it, when it is left for the night. This is done by lowering down the whole of the fire from the grate into the chamber, or magazine, beneath the grate: the supply of air is thus interrupted, and the fire is completely inclosed in a deep chest, so that it is impossible sparks can fly out, and the fire soon becomes extinguished. The advantages of these improvements are by no means trifling.

By burning the smoke, the whole effect of the fuel consumed is produced; and were this invention universally introduced into London, that pernicious foamy atmosphere in which it is hidden would be so improved, as to be equally pure with that of Paris, or other continental cities, where wood alone is used for fuel.

The burning of the smoke renders the sweeping of the chimneys unnecessary, and the danger of fire from the smoke contained in the flue is avoided; also chimneys which throw out smoke into the room will, in almost all cafes, be cured by this improvement, because the quantity of air or gas which must pass through the chimney is so small.

To avoid the trouble of throwing on coals, and to have at all times a bright and cheerful fire, are matters of convenience, but are not wholly to be overlooked: and, lastly, to have the means of extinguishing the fire, when it is left for the night, is a most important improvement; when it is considered that amongst the fires which happen every year in London, how many break out in the hours when the fires are left, and a great proportion are doublets occasioned by fires left unextinguished.

The machinery for raising the moveable bottom of Mr. Cutler's flue is very simple. The magazine-chamber is composed of iron plates screwed together, and the moveable bottom is fitted to it, so as to leave as small a space round the edges as possible. A bar is fixed across, beneath the bottom plate; and the ends of this bar pass through slits, or narrow openings, in the plate plates of the chamber. To the extremities of the bar the ends of two chains are attached, and the upper ends of these chains are made to pass over the top of the flue, so as to be within the chimney, and out of sight. The axle is turned round by a face or crown-wheel, fixed upon the extremity of it, and the teeth thereof are engaged by the teeth of a small pinion, the axis of which comes through the iron work of the flue; and the end has a small square hole in it, to receive a square or key upon a small winch handle. By means of this handle, the iron axle is turned round, and winds up the chains, so as to elevate the bottom plate of the magazine, and thereby raise up a portion of fresh fuel into the lower part of the grate, where it is burned, as before mentioned; and the smoke which rises from the coal rifies through the fire, and is thereby consumed.

Mr. Cutler has made a great number of these flues, which are found to answer very well: they have all the same properties as Dr. Franklin's cylindrical grate, but in a greater degree; and the fire can be supplied with fresh coals at the lower part, without the trouble of inverting the grate.

STOVES, American, are contrivances for warming of rooms,
rooms, &c. by a continual introduction and exchange of dry fresh air. These flues are called American, because the first patterns in call-iron upon this principle were the invention of Dr. Franklin, who then resided in Philadelphia.

See Fire-Places.

STOVES, Dutch and German. See Fire-Places.

STOVE, in Gardening, a sort of garden-building or erection, constructed with brick-work behind and on the north, as well as partly in front, and roofed wholly with glais fashes to the south; being furnished internally with a pit, or long, wide, deep cavity, for a bark hot-bed or beds, and with flues round the inside of the walls for fire-heat: the whole calculated to produce a certain temperature at all seasons, adapted to the culture of the tenderest exotic plants, as well as for forcing various kinds, both hardy and tender, into flower and fruit, &c. at an early season; and which was so named before the use of bark-beds, from being worked only by means of fire-heat.

By their means the gardener is also enabled to forward many hardy plants to early perfection, such as various sorts of curious flowers, fruits, fidal-g-herbs, dwarf kidney-beans, strawberries, &c.; and likewise many sorts of seeds, cuttings, and layers of exotics are made to grow freely in the bark-bed of the stove, that without such aid would not grow at all.

There are different sorts of flues used occasionally for different purposes: as the bark-flue, for common use, which has both a bark-bed and flues; the dry-flue, for particular succulent plants, &c. which is furnished only with flues for fire-heat, having no bark-bed; the forcing-flue, which is employed purposely for forcing hardy fruits, flowers, &c. into early perfection, being constructed both with bark-bed and flues, or only with flues. By the uniform, moderate, moist, growing heat in the first sort of flue, many kinds of such plants as have been mentioned are brought forward and preferred, and in which some require the bark-bed, others succeed in any part of the house; and still others, as the succulents, require the driest situation near the flues. Many of the more tender herbaceous and shrubby plants succeed best when placed in the bark-bed, though the greater part of the herbaceous and woody sorts succeed well enough in any part. The bark-bed is principally allotted for the pine-apples; and most of the smaller succulents, particularly, may be stationet mollly over the top of the flues upon shelves, out of the way of moisture, as being naturally very replete with humidity; and the hardy plants desigued for forcing, such as strawberries, kidney-beans, and various sorts of flowers, &c. that are potted, may be placed upon shelves, or on the parapet wall of the bark-bed; but the nearer the glasses the better, particularly strawberries, but good early kidney-beans may be raised in almost any part of the flue. When any sort of flowers are to be forwarded, such as roses, pinks, &c. or any bulbous flowers, as early as possible, they may be plunged in the bark-bed, and some be placed upon shelves, &c. to succeed them. This sort of flue is sometimes called the moist flue.

The second sort of flue, from its affording a dry heat, is intended principally for the culture of very succulent tender exotics of pachet foils, that require to be kept always dry. Where there are large collections of this sort of plants, it is very useful to deposit the moist succulent of them in separate flues, for fear of the others, which perhaps more freely, occasioning a damp air in winter, which may be imbied by the succulents, and injure them, as being impatient of much moisture, particularly in that

feason. In this kind of flue, movable frames or shelves are erected above one another, on which to place the pots of plants, such as the tenderer sorts of aloes, cereales, euphorbias, melon-thistle, and other very tender succulent plants, &c.; but most of them may be cultivated in a common flue, with proper care.

The third sort of flue is sometimes used principally for flowers, as is common about London, to force large quantities of early roses, pinks, and numerous other flowers for market, at an early season; others are intended principally for fruit-trees; and some serve both for forcing flowers and fruits, and several sorts of small plants, such as strawberries, kidney-beans, &c. so that they confit of two kinds, which are a bark forcing flue, furnished with a bark-bed and flues; and a fire forcing flue, having only flues for fire, without any bark-bed: the former of which is constructed like a common bark-flue, being furnished with a pit for a bark-bed to receive the pots of particular sorts of plants intended for forcing, in order to forward them as early as possible; and with flues for fire-heat occasionally; and sometimes it is formed capacious enough to admit of a border of earth behind the bark-bed, next the back wall, serving for fruit-trees to be planted in the full ground, such as cherries, peaches, apricots, &c. for early forcing. The bark-bed is for receiving various sorts of plants in pots in winter, for forcing to maturity of growth or production in that season, or early in the spring, as pots of roses, pinks, dwarf tulips, hyacinths, narcissi, honey-fuckles, hypercums, and many other flower-plants of small or moderate growth, both of the shrubby and herbaceous kinds: also any curious tender annual flowers, such as balfamines, &c. may be forwarded in it: likewise pots of strawberries, dwarf cherries, and other small fruits, plunged either in the bark-bed, or placed any where towards the glasses; also pots or boxes of kidney-beans, falling, &c.

But besides these large flues, it is necessary to have what are called fuchsia flues, and small pits for striking, forwarding, and nursing the plants in, while they are in their infant state of growth, especially when the collections of them are large, in order to prevent the large flues from being uselessly filled with improper or unproductive plants, and for the purpose of greater convenience. The pits serving to strike the plants in, and the fuchsia flues for placing and continuing them in afterwards, until they become ready and fit for fruiting or setting into the large flues.

Stoves are constructed in various ways, and of many different sizes and forms, so as to suit the sorts of culture and management that are to be carried on in them; but the most generally useful dimensions for them are probably those of from about ten to twelve or fifteen feet in height behind, with any suitable length, and eight, ten, twelve, or more in width, having from two or three to six feet of height in the front. Very lofty or capacious flues are but rarely wanted.

The most economical form of flue, Mr. London supposes, is that of a parallelogram, placed from east to west, of glass fashes on the south side, roof, and ends; and facing toward the north: but that the most elegant and eligible for the plants, is one placed north and south, and of glass on all sides; however, unless an inner roofing be used in this case, glasses on all sides is precarious, especially in the northern parts of the island. Stoves of the dry kind are kept of a temperature, in general, between fifty-five and seventy degrees Fahrenheit's scale, and moist flues between sixty-five and ninety degrees of the same thermometer. Where the plants are grown in pots, and plunged in earth
earth or bark, the pits should be made of considerable depth, to admit of those materials, as in the usual culture of the pine; but pits filled with earth, and managed in the manner prescribed by the above writer for growing this sort of plants, is so decidedly preferable, both in respect to beauty and economy, that few, who well understand the plan and think for themselves, will reject it for flower-plants, though they should even think it unfit for raising or growing those of the pine kind. See Bromelia.

The different modes of constructing houses of this kind are now so well understood, that they need not be noticed in this place, especially as they have, in some measure, been pointed out under the culture of the several plants which are raised or managed in them, and under some other heads. Befide, most of the late improvements in the flowers of them, which are the most material parts, will be seen below.

The succelion flowers and pits are probably the belt and most conveniently arranged and formed, either in connection with or contiguous to the large flowers, so as to admit of the plants being readily removed into them. They may be made of different sizes, in proportion to those of the flowers, and be provided with flinging glass in different ways, according to circumstances, but moley in the manner of the principal flowers, especially in the former.

The striking and nurting pits seldom need be of any large dimensions, but have flinges somewhat proportionate to those of the succelion flowers, having flus and glass in the most part, only upon the top parts of them.

The season to begin forcing in these flowers is principally from about the latter end of December to the end of January, according as the flowers, fruits, &c. may be wanted: the plants and trees intended for forcing in pots should have been potted either a year before, or in the preceding spring or autumn; and in winter sheltered from severe frost till the forcing time: it is necessary for the shrub and tree kinds in particular, as if planted or potted the preceding year, or before, and they are well rooted and finely establisht in the earth, it is of essential advantage; being all previously raised in the open ground, till advanced to proper growth for flowering and fruiting; and the fruit-trees at the fame time trained in the requisite order: thofe intended for planting in the internal border of earth behind, should be planted fully therein early in autumn, without being potted; some of which, such as peaches, nectarines, apricots, &c. being trained as wall-trees, others as low standards, particularly cherries; and vines, planted also against the front without-side, have the flumes trained in through small holes, and conducted up under the floping glass: but such plants as are to be raised from seed, shold not generally be bown till the time the pots are placed in the floue for forcing. When the plants, feeds, &c. have been properly arranged in these flowers, they are then set in motion by the bark-bed heat, and afterwards by making moderate fires on cold nights, and on days occasionally, in very fever weather, to support a confluent proper warmth to continue the plants always in moderate growth; by which means, various flowers and fruits may be obtained two or three months before their natural seafon in the open air.

But thofe of the latter kind, or fuch flowers as are worked by fire-heat only, are moley used for forcing fruit-trees, having the whole or moft part of the bottom space within formed of good rich earth, full two feet deep, in order to plant the fruit-trees entirely in the ground to remain; an alley or walk being either formed next the back wall, or carried along the middle, allotting a raised border along the back part for the reception of the choicer fruits to be trained as wall-trees; and the main middle space for small standards of moderate growth: in thefe, the belt forts of apricots, peaches, nectarines, cherries, plumbs, vines, and figs: like-with any small fruit-plants, as gooseberries, currants, raspberries; also tufta of strawberries, which should all be fernt trained in the open ground to a bearing flate: may be introduced: the peaches, nectarines, apricots, and figs, should be planted principally toward the back wall, and trained to a trellis, as wall-trees: the cherries as standards, both small-headed, moderate, full standards, half standards, and dwarfs, disposed in the middle space, the tallest behind, and the loweft forward; with pots of strawberries and low flowers upon shelves near the glashes; and the vines either within, towards the front, or wholly without, close against the front wall; and the flumes, or a ftrong fhoot of each plant, drawn in through a small hole made for each, either in the wall, or in the tumber of the front creafions; and the branches within trained up to the inside of the flopen glafs upon trellis-work: in the vines planted on the outside, it is necessary to guard the flumes in winter, especially some time previous to and during the forcing weather, with lay-bands wrapped clofly round them, also to lay some dry mulch over the roots, to protect the whole as well as possible, that the progres of the sap may not be much retarded by the external cold, and to promote its flowing more freely for the advantage of the internal growth of the vines, &c.

The feafon to begin forcing or making the fires in these flowers is in January, or early in February, continuing it moderately every night and morning, during the cold weather in winter and spring, to forward the different fruits to as early perfection as possible.

Great improvements have lately been made in the construction of houses of this as well as other similar kinds in which fire-heat is required; and better and more effectual modes of applying it in these and other cafes and utes fouged. In a communication from C. Lorimer, esq. to the Caledonian Horticultural Society, can-flues are strongly advised in the construction of such forts of houses. The flues of this kind there employed, were, it is said, from twenty-five to twenty-six inches long, of a conical or taper shape, from thirteen to thirteen and a half inches in diameter at the large end, and from eleven to eleven and a half inches at the small end, measured from the inside. In laying them for a flue, the small end is inserted into the large one an inch or an inch and a half, and the joinings closed and made secure with lime-plaster. At first, fire-clay was employed for this purpose, but it cracked and fell off, and let the flame get into the house; however, since the lime-plaster has been used, the flue has been perfectly tight, and the house free from smoke. It is thought, that perhaps it might be an improvement, if the slabs were made of a cylindrical or drum shape, all the length of the fame diameter, so that the ends would exactly fit one another, with about the half of the thickness of them taken off on the outside, for three-fourths of an inch each, in order to hold the plater. This would make the flue, it is supposed, look much neater and better on the outside, as the swelling at the joinings from the plater would thereby be greatly reduced; and when the flue was cleaned, the foot would be more readily and with greater facility got out, as it would be quite smooth in the inside from end to end.

It may be urged as an objection, it is said, that the houses must not have too much flame from the can-flues as from those of the old construction, but this, it is allerted, will not be found to be the case. As full as much flume has been railed by sprinkling the cans by means of a fine-rosed water-
STOVE.

ing-pan or pot, after they have been sufficiently heated, as could ever be done by the flues of the former conduction.

In one instance, though the cans had been made of common clay, they stood the heat very well, and notwithstanding the flue once took fire, only the can next the furnace became cracked, but those made of fire-clay are thought to be safer, the strongest fire that has been applied not having in the leaf injured them.

In consequence of the cans not being half an inch thick, it is evident, it is said, that they must transmit the heat sooner, and in much greater proportion, than flues of the old construction, which are commonly three inches thick in the sides, and one in the tile-covering at the top.

In laying the can-flues, the ends of them should rest upon a brick let on edge, which keeps the under sides or parts of them five inches from the ground, and of course none of the heat is drawn off or lost in that way.

It may be objected also, it is said, to the can-flues, that they will cool sooner than the brick and tile ones; but so long as any fire remains in the furnace, the can-flues will transmit the heat, which is not the case with the old form of flues, when the fire becomes weak.

The invention of these flues is said to belong to Mr. Burnet, of Viewfield, near Dunbar, in Scotland, who some time since built a house for forcing vines thirty-five feet in length by thirteen feet in width, measuring in the inside, with one furnace, which is found fully sufficient to keep up a proper temperature in the coldest weather. This plan of flue was had at most three degrees of success, as he has since had the largest crops of grapes that have been there known upon vines of such an age: lately, indeed, every part of the house, from the bottom to the top, has, it is said, been loaded with a profusion of fine clusters, so thick, that they appeared every where almost touching each other. It has been found, that after the eyes of the grape-vines in this house are all fairly broken in the spring, and the gardener is at liberty to increase the heat in the house, the thermometer at eight or nine o'clock in the evening, commonly stands at from seventy-two to seventy-five degrees. The fire is then mended for the night; and the succeeding morning, about six o'clock, the thermometer has kept up within two, or at most three, degrees, of what it was the night before.

The furnace of the house is built on the plan of the late Mr. Nicol, with Rumford doors; and when the fire is mended for the night, the ash-pit door is shut quite close, which prevents the heat being too much increased, and occasions a very small consumption of fuel; yet from the cans being so thin a proper degree of heat is transmitted, so as to forward the growth of the vines astonishingly fast.

In two small houses of this fort for vines, which have one of Mr. Nicol's or Mr. Loudon's furnaces to each, one of which has the flue built with bricks, and the covers in the old method; but in the other the flue was some time since taken down, and a can-flue put in its place, which is considered to be a real improvement. In the former of these houses, a fire was put on the 14th of February, while in the latter there was no fire until the 30th of March following, yet the house with the can flues ripened the grapes sooner than the other which commenced the fire-heat fix weeks earlier, and with a considerable saving in fuel.

In other trials since the above the result has been the same. And the can-flues have been found equally advantageous in producing large crops of grapes in other instances, and are capable of being beneficially employed for different other sorts of fruit-trees that are forced in houses of this kind.

The superiority in the use of these earthen-ware tubes, in the place of those which are forced by flues, brick, or tile, is, it is said, very great indeed. On the bell authority, they are fluted to have been attended with remarkable success. Great crops, not only on those forts of vines which are considered the bell bearers, but on those which are less productive, such as the Frontiniac, have been afforded by means of them in many different cases and situations; in all of which, the grapes were not only fine, but as well-tasted as those in any foreign climate or country: and, it is thought, that they promise not only to be greatly successful in this fort of culture, but also in that of the peach and nectarine. In short, two very great advantages may, it is suppos'd, be derived from the use of these flues; first, that an equal degree of heat may be had from much less fuel; and, secondly, that the fame degree of heat may be easily supported, with much greater uniformity, both during the day and night. In order to procure any heat in the air of forcing-houses, when the flues are built of brick or stone, a strong fire is required, which is very apt to give too much. But with the can-flues, a very little fire, burning very slowly, will give out a sufficient degree of heat. Upon the whole, therefore, there appears no doubt that the introduction of can-flues into the forxing culture in houses of this kind, may be considered a very important improvement in the horticultural art.

The can-flues which are thus used are capable of being easily made by any potter; for which, however, fire-clay instead of common should be employed, as having some advantages, which have been already seen.

A more improved and economical mode of constructing houses of these flues, has also lately been suggested, and communicated to the same society, by Mr. G. S. Mackenzie, as the result of careful experiment. Sir George having often been surprised at the cobt of houses of this nature, the most moderate of which seemed to him to put the innocent luxuries afforded by them out of the reach of persons of moderate fortunes, he resolved to attempt to erect one that should combine the least possible expense, with the means of raising more fruit in a given space than was done by any of the plans which are in common use. This bold attempt, considering the vast number of plans for the purpose which are in use, in which have been proposed at different times, may be suppos'd difficult, or probably impracticable. It has, however, it is said, been accomplished, and attended with such success, that the inventor is inclined to flatter himself it will be the means of enabling many persons to enjoy the productions of such houses who never thought of poffefling them, and of adding so much to the produce of market-gardens, as to increase the quantity of the richer fruits brought to towns, and consequently to lower the price, as this plan of training may be applied to such houses as have been already built.

The first matter that occurred to him as an object in which economy might be exercised, was the cost of furnaces being constructed with glafs. He cou'd fee no reason or necessity for this; and it appeared plain, that a fold end of masonry, with a porch and double door, would be more effectual in preventing the escape of heated air, or the rushing in of cold, than a glafs end and a glafs door. The next object which he had in view in this intention, and for which he defired a remedy, was the frequent occurrence of breakage, during the movement of the lathes in giving air; and he conceived it poiffible to have them always fixed, and yet to have ample means of ventilating the house. It was likewise confidered, that much expence workmanship might thus be avoided. These are matters of some importance in the business; but the principal improvement is conceived to be the method of training the plants in the house.
STOVE.

This and some other purposes are effected in the following methods. The training is done by means of a frame-work, which is set up at the distances of five feet across the house, and the moving of the frames, the ventilation, and regulation of the heat, by the roof being covered with a composition, in which there are hatches fixed that may be opened by cords and pulleys, or by levers, and which shut by their own weight. The number of these hatches is, of course, to be regulated by the sizes of the houses, and the degree of ventilation that may be required. In the front, there are fah-frames made to slide past each other; so that in each division, about eight square feet may be opened. When the front is opened, and the hatches raised, a current of air instantly passes through, which may be regulated at pleasure; while all motion of the great front father is avoided, and, of course, all risk of breakage from that cause prevented.

A trellis is formed on the crofs frame-work, on which the branches of the vines, peaches, nectarines, or other fruit-trees are trained. There are two trellises on each frame; and where vines are cultivated, they are planted two in each division, and one at every five feet on the back wall, which in such houses is fifteen feet high in that part, and two feet in height in the front one. Each vine in the division is trained to its respective trellis, and on half of the front fah, so that this method does not supercede, but is merely an addition to the common mode of training in such cases. The house that the inventor built some years ago on this plan, is, it is said, forty-two feet long inside; and part of it is separated for peaches and nectarines. The plan is twenty-four feet, which, by the ordinary mode, would, it is said, give a surface for training of about 1000 square feet. The addition which is proposed nearly doubles this, by adding about 950 square feet. It also allows of a great variety of vines being planted, so that there may be a sufficient number to choose from when they come to the bearing state. In large houses of this fort already built, by raising vertical trellises across them, many kinds of fruit, it is said, may be forced, for which, if we deem at present, there is no room, and many fine exotics be cultivated.

The flue on such a plan may, it is suggested, be conducted so as to have spaces for passing into the divisions, which, by contrariety at different places, retard the heated air in the higher parts, the advantages of which are quite obvious. The rest of the flue is low, but which can be managed in different ways.

It is affected from experience, that as good fruit has been had on the vertical crofs trellises, as under the glass, or on the back wall; and that it is this which only that could have induced the ingenious inventor to bring the plan into public notice. He has the intention, some time hence, to construct a house of this fort with partitions of brick instead of trellises; which last, however, look the best. But when utility and not appearance is studied, he should be inclined to give brick a decided preference, for many reasons; and among others, on account of the facility with which the temperature could be regulated. There is to houfes of this fort a small porch, the outer door of which is always shut before that of the house is opened, to prevent, when necessary, the rushing in of the external air.

It has also been suggested by R. Stevenson, esq. an able engineer, that the same principle which is employed in constructing the flues for heating drying-houses for different manufacturing purposes, may be usefully applied and employed in heating flues, vineries, and other forts of forcing-houses in gardens. From experiments and trials made in different houfes of the drying-house kind, with flues built and constructed in different manners, as with the fire-place at one end, and the flue six inches by ten, conducted under the floor, and made with tile-brick, the flues being made to cross several times under the floor, before reaching the chimney at the other end of the room; by which the smoke and heat were detained longer in their passage to it, and from traversing the whole of the floor, was confidently expected to raise the heat of the place to 1050 of Fahrenheit's scale; but it was found to be different, and with difficulty a temperature of from 60° to 70 could be raised and kept up; but that on the flues being removed, and crofs-walls of open brick-work made for supporting the floor, so that the whole space under it formed one large flue for the smoke and heated air, the same quantity of fuel put into the same fire-place as before, speedily raised the temperature to 150°, at which it could be maintained for any length of time, with the ordinary expenditure of fuel; and with the fire-place opened at one end of the house, and the flue carried to the other end, then turned and brought down the middle of the floor, and after being conducted a second time to the end of the house opposite the fire-place, communicated with a chimney which took off the smoke, the flue mesuring three feet in height, and two feet in breadth, made its evolutions in a space equal to the area of the building, and four feet in depth under the sole of the door; such flues being consequently not only much larger than is common even in these cases, but having the division-walls for supporting a pavement-floor over the flues, all made of open brick-work, the whole space, as above, was thereby converted into one large flue, or chamber for heated air, which being made to influx from the joints left in the flone-floor, circulates freely to every part of the house; so that with one common fire, the temperature of it, the area of which is 30 feet by 18, and 14 in height from the floor on which the flues rest, is speedily raised to, and easily kept at, from 70° to 90° of the above scale, while the wet materials are hanging in it, and the shutters in the upper part let open. This effect, which is much greater than in other cases of smaller flues, is, it is said, entirely to be ascribed to the largeness of the flues. On these grounds it is conceived, that the simple application of as large flues as the circumstances of flues and other houses of that kind will admit, would not only be attended with great advantage in point of economy, as a very small fire would be sufficient to maintain the temperature usually required in such houses; but what is perhaps, it is thought, of more consequence, flues properly constructed upon this principle are capable of being easily regulated, and will induce a much more uniform degree of heat. It would seem from the above that it is said, that the flues in general ufe are of too small dimensions; that there is not capacity in them for allowing the heated particles of air to expand; and that the heat piffles through the narrow flues, and makes its escape with the smoke in a latent state, without being allowed to act upon a surface large enough to rob it of its caloric.

Upon this principle, large buildings and halls might, it is thought, be heated; and one fire might be made to heat a much greater range of vineries, or other houses of the same kind, than is the practice at present. It would also be a great improvement in the construction of heated houfes, and even the inclosing of gardens, where they are of the wall kind, to make the walls hollow, as well on account of such a mode of construction inclosing a space for air, which is an excellent non-conductor, as of the facility with which the fire may be applied, by converting the whole, or the greatest part of the wall, into a flue or receptacle for heated air. When this is to be done, the fire-place should be kept as low as possible; and after anwering its purpose in the
STOUPEE, in Geography, a town of Lithuania; 33 miles E. of Novogrodek.

STOUR, a river of England, which rises near Haverill, in Suffolk, and passes by Clare, Sudbury, Nayland, Dedham, Manningtree, &c. forming a boundary between the counties of Essex and Suffolk, and runs into the German sea at Harwich.—Also, a river of England, which rises near Wincanton, in Somersetshire, and runs into the English Channel at Chittlechurch, in Hampshire.—Also, a river of England, in the county of Kent, which runs into the sea at Sandwich.—Also, a river of England, which runs into the Trent, 4 miles S. of Kidderminster, in the county of Worcesters.

STOUR HEAD, a cape of Denmark, on the N.W. coast of the island of Funen. N. lat. 55° 37'. E. long. 9° 48'.

STOURBRIDGE, a town, the name of which is derived from a bridge built over the river Stour, in the county of Worcestershire, England. Being for a considerable period a hamlet belonging to Swinford, it had, until the time of Henry VIII., a chapel dependent on the church of that place: but having now increased to a large and populous town, a chapel was erected of brick, in 1742, on the western side of the town; which, by act of parliament, has been made parochial, and independent of the mother-church. The various classes of Protestant Dissenters have also meeting-houses in this town. A free-school was founded by Edward VI.; but anterior to that reign, there appears to have been an establishment for a similar purpose: the present one is handsomely endowed, and is under the inspection of eight governors.

The manufactures of Stourbridge, which are aided by the vicinity of the Staffordshire canal, are various: the principal is that of glass, both in making and cutting of which, a great degree of elegance and ingenuity is shewn. This art, in which the English now excel, was not introduced into England till 1557, at which period the Venetians parfayed all other nations in the production of crystal looking-glasses. The other branches of manufacture here practised, are the procises of making leather from sheep-kins, iron articles and nails, and fine cloth from British wools. There are also mines of crucible clay, which afford ample employment to the town and neighbourhood. Stourbridge has a weekly market on Friday; two annual fairs, celebrated for cattle; and contained, according to the report of 1811, 866 houses and 4074 inhabitants.—Beautiful of England and Wales, vol. xx. Worcestershire, by Mr. Laird.

STOURHOLM, one of the smaller Shetland islands, between Yell and Shetland. N. lat. 60° 54'. W. long. 1° 35'.

STOURPORT, a town about four miles from Kidderminster, on the banks of the river Severn, and in the county of Worcestershire, England. Its origin is chiefly owing to the Staffordshire and Worcestershire canal, which entering this county at Wolverley, continues parallel with the river Stour for a distance of nine miles, and is terminated by a bascule at Stourport, where it joins the Severn. The houses of this place are commodious and neat, amounting to upwards of 250, with about 3000 inhabitants; and is also established a weekly market, which in the winter months greatly abounds in hops, with two annual fairs. Over the river Stour, there was erected a stone bridge at Stourport in 1773; but which having been destroyed by a violent flood, was replaced by the present one, of iron, consisting of a single arch of 150 feet span.

About two miles east is Hartlebury castle, once defended by fortificatious and a moat, and for many centuries past

Pp
the residence of the bishops of Worcester. It was given to the diocese by Burdred, king of Mercia, and several of the bishops have strengthened and decorated it. In the reign of Charles I. it was taken and held by the parliament, but after the restoration, it was re-occupied by the succeeding bishops: it is a brick structure, with battlements, turrets, &c.—Beauties of England and Wales, vol. xv. Wor-
casterbiurn, by Mr. Laird.

STOUSE HEAD, a cape on the east coast of the island of South Ronaldsay, N. lat. 58° 40'. W. long. 2° 47'.

STOW, John, in Biography, an industrious antiquarian and historian, was the son of a merchant-taylor in London, and born about the year 1525. About the year 1560 he formed the design of composing annals of the English history, and to this object he sacrificed his trade and domestic concerns; travelling on foot to several cathedrals and other public establishments, in order to examine records, charters, and ancient documents. He also purchased, as far as he was able, old books, manuscripts, parchments, &c. of which he made a large collection. But wanting patrons, and pressed by necessity, he was obliged to intermit his favourite pur-
uits, and to renew his application to business with a pro-
erty that had been much lessened. Benefactions, however, from Dr. Parker, archbishop of Canterbury, enabled him to prosecute his studies; but being suspected of an attachment to popery, an information against him was laid before the council, in 1568, as a dangerous person, and as having pollu-
tion of many pernicious books of superstition. His study was searched by order of Dr. Grindal, bishop of London, and many popish books were found in it; which discovery fixed upon his character the reproach of a suspected person; and two years after, an unnatural brother, who, having defrauded him of his goods, was desirous of taking away his life, preferred against him above 140 articles before the ecclesiastical commissary. But the infamous character of the wretches who were engaged to prove the charges, caused him to be acquitted. His first work, undertaken at the re-
quittal of the powerful favourite, Robert Dudley, earl of Leiceste, had been already published: and as it had been dedicated to the said nobleman, his countenance was of service to him in his present circumstances. This was "A Summarie of English Chronicles," first printed in 1565, and several times reprinted. This book contained an ac-
count of the reign of every English king from the era of the fabulous Britoe, down to his own time, with a list of the principal magistrates of London from the Conquest. It was afterwards continued by Edmond Howes, who printed several editions, so that the work must have been popular.

In 1575 he lost his best patron, archbishop Parker; but his mind was so ardently engaged in his antiquarian studies, that he prosecuted them with uninterriting diligence and zeal, amidst all the inconveniences and difficulties of penury. In 1585 he presented a petition to the lord mayor and court of aldermen, stating, that for 25 years he had been employed in compiling and publishing divers fumaries, recording the memorable acts of famous citizens, and that he contemplated the publication of a larger fomary, and soliciting en-
couragement and assistance; and four years after he pre-
fented another petition, requesting a pension, or some other benefaction; but it does not appear whether or not he suc-
cceeded in his solicitations.

To the improvement of the second edition of the Chroni-
cles published by Hollingshed in 1587, Stow largely con-
tributed; and he also supplied corrections and notes for two editions of Chaucer. His "Survey of London, &c." on which he had been long employed, appeared in 1598, and a second edition was presented to the public before his death. It was several times reprinted, with successive improvements, and has been the basis of all the subsequent histories of the metropolis. For his large Chronicle or History of Eng-
land he had been for 40 years collecting materials; but he only lived to print an abstract of it in 1600, entitled "Flores Historiarum, or Annals of England," 4to. dedicated to archbishop Whitgift. Edmond Howes published from his papers a folio volume, entitled "Stow's Chronicle," but this does not seem to contain that "far larger work," men-
tioned by Stow, and which he left in his study fairly written out for the press. It is said to have come into the posses-
sion of Sir Symonds Dewes, but is not found among his MSS. in the British Museum. Stow having spent his patri-
mony, and acquired no certain income, sunk into wretched poverty in his old age, and was under a necessity of applying for public charity: and James I., "by one of the meanest acts of his very mean reign," granted a licence, authorizing him, then in his 75th year, "to repair to churches, or other places, to receive the gratuities and charitable benevolence of well-disposed people." Of the amount of this bounty, we may form some conjecture from the collection in the parish of St. Mary Woolnoth, which reached the sum of 71. 6d. The city of London was not more liberal than the sovereign of the country; and it must reflect no small degree of reproach upon it, that it could not extend its libe-
rality towards its own historian. Stow, oppressed by poverty and painful diseases, obtained a release in the year 1655, at the age of 80 years. His aspect is said to have been cheer-
ful, and his behaviour mild and courteous.

In his writings, says one of his biographers, "he displayed a sincere love of truth, and great diligence in in-
vestigating it, with the moral feelings of a worthy man. His brother antiquarians speak of him with respect; and if he ranks, in point of style and matter, with the inferior clafs of historians, he may claim the praise of humble utility." Biog. Brit. Gen. Biog.

Stow, in Geography, a township of Middlesex county, in the state of Massachusetts, incorporated in 1683, and containing 885 inhabitants; 26 miles N.W. of Boston.—Alfo, a township of Vermont, in Chittenden county, about 25 or 30 miles E. of Burlington, containing 650 inhabit-
ants.

STOW CREEK, one of the eight townships into which Cumber-
land county, in New Jersey, is divided, containing 1039 inhabitants.—Alfo, a river of New Jersey, which runs into the Delaware, N. lat. 39° 58'. W. long. 75° 26'.

STOWAGE, the general arrangement of the several materials by which a ship is to be laden, with regard to her figure, magnitude, and solidity.

In the stowage of different articles, as ballast, cafks, boxes, cafks, and bales, there are several general rules to be observed, according to the circumstances or qualities of those materials. The iron ballast, which is mostly used in king's ships, should not be flowed too near the keelfon, but winged up from two to four feet from the sides of the keelfon, according to the make of the ships. Cafks which contain any liquid, are, according to the sea-phrase, to be hung-up and bilge-free, i.e. closely wedged up in a horizontal position, and reeling on their quarters; so that the bilges, where they are thickest, being entirely free all round, cannot rub against each other by the motion of the vessel. Dry goods, or such as may be damaged by the water, are to be carefully inclosed in cafks, cafks, bales, or wrappers; and wedged off from the bottom and sides of the ship, masts, and pum-pell.

The knowledge of stowing a ship's hold with propriety requires
requires the greatest attention of the skilful mariner; for although it is well known that ships in general will not carry a sufficient quantity of sail, till they are laden so deep that the line of floatation is well with the extreme breadth amidships, or nearly so, yet there is more than this general knowledge required; for should the cargo consist of very heavy materials, as lead, iron, \&c., and they be unskillfully flowed too near the bottom, it will place the centre of gravity too low; and although this will enable her to carry a great press of sail, she will nevertheles roll heavily, and consequently rule the handling of her masts. On the other hand, should the cargo be light, it is very evident that, without a sufficient quantity of heavy ballast, or other materials of like weight, flowed low down in the vessel, she would be cramped, that is, the centre of gravity would be raised too high, whereby the vessel is rendered incapable of carrying sail without being exposed to the danger of overfetting.

Thus the whole art of flowing or lading a vessel, therefore, consists in placing the centre of gravity to correspond with the trim and shape of the vessel, so as neither to be too high nor too low; neither too far forward, nor too far aft: thus it will be readily seen, that all the weightier part of the cargo should be placed as near amidships as possible, and the lighter part of it as near the masts as possible, also at the fore-part of the vessel, and likewise at the stern: hence, if the vessel be judiciously flowed, the will neither roll nor pitch heavily, and will be enabled to carry a good sail and ply well to windward, especially if due regard has been paid to these qualities in the construction of the vessel. See Ballast.

STOWAGE Room, in Hop Management, the apartment or place constructed for receiving and containing the hops, after they have been dried, until they are ready or in proper condition for bagging. It has a suitable hole made in some part of the floor, round which a frame of wood is placed, so as to exactly fit the mouths of the bags, which are securely fixed all round it, for the convenience of flowing the hops into them. See Hop.

STOWE, in Geography, a parish in the county of Buckingham, England, nine miles N.W. of the county-town, is noted for the magnificent seat of the marquis of Buckingham. Peter Temple, esq., was the first of the family who settled at Stowe in the year 1554, and who erected a mansion on the estate; but this was taken down and rebuilt by Sir Richard Temple, K. B., who died in 1667. His son, Lord Cobham, enlarged the mansion by building a new front, and adding two wings; but the late marquis of Buckingham, and his father, Earl Temple, made still greater alterations and improvements at this place. The whole front, of regular and uniform architecture, now extends 916 feet, of which the centre is 454 feet. It consists of a centre, or body, with two wings, connected by apartments. A flight of 31 steps leads to the grand saloon, an oval apartment, 60 feet by 40, surrounded by Scaliola columns, imitative of Sicilian Jasper. The pannels, cornice, and dome, are all adorned with sculpture and other ornaments, to produce a splendid effect. A large drawing-room, 50 feet by 32; a large gallery, 70 feet by 25; a library; and several drawing rooms, eating-rooms, &c, constitute the principal floor. A library, fitted up to receive Saxon MSS. and old literature, has recently been formed here from the deigns of John Soane, esq. Most of the apartments are enriched with pictures, and fitted up in a splendid style. The gardens or pleasure-grounds of Stowe are, however, more celebrated than the mansion; they consist of 450 acres, and present a great variety of surface, fenery, and objects. In some places they display bold swells, with narrow and winding valleys; the principal of which is filled with a broad and pellucid lake. In one part this forms a cascade, and over it is a palladian bridge. In different parts of these gardens are several ornamental buildings, consisting of temples, columns, arches, &c. The beauties and characteristic features of this jolly noted seat have been extolled in the poetry of Weel, Pope, and Hammond; and are fully described in an octavo volume, published in 1797, entitled "A Description of the House and Gardens of Stowe," with thirty-three plates, most of which were drawn and engraved in a taste ful style by T. Midland. An account of it is also given in the first volume of the Beauties of England and Wales.

Midland. An account of it is also given in the first volume of the Beauties of England and Wales.

STOWEY, a small market-town in the hundred of Williton and Freemasons, in the country of Somerset, England, is situated eight miles W.N.W. from Bridgewater, and 149 miles W. from London, at the foot of Quaintock hills, on the banks of a rivulet, which paffing through Fiddington, falls into the Bridgewater river at Combe. The town consists of three streets, and was returned to parliament, in the year 1811, as containing 119 houses, occupied by 620 persons. A weekly market is held on Tuesdays, and an annual fair for cattle. Here is a small market-croft, of an octagonal form, standing on eight small round pillars, with a clock, and a bell, which is usually rung to proclaim the opening of the market-service, as the church stands a quarter of a mile from the town. "STOWEY is a reputed borough, the inhabitants whereof anciently held their houses and lands of the castle by burgage. The castle stood on a hill to the westward of the town, and near it was a church dedicated to St. Michael; but both are now ruined, so that none vestiges remain of either but the castle-ditch; the site of the castle being pature-ground." The present church, St. Mary's, is a substantial edifice, having at the west end an embattled tower 70 feet in height, with a turret at one corner. Col- linson's History of Somersetshire, vol. iii. 470.

STOW-MARKET, a town in the hundred of Stow, and county of Suffolk, England, is seated at the junction of three rivulets, which form the river Gipping. In 1801 it contained, according to the parliamentary report, 283 houses, and 1761 inhabitants; and by the report of 1811, these appear to have increased to 2006 persons, and 401 houses. Stow-Market is certainly a flourishing town, and contains many handsome houses, especially near the market-place. The church is a spacious and beautiful building, with a square tower, surmounted by a steeple 120 feet high, which, though of wood, has a light and neat appearance. In this church are interred several of the Tyrrel family, of Gipping-Hall, in this hundred. Here is also the monument of Dr. Young, once vicar of this place, and tutor to the immortal Milton. The contiguous parish of Stow-Upland, which has neither church nor chapel, is now consolidated with Stow-Market; but they have still different officers for each parish.

The county meetings for Suffolk are chiefly held in this town; and here is a manufacture of facking, ropes, twine, and hempen, which has succeeded that of stuffs and bombeazes. Being well situated for the barley trade, the market of this town is much frequented by the farmer, and much busines is done in the melting line. A principal source of the prosperity of Stow-Market is the navigable canal from this place to Ipswich, which was opened in 1793. It is sixteen miles in length, and has fifteen locks, each sixty feet long, and fourteen wide; three of these are built with timber, and twelve with brick and stone. The whole expense of this undertaking was 26,380l. Independently of its utility, this canal is an ornament to the town. There are about 150 acres of hop-plantations in this neighbourhood.
An old manor-house, called Abbots' Hall, together with the manor of Stow-Market, were given by king Henry II. to the abbey of St. Olyth, in Elfrith; but was granted, 38 Henry VIII., as part of the poffeilion of that monaftery, to Thomas Darce. The house of industry for the hundred of Stow stands on an eminence, about a mile from the town. It has rather the appearance of a gentleman's seat than of a receptacle for paupers. It was erected at an expense of more than 12,000l., and was opened in 1781.

Finshull, near Stow-Market, was the birth-place of Sir William Coppinger, lord mayor of London in 1512. At his death, he bequeathed half of his large property to charitable purposes; the other half was devoted to his relations.

Finborough-Hall, in the parish of Great Finborough, was built in 1705, by the present proprietor and lord of the manor, Roger Petteward, esq. An embowered walk leads behind the hall to the church, which contains several monuments of the Wollaston family, formerly proprietors of Finborough; and particularly one to the memory of William Wollaston, author of the "Religion of Nature delineated," who refided and is interred here. He was born in 1659, at Coton Clanford, in Staffordshire, and died in 1724.

The hamlet of Gipping derives its name from its situation near the source of one of those springs that form the river Gipping. It was once the seat of the ancient family of Tyrrel, whose residence, Gipping-Hall, is now held by Sir John Shelly, bart. Haughley was formerly a market-town, out of the ruins of which Stow seems to have risen. Near the church stand the remains of a very strong castle, conjectured to have been built by the Saxons. The figure of the building approaches to a square, fortified with a deep ditch, or moat; and, except on the north side, a proportionable rampart, still entire. Towards the north, upon a high artificial hill, of steep ascent, and also surrounded with a deep moat, flood the keep; of which the foundation, now remaining, is very thick, and apparently circular. On the west side, a large oblong-square space seems to have contained some outwork of the castle. The ground occupied, or inclosed by all these works, exceeds seven acres.

The manor and park of Haughley formerly belonged to Charles Brandon, duke of Suffolk; from whom they devolved by purchase, or exchange, to the crown; and were afterwards granted to Sir John Sulyard, of Wetherden. The manor is very extensive, and the lord formerly professed a power of trying all causes in his own court of oyer and terminer. Beauties of England and Wales, vol. iv. Suffolk, by F. Shoberl.

STOW-ON-THE-WOLD, a market-town and parish in the hundred of Wiltshire, and county of Gloucester, England, is irregularly built on the summit of a high hill, the base of which is about three miles in diameter. From this elevated situation it is generally said to want three elements out of the four; fire, earth, and water; air it possesses in plenty, and, though uncommonly sharp, it is reputed to be very healthful. Water is scarce, especially since the decay of an horizontal wind-mill at the north end of the town, which formerly raised it from a very deep well, and forced it through pipes to the houses. The charter for the market was granted, in the fourth year of Edward III., to the abbey of Ewelham, by which establishment some part of the manor was held in the time of Edward the Confessor; and within a century, it had obtained possession of the remainder. The manor now belongs to Edmund John Chamberlayne, esq., a descendant of a respectable family of Norman extraction, who settled in the hamlet of Mangersbury, on the east side of Stow, in the time of queen Elizabeth; and one of whom, Edmund Chamberlayne, esq., was sheriff of this county in the 39th year of that sovereign.

The church is a well-built edifice, apparently the workmanship of different periods during the fourteenth and fifteenth centuries. It consists of a nave, aisles, and chancel, with an embattled tower on the south side, 81 feet in height, which, from its lofty situation, constitutes a principal object through a circumference of many miles. The arches are pointed, and supported by clustered pillars. At the east end is a rich window of quatrefoils; and at the west end a window of ovals, with two trefoils in each. Several monuments and inscriptions, to the memory of the Chamberlaynes, are contained in this edifice; and in the midst of the chancel is a large altar-tomb, in remembrance of Duke Hatlings Keyt, of Edington, an officer on the part of Charles I., who died in the year 1645. His effigy in armour is engraved on the slab which covers the tomb.

The principal charitable institutions are an almshouse for nine poor persons, and a school; both situated on the south side of the church-yard. The former was founded under the will of William Chaftre, dated as early as the sixteenth of Edward IV. Althorne, or Ethalmore, earl of Cornwall and Devon, in the tenth century, is the reputed founder of the original church in this town, and it is also said to have erected an hospital here, which Rudder mentions as being yet charged in the Fitch-fruits office with the annual sum of 13l. 4s.

The population of Stow, as returned under the act of 1811, amounted to 1188; the number of houses to 264; the latter are mostly low, and built with stone, and have generally a very ancient appearance. The principal manufacture is that of shoes.

At Adelotrop, or Adelthorpe, about three miles east of Stow, is the seat of James Henry Leigh, esq., a lineal descendant of Sir Thomas Leigh, to whom the manor, which had previously belonged to the abbey of Ewelham, was granted in the year 1554. The manor is a very ancient building, but has been much enlarged, and otherwise improved. The pleasure-grounds have been laid out by Mr. Repton. About three miles south of the town is an old encampment, called Income-camp.—Beauties of England and Wales, vol. v. by J. Britton and E. W. Brayley.

STOWRE, in Rural Economy, a term signifying a round of a ladder; a hedge-stake; alfo the flaves of the sides of a waggon, in which the caue-rings are faffened. It alfo signifies a iaff or round fick, fuch as a tuck or rack iaff.

STOWS, in Mining, are seven pieces of wood, fet upon the surface of the earth, faftened together with pins of wood. See Spindie.

STRABANE, in Geography, a poll-town of the county of Tyrone, Ireland, situated on the river Moune. It is a flourishing town, and has a good market for many articles, especially linen cloth. Its canal, connecting it with the navigable river Foyle, is a principal cause of its prosperity, which is daily increasing. Strabane, before the union, was represented in parliament. It is 101 miles N.N.W. from Dublin.

Strabane, two townships of Pennsylvania, one in Adams' county, the other in that of Washington; the latter containing 2395 inhabitants.

STABISMIUS, in Medicine. See Squinting.

STRABO, in Biography, a celebrated geographer, was born at Amasia, a city of Pontus, but in what year we cannot ascertain. From his acquaintance with C. Gallus, prefect
prefect of Egypt, and from his having composed his geography in the fourth year of the emperor Tiberius, we may infer that he flourished in the century B.C., and Bishop assigns his death to the year 25 before the commencement of the Christian era. It appears that he studied grammar and rhetoric at Nysa, and that he was instructed in the principles of the various sects of philosophers in several of the most celebrated schools of Asia. He owns himself a Stoic, and he followed their dogmas. Of the general course of his life little is known; but he appears to have been a great traveller, and to have visited most of the countries which he describes. Besides his Geography, contained in seventeen books, which was written in his advanced age, and which is highly valued, he was the author of some historical works, which have been lost. His Geography, though since the time in which he lived it must be imperfect and erroneous in various particulars, is very useful for the illustration of the history and writings of the ancients; more especially as he interperses many philosophical remarks, which indicate a cultivated mind, and many short narratives, which serve to extend our acquaintance with the history and antiquities of remote periods.

Several editions of a Latin version of Strabo appeared before the Greek text was printed. Of the Greek and Latin editions, the first that claims commendation for its erudition was that of I. Caffaron, fol. Genev. 1587, and Paris, 1626. That of Janfon ab Almecevo, cum notis variorum, 4to. 2 vols. fol. 1727, is much esteemed, though not very correct. An Oxford edition has lately appeared, under the inspection of Mr. Falconer. Fabr. Bibl. Græc. Gen. Biog.

Strabo frequently mentions music, and the illustrious musicians of antiquity, with great respect. He places Zeno at the head of all sciences; and says, that the principal invention of the poet does not consist in teaching, but in delighting mankind. Whereas, according to the more ancient fuges, poetry was a first philosophy, which conducted youth through a pleasant path to prudence, morality, manners, human affections, and focial laws; while the moderns of our times (adds Strabo) say, that wisdom is only to be found amongst poets; on which account, the cities of Greece teach poetry to youth before all other things, not only for pleasure, but as a useful and virtuous discipline. In the fame manner, musicians, while they are teaching to sing and play on instruments, making this faculty a profession, are called masters, and correctors of manners. And this was not only the opinion of Pythagoras, but is manifestly demonstrated by Arisoxenus; and for this reason Homer placed a musician over Clytemnestra. as a guardian and guide of her conduct. All this has been copied from Strabo by Athenæus, l. i. c. 17.

But though a grave and solid writer, and a Stoic, Strabo has related a story in his fourth book, which throws a ridicule, not only on an eminent individual musician, but on the pretended lovers of music. He says that in Greece, near Bargilia, on the sea-coast, there was a market-town in a barren country, in which the inhabitants subsisted chiefly on fish; and a great performer on the cithara palling that way, wished to display his talents in public. On notice being given, the inhabitants assembled in great crowds to hear him. But soon after he had begun to perform, on hearing the fish-market bell, the audience haffened away, and left the citharist only one solitary person behind, who had not heard the bell, for he was deaf. The musician complained of his ill-treatment, but finithed by saying to the remaining gentleman, "Kind sir! I thank you for your politeness, in staying after all the rest had left me; but I perceive that you are a man of taste, a true lover of music, and did not run away in the midst of my performance, merely because the fish-market bell rang. What do you say? Why, has it rang?" demands the deaf gentleman; and the performer answering in the affirmative—'Oh, then, I wish you a good day, sir!'—and haffened to the market as fast as he could.

STRABRAGY, in Geography, a bay on the north coast of Ireland, in the peninsula of Inishowen, and county of Donegal. It is south of Malin head, and the village of Malin is situated on it.

STRACAIOA, a town of Wahachia; 18 miles N.W. of Krajowa.

STRADA, Famiano, in Biography, a celebrated Italian writer, born at Rome in 1572, who entered into the society of Jesus in 1592, and became professor of eloquence in the Roman college, where he resided till his death in 1659. His most famous work was a "History of the Wars in the Low Countries," in Latin, consisting of two decades: the first, comprising the events from the death of Charles V. to the year 1573, and published in 1632; and the second, as far as 1592, published in 1647. Strada's work was criticized with some severity by cardinal Bentivoglio; and it is allowed to have been more the production of a rhetorician than of an impartial and correct historian. The style, however, is animated, and the language pure, though defective in the good taste of some other modern Latins. It was attacked with virulence by Gaspar Scipiosus, in his "In Praise Famiano Strada," which injured his own reputation more than that of the historian.

The "Prolusiores Academicae" of Strada, containing various dissertations on literary subjects, is an ingenious and elegant performance, particularly admired for its imitations of the most celebrated Latin poets. Addison pronounces this effusion to be "one of the most entertaining, as well as the most just pieces of criticism he had ever read;" and he has made it the subject of three papers in the Guardian.
