This is a digital copy of a book that was preserved for generations on library shelves before it was carefully scanned by Google as part of a project to make the world’s books discoverable online.

It has survived long enough for the copyright to expire and the book to enter the public domain. A public domain book is one that was never subject to copyright or whose legal copyright term has expired. Whether a book is in the public domain may vary country to country. Public domain books are our gateways to the past, representing a wealth of history, culture and knowledge that’s often difficult to discover. Marks, notations and other marginalia present in the original volume will appear in this file - a reminder of this book’s long journey from the publisher to a library and finally to you.

Usage guidelines

Google is proud to partner with libraries to digitize public domain materials and make them widely accessible. Public domain books belong to the public and we are merely their custodians. Nevertheless, this work is expensive, so in order to keep providing this resource, we have taken steps to prevent abuse by commercial parties, including placing technical restrictions on automated querying.

We also ask that you:

+ **Make non-commercial use of the files** We designed Google Book Search for use by individuals, and we request that you use these files for personal, non-commercial purposes.

+ **Refrain from automated querying** Do not send automated queries of any sort to Google’s system: If you are conducting research on machine translation, optical character recognition or other areas where access to a large amount of text is helpful, please contact us. We encourage the use of public domain materials for these purposes and may be able to help.

+ **Maintain attribution** The Google “watermark” you see on each file is essential for informing people about this project and helping them find additional materials through Google Book Search. Please do not remove it.

+ **Keep it legal** Whatever your use, remember that you are responsible for ensuring that what you are doing is legal. Do not assume that just because we believe a book is in the public domain for users in the United States, that the work is also in the public domain for users in other countries. Whether a book is still in copyright varies from country to country, and we can’t offer guidance on whether any specific use of any specific book is allowed. Please do not assume that a book’s appearance in Google Book Search means it can be used in any manner anywhere in the world. Copyright infringement liability can be quite severe.

About Google Book Search

Google’s mission is to organize the world’s information and to make it universally accessible and useful. Google Book Search helps readers discover the world’s books while helping authors and publishers reach new audiences. You can search through the full text of this book on the web at [http://books.google.com/](http://books.google.com/).

1819.
STARCH.

STARCH, a substance which is extracted from wheat flour, by washing it in water. All farinaceous seeds, and the roots of most vegetables, afford this substance in a greater or lesser degree; but it is most easily obtained from the flour of wheat, by moistening any quantity thereof with a little water, and kneading it with the hand into a tough paste: this being washed with water, by letting fall upon it a very slender stream, the water will be rendered turbid as it runs off, in consequence of the fecula or starch which it extracts from the flour, and which will subsist when the water is allowed to stand at rest. The residuum of the flour, which remains after the water has extracted all the fecula, and runs off colourless, will be found to be gluten; which see.

The starch so obtained, when dried in the sun, or by a stove, is usually concocted into small masses of a long figure and columnar shape, which have a fine white colour, scarcely any smell, and very little taste. If kept dry, starch in this state continues a long time uninjured, although exposed to the air. It is not soluble in cold water; but forms a thick paste with boiling-hot water, and when this paste is allowed to cool, it becomes semitransparent and gelatinous, and being dried, becomes brittle, and somewhat resembles gum.

Starch, although found in all nutritious grains, is only perfect when they have attained maturity, for before this it is in a state approaching to mucilage, and so mixed with saccharine matter and essential oils, that it cannot be extracted in sufficient purity to concretize into masses.

Wheat, or such parts of it as are not used for human food, are usually employed for manufacturing starch, such as the refuse wheat and bran; but when the finest starch is required, good grain must be used. This, being well cleaned, and sometimes coarsely bruised, is put into wooden vats, full of water to ferment; to afford the fermentation, the vats are exposed to the greatest heat of the sun, and the water is changed twice a day, during eight or twelve days, according to the season. When the grain bursts easily under the fingers, and gives out a milky white liquor when squeezed, it is judged to be sufficiently softened and fermented. In this state, the grains are taken out of the water by a sieve, and put into a canvas sack, and the husks are separated and rubbed off, by beating and rubbing the sack upon a plank; the sack is then put into a tub filled with cold water, and trodden or beaten till the water becomes milky and turbid, from the starch which is taken up from the grain. A scum sometimes swims upon the surface of the water, which must be carefully removed; the water is then run off through a fine sieve into a settling-veil, and fresh water is poured upon the grains, two or three times, till it will not extract any more starch, or become coloured by the grain. The water in the settling-veils being left at rest, precipitates the starch which it held suspended; and to get rid of the saccharine matter, which was also dissolved by the water, the vats are exposed to the sun, which soon produces the acetic fermentation, and takes up such matter as renders the starch more pure and white. During this process, the starch for sale in the shops receives its colour, which consists of small mixed with water and a small quantity of alum, and is thoroughly incorporated with the starch; but this starch is unfit for medicinal purposes. When the water becomes completely clear, it is poured gently off from the starch, which is washed several times afterwards with clean water; and at last is placed to drain upon lines clothed supported by hurdles, and the water drips through, leaving the starch upon the cloths, in which it is pressed or wrung, to extract as much as possible of the water; and the remainder is evaporated, by cutting the starch into pieces, which are laid up in airy places, upon a floor of plaster or of slightly burnt bricks, until it becomes completely dried from all moisture, partly by the access of B
warm air, and partly by the floor imbibing the moisture. In winter-time, the heat of a flove must be employed to effect the drying. Lastly, the pieces of dried flarch are scraped, to remove the outside crust, which makes inferior flarch, and these pieces are broken into smaller pieces for sale.

The grain which remains in the sack after the flarch is extracted, contains the husks and the glutinous part of the wheat, which are found very nutritious food for cattle.

The French manufacturers, according to Les Arts et Meiters, pursue a more economical method, as they are enabled, by employing an acid water for the fermentation in the first infusion, to use the most inferior wheat, and the bran or husks of wheat. This water they prepare, by putting a paiful of warm water into a tub, with about two pounds of leaven, such as some bakers use to make their dough rise or ferment. The water stands two days, and is then fired up, and half a paiful of warm water added to it; then being left to settle till it is clear, it is poured off for leue. To use this water in the fermentation of the materials, a quantity of it is poured into a tub, and about as much fair water is poured upon it as will fill the tub half full: the remainder of the tub is then filled up with the materials, which are one half refuse wheat, and other half bran, and the other half of the materials is divided into two similar tubs and ferments during ten days, or less, according to the strength of the leaven-water, and according to the disposition of the weather for fermentation. When the materials have been sufficiently steeped, or fermented, an unctuous matter, which is the oil of the grain, will be seen swimming on the surface, having been thrown up by the fermentation. This must be scummed off; and the fermented grain, being taken out of the tub, is put into a fine hair-fieve, placed over a settling-tub, when fair water is poured upon it, and washed through the fieve into the tub; by which means the flarch is carried through the fieve with the water, of which about six times the quantity of the grain are used.

The water stands in the settling-tub for a day, and becomes clear at top; when it is carefully laded out of the tub, leaving at the bottom a white sediment, which is the flarch. The water which is taken off is four, and is called fare water; this is the proper leuen for the first steeping of the materials. The flarch now obtained must be rendered marketable; for which purpose, as much water is poured upon it as will enable it to be pounded with the hovel and hoved through the fieve, and then it is filled up with fair water. Two days after this, the water is laded out of the tub, and the flarch appears in the bottom, but covered over with a dark-coloured and inferior kind of flarch, which is taken off, and employed for fattening hogs. The remainder of the sediment, which is good flarch, is washed several times, to remove all the inferior flarch; and when this is done, about four inches of thick flarch should be found at the bottom of each tub: but the quantity varies, according to the goodness of the meal or bran which has been used. It is evident that the refuse wheat, when employed for making flarch, ought to afford more, the whole being used, than the bran or husks; but the flarch so extrasted is always of an inferior quality to that which is extrasted from the bran of good wheat, particularly in the whiteness of its colour. The flarch in the different tubs is brought together into one, and there worked up with as much water as will dilute it into a thin paste, which is put into a filk fieve, and strained through with fresh water. This water is settled in a tub, and afterwards poured off, but before it is to completely settle as to lode all its white colour; this renders the flarch which is deposited still finer and whiter, and the flarch which is deposited by the water so poured off is of a more common quality.

The flarch thus purified is taken out of the bottom of the tubs, and put into wicker-baskets, about 18 inches long and 2 feet, rounded at the corners, and lined with linen cloths, which are not fastened to the baskets. The water drips from the flarch through the cloths for a day, and the baskets are then carried up to apartments at the top of the house, where the floor is made of very clean white plaster; and the windows are thrown open, to admit a current of air. Here the baskets are turned downwards upon the plaster-floor, and the linen cloths, not being fastened to the baskets, follow the flarch, and, when taken off, leave loaves, or cakes of flarch, which are left to dry a little, and are then broken into small pieces, and left on the plaster-floor till very dry. But if the weather is at all humid, the flarch is removed from the plaster-floor, and spread out upon shelves, in an apartment which is warmed by a flove, and there it remains till perfectly dry. The pieces are afterwards scraped, to remove the outside crust, which makes common flarch; and the foraped pieces being again broken small, the flarch is carried to the flove, and spread out to a depth of three inches, on hurdles covered with cloths. The flarch must be turned over every morning and evening, to prevent it from turning to a greenish colour, which it would otherwise do.

Those manufacturers who are not provided with a flove, make use of the top of a baker's oven to spread the flarch upon; and after being thoroughly dried here, it is ready for sale.

Starch may be made from potatoes, by soaking them about an hour in water, and taking off their roots and fibres, then rubbing them quite clean by a strong bruishe: after this they are reduced to a pulp, by grinding them in water. This pulp is to be collected in a tub, and mixed up with a large quantity of clear water: at the same time, another clean tub must be provided; and a hair-fieve, not too fine, must be supported over it by two wooden rails extended across the tub. The pulp and water are thrown into the fieve, and the flour or flarch is carried through with the water; fresh water must then be poured on, till it runs through quite clear. The refuse pulp which remains in the fieve, being boiled in water, makes an excellent food for animals; and the quantity of this pulp is near seven-eighths of all the potatoes employed. This pulp is sometimes, when the flour is turbid, and of a darkish colour, from the extractive matter which is dissolved in it. When it is suffered to rest for five or six hours, all this matter departs or settles to the bottom, and the liquor which remains is to be poured off as ufeles; and a large quantity of fresh water is thrown upon the flour, and stirred up; it is then settled for a day, and the water being poured off, the flour will be found to have again settled in a whiter fiate. But to improve it, another quantity of water is poured on, and mixed up with it; in which state it is passed through a fine filk-fieve, to arrest any small quantity of the pulp which may have escaped the first hair-fieve. The whole must afterwards be suffered to stand quiet, till the flour is entirely setteled, and the water above become perfectly clear; but if the water has any sensible colour or taste, the flour must be washed again with fresh water, for it is absolutely necessary that none of the extractive matter be suffered to remain with it. The flour, when thus obtained pure, and drained from the water, may be taken out of the tub with a wooden hovel, and placed upon wicker-frames covered with paper, to be dried in some situation properly defended from dust.

When the manufacture of flarch from potatoes is attempted in a large way, some kind of mill must be used to reduce
STARCH.

reduce them to a pulp, as the grating of them by hand is too tedious an operation. A mill invented by M. Baume is very complete for this purpose. In its general structure it resembles a large coffee-mill: the grater consists of a cone of iron-plate, about seven inches in diameter, and eight inches in height, the exterior surface of which is made toothed, like a rasp, by piercing holes through the plate from the inside. This cone is fixed upon a vertical axle, with a handle at the top to turn it by; and is mounted on the pivots of the axe, within a hollow cylinder of plate-iron, toothed within like the outside of the cone; the smallest end of the interior cone being uppermost, and the larger or larger end being as large as the interior diameter of the hollow cylinder. A conical hopper is fixed to the hollow cylinder, round the top of it, into which the potatoes are thrown; and falling down into the space between the outside of the cone and the inside of the hollow cylinder, they are ground, and reduced to a pulp, when the interior cone is turned round by its handle; and as the lower part of the cone is fitted close to the interior diameter of the cylinder, the potatoes must be ground to a fine pulp before they can pass through between the two. The machine, when at work, is placed in a tub filled with water; and as fast as the grinding proceeds, the pulp mixes regularly with the water, ready for the process before described.

Mr. Whately of Cork has also proposed a mill for the same purpose, on a different plan. The grater is a cylinder, with its axis horizontal, and turned by a handle at one end, with a fly-wheel to regulate the motion. A hopper is placed over the cylinder, into which the potatoes are thrown, and are grated by resting upon the cylinder, as it revolves round. There is also an horizontal box opposite to the cylinder, into which the potatoes are received from the hopper, through a sliding-door; and a moveable end, which is fitted to the box, is pressed forwards towards the cylinder by a lever and weight, so as to force the potatoes contained in the box against the cylinder, which, being kept in constant motion, shreds away the potatoes into a pulp with great rapidity, and it falls into a box beneath.

In the year 1796, lord William Murray obtained a patent for manufacturing starch from horse-chestnuts. The method was to take the horse-chestnuts out of the outward green prickly husk, and either by hand, with a knife or tool, or else with a mill adapted for the purpose, the brown skin was carefully removed, leaving the chestnuts perfectly white, and without the smallest speck. In this state the nuts were rasped or ground to a pulp with water, and the pulp washed with water through a coarse horse-hair sieve, and twice afterwards through finer sieves, with a confluent addition of clear cold water, till all the starch was washed clean from the pulp which remained in the sieve; and the water being letted, depotted the starch, which was afterwards repeatedly washed, purified, and dried, in the same manner as the potato-starch before described. We are not informed if this manufacture has been carried into effect.

The starch was used along with malt, or stone-blue, to stiffen and clear linen. The powder of it is also used to whiten and powder the hair.

It is also used by the dyers, to dispense their stuffs to take colours the better.

Starch is sometimes used instead of sugar-candy for mixing with the colours that are used in strong gum-water, to make them work more freely, and to prevent their cracking.

It is also used medicinally for the same intentions with the viscous substance which the flour of wheat forms with milk, in fluxes and catarrhs, under various forms of powders, mixtures, &c. A drachm of starch, with three ounces of any agreeable spirituous water, and a little sugar, compone an elegant jelly, of which a spoonful may be taken every hour for two. These gelatinous mixtures are likewise an useful injection in some diarrhoeas, particularly where the lower intestines have their natural mucus abraded by the flux, or are constantly irritated by the acrimony of the matter. Starch is the common vehicle for the exhibition of opium per anum.

By 43 Geo. III. c. 68. sched. (A), upon every hundred weight of starch imported a duty is imposed; and by 49 Geo. III. c. 98. sched. (A), another duty upon every hundred weight is imposed.

No person shall be a maker of starch within the limits of the head-office of Excise in London, unless he occupies a tenement of 10l. a year, or upwards, for which he shall be assessed in his own name, and also pay to the poor-rates; nor elsewhere, unless he pay to the church and poor; or if there are no such rates, to the rate on houses and windows, under the same penalty as for making starch without entry. (19 Geo. III. c. 40. f. 3. 26 Geo. III. c. 51. f. 20.) By 43 Geo. III. c. 69. sched. (A), every starch-maker shall take out a licence, for which he shall pay 5l., and renew the same annually within ten days before the end of the year, on pain of 50l. 24 Geo. III. c. 41. And the places of making starch are to be entered, under penalty of 200l. (24 Geo. III. c. 48. 2.) All rooms and places, vellies and utensils, shall be marked and numbered, under the penalty of 50l. (19 Geo. III. c. 40. f. 12.) Flour, and other materials, found in any private place, and all private utensils and vellies for making or keeping starch, unentered, shall be forfeited, or their value. (10 Ann. c. 26. f. 22.) Every starch-maker shall cause his name to be painted over his door, or on some conspicuous part of the front of his house, with the addition of "starch-maker," on penalty of 100l. (24 Geo. III. c. 48. 2.) Officers may at all times enter and survey, and make return to the commissioners, leaving a true copy of the quantity, if demanded, under his hand, with the maker; and if he leave not such copy, after it has been demanded in writing (12 Geo. I. c. 28.), he shall forfeit 40l. (10 Ann. c. 26. f. 14.) Notice of emptying the vats, and of taking the waters out of the tubs, shall be given, on pain of forfeiting 100l. (19 Geo. III. c. 40.) The maker shall use regular, square, or oblong boxes only, for boxing and draining his green starch, before it is dried in the flore, on pain of 10l.; and give notice of boxing, and an account of drying, &c. Nor shall he remove any starch after it is dried, before it be weighed, &c. by the officers, on pain of 200l. (4 Geo. II. c. 14. 19 Geo. III. c. 40.) All starch, before it be put into any flore or place to dry (except for crusting), shall be put in papers, tied up with wrappings, palled over with a piece of paper of a different colour, and stampt by the officer, under penalty of 100l. (26 Geo. III. c. 51.) Forging or using forged stamps incurs a forfeiture of 50l. (26 Geo. III. c. 51.) The maker shall have just scales and weights, on pain of 10l.; and if he shall use insufficient scales or weights, he shall forfeit 100l. (10 Geo. III. c. 44.) Removing starch before due notice is prohibited by 10 Ann. c. 26. f. 19. And if it be removed before it is weighed by the officers, the person so offending shall forfeit 200l. (19 Geo. III. c. 40.) And if any dealer in starch shall receive more than 28 lbs. not duly marked, he shall forfeit 200l. 24 Geo. III. c. 48. 10 Ann. c. 26. f. 16.

Clandestine manufacture, or concealing of starch, exposes the party concerned, unless he can make it appear that the duty...
STA

duty has been paid, to a forfeiture of 50l.; and obstructing the officer in entering, seizing, &c. the same, incurs a forfeiture of 100l. (4 Geo. II. c. 14. 23 Geo. II. c. 21.)

And by 19 Geo. III. c. 40. if the maker shall conceal any starch, with intent to defraud his majesty of the duties, he shall forfeit 100l. Weekly entry shall be made, on pain of 50l.; and the duties shall be cleared within one week after entry, on pain of double duty. No starch shall be imported, except in packages containing at least 224 lbs., on pain of forfeiture, and of 50l. from the matter of the vessel. (42 Geo. III. c. 93.) Starch that hath paid the duties may be exported with a drawback of the duties. (10 Ann. c. 26. 27 Geo. III. c. 13.)
The officers of excise or customs may seize any starch or hair-powder, with the horse and package, suspected on good reason to have been privately made, or imported without payment of duty, or relanded after drawback; and if the party doth not make it appear that the duty hath been paid, they shall all be forfeited, with an additional forfeiture of 50l. for every hundred weight. (4 Geo. II. c. 14.) If any person shall knowingly harbour or conceal any starch unlawfully imported, or relanded after shipping for exportation upon debenture, he shall, whether he claim any property in it or not, forfeit 50l. for every hundred weight, together with the goods and package. (23 Geo. II. c. 21.)

No perfumer, &c. shall make use of, or offer to sale, any hair-powder made of or mixed with alabaster, talc, plaster of Paris, whiting, lime, &c. (sweet scents only excepted), on pain of forfeiting the same, and 50l. (12 Ann. stat. 2. c. 9.)

And if any maker of hair-powder shall mix any powder of alabaster, &c. (rice first made into starch, and sweet scents only excepted), he shall forfeit the same, and 50l. (12 Ann. stat. 2. c. 9.)

Or if any one maker or seller shall mix any such materials in the making of starch, or powder of starch, or rice made into starch, he shall forfeit the same, and 10l. Places for making hair-powder are to be entered, and officers may enter and survey them, under a penalty of 20l. 4 Geo. II. c. 14.

Every maker of flax-blue for sale shall make entry of his name, place of abode, place of manufacture and keeping, and materials, on pain of 50l. (26 Geo. III. c. 51.) Officers may enter and survey without obstruction, under penalty of 50l.; nor shall any flour, meal, or other ingredients (other than for colouring the same), be used, except starch for which the duties have been paid, on pain of forfeiting the same and 100l.

Nor shall any maker of flax-blue or hair-powder for sale receive into his possession any starch in papers not stamped, under pain of forfeiting 10l. a pound, together with the same; and if any maker shall keep above 28 lbs. of starch or hair-powder in any unentered place, the same shall be forfeited and also 50l. 26 Geo. III. c. 51.

All the preceding forfeitures shall be sued for, levied, and mitigated, as by the laws of excise, or in the courts at Westminster; and be distributed, half to the king and half to the person in whose possession.

STARCHY Matter of Roots, Plants, and Seeds, in Rural Economy, is a material which forms a principal part of a great number of excellent articles of different kinds, upon which their nutritive properties and qualities probably in a great measure depend when used as the food of man, or employed in the feeding and fattening of several different kinds of domestic animals. See STARCH.

Thus, it is ascertained to exist in considerable quantities in the root of the potatoe and some other roots, in many different plants of the edible kind, and to constitute the greatest part of most grains, pulse, and seeds which are employed as food. It is met with in a large proportion in the different nourishing vegetable substanices which are known and made use of under the names of fage, falep, arrow-root, tapioca, cattava, and some others. In regard to the roots, plants, and perhaps seeds, derived from weeds, it is known to abound much in the root of arum maculatum, or wake robin, of the wild or English hyacinth, of white bryony, of meadow saffron, and of a variety of others. It is very predominant in numerous wild plants, and most probably in most of their seeds.

Sir Humphrey Davy conceives, that this matter or coagulated mucilage, which forms the greatest part of all grains and seeds which are used in the way of food, is generally combined with gluten, oil, or albuminious matter. In corn, with gluten; in pulse, such as peas and beans, with albuminous matter; and in rape-seed, linseed, hemp-seed, and the kernels of most nuts, with oils. He found that one hundred parts of good full-grained wheat sown in the autumn, afforded seventy parts of starch and nineteen parts of gluten: that one hundred parts of wheat sown in the spring yielded seventy-five parts of starch and twenty-four parts of gluten: that the same number of parts of Barbary wheat gave seventy-four parts of starch and twenty-eight parts of gluten; and that an equal number of parts of Sicilian wheat afforded seventy-five parts of starch and twenty-one parts of gluten. He has also tried different species of North American wheat, all of which have contained rather more gluten than the one of British growth.

In general, it is said, the wheat of warm climates abounds more in gluten and in soluble parts; and is of greater specific gravity, harder, and more difficult to grind, than that of others: and that the wheat of the south of Europe, in consequence of containing a larger proportion of gluten, is peculiarly fitted for making macaroni, and preparations of flour in which a glutinous quality is considered as an excellence.

In some trials made on barley, he obtained, from one hundred parts of a full, fair, Norfolk, foot, seventy-nine parts of starch, fix of gluten, and eight of hulk; the remaining seven parts consisting of sweet or facharine matter. The fugar in barley is suggested as probably the chief cause why it is more proper for malting than any of the other sorts of grain. It is stated that Einhoff, in his minute trials on barley-meal, found in three thousand eight hundred and forty parts, three hundred and fifty of volatile matter, forty-five parts of albumen, two hundred of facharine matter, one hundred and seventy and four parts of mucilage, nine pounds of phospate of lime, with some albumen, one hundred and thirty-five of gluten, two hundred and fifty of hulk, with some gluten and starch, two thousand five hundred and eighty of starch not quite free from gluten, and seventy-eight parts of losl in the whole. And that rye afforded to the same experimenter, in the same number of parts, two thousand five hundred and twenty of meal, nine hundred and thirty of hulk, and three hundred and ninety of moisiture: the same quantity of meal, on being analyzed, gave two thousand three hundred and forty-five of starch, one hundred and twenty-five of albumen, four hundred and twenty-five of mucilage, one hundred and twenty-five of starch, and two hundred and fifty-five of facharine matter, and three hundred and sixty-five of gluten not dried. The remainder bulk and losl.

The first of these writers obtained from one thousand parts of rye, which was grown in Suffolk, sixty-one parts of starch and five of gluten.

One hundred parts of oats, from Suffex, afforded him fifty-nine parts of starch, fix of gluten, and two of facharine matter.

One thousand parts of peas, grown in Norfolk, also afforded
STA

forsed him five hundred and one parts of starch, twenty-two of saccharine matter, thirty-five of albuminous matter, and sixteen parts of extract, which became insoluble during the evaporation of the saccharine fluid.

From three thousand eight hundred and forty parts of marsh beans, *vicia faba*, the latter writer is flated to have obtained one thousand three hundred and twelve of starch, thirty-one of albumen, and one thousand two hundred and four of other matters which may be conceived to be nutritive; such as gummy, flarchy, fibrous matter, analogous to animal matter.

The same quantity of kidney beans (*phaseolus vulgaris*) is said to have afforded him, one thousand eight hundred and five parts of matter analogous to starch, eight hundred and fifty-one of albumen and matter, approaching to animal matter in its nature, and seven hundred and ninety-nine of mucilage.

From the same number of parts of lentils he is also flated to have obtained one thousand two hundred and sixty-five parts of starch, and one thousand four hundred and thirty-three of a matter analogous to animal matter, which he describes as a glutinous insoluble or semi-insoluble in water; but soluble in alcohol when dry, having the appearance of glue; probably, it is supposed, a peculiar modification of gluten.

Different tuberous, bulbous, and common roots contain a large portion of starch matter, but it probably abounds most in the potato. It is said that these roots in general afford from one-fifth to one-seventh of their weight of dry starch. And that from one hundred parts of the common potato obtained from twenty to twenty-five parts of starch and mucilage; the same number of parts of the apple potato afforded for Humphrey Davy in various trials, from eighteen to twenty parts of pure starch. From five pounds of several other different varieties, in the trials of another experimenter, from twelve to eighteen ounces and a quarter of starch have been ascertained. It is added, that from the analysis of Einhoft, it appears that seven thousand fix hundred and eighty parts of potatoes afford one thousand one hundred and fifty-three of starch, five hundred and forty of fibrous matter analogous to starch, one hundred and seven of albumen, three hundred and twelve of mucilage in the state of a fat solution; in the whole, two thousand and one hundred and twelve parts. So that a fourth part of the weight of the potato at least may, it is said, be considered as nutritive matter. Hence its great utility as an article of food for man, and its great application in the feeding and fattening of animals.

The propriety of encouraging the production of starch from vegetable roots, plants, and products, has been some time since suggested by Mr. Pitt in his account of the Agriculture of Staffordshire, and which is said to equally apply to the preparation of this substance from any other vegetable which may not be a leading article of food, as well as to the production of hair-powder, paste, and other articles generally made from starch.

STAREIN, a town of Austria; 4 miles S. of Hardegg.

STARENBERG, a town of Upper Bavaria, on the Wurmfe; 14 miles N.E. of Weilheim.

STARDARD, or STARGARD, a town of Prussian Pomerelia, situated on the forts; now belonging to Prussia; 20 miles S. of Danzig. N. lat. 53° 57'. E. long. 18° 20'.

STARGARD, or Old Stargard, a town of Germany, which gives name to a circle in the duchy of Mecklenburg; 55 miles S.E. of Gutfro. N. lat. 53° 30'. E. long. 13° 17'.

STARGARD, or New Stargard, a town of Germany, in the circle of Upper Saxony, capital of a duchy, and like-wise of the whole Hinder Pomerania. Its vicinity produces corn and excellent vegetables in great plenty. As it lies on the Ina, it has a free communication with the Baltic. It is a large and well-built town, containing two churches, with one in the suburb, and a conventual church, where Lutherans, Germans, and French Calvinists, perform their public worship. Near the town is a noble college, founded in 1481, by burger Master Peter in the year 1481; and improved with regard to its constitution in 1704. Here are likewise a free-school, with divers good manufacturies and a considerable trade; 74 miles N.E. of Berlin. N. lat. 53° 28'. E. long. 15° 20'.

STARI-BESUSITZ, a town of Croatia; 30 miles W. of Bihacs.

STARIOGARD, a ruined town of Servia; 12 miles S.S.E. of Noribiar.

STARIKILIA, a town of European Turkey, in Dobrudia, on a branch of the Danube; 6 miles E. of Ismail.

STARING, in Rural Economy, a term signifying the fame as hidebound.

STARIKT, in Geography, a river of Silezia, which runs into the Biella, near Fryewald, in the principality of Neisse.

STARIKA, a town of Russia, in the government of Tver, on the Volga; 44 miles S.W. of Tver. N. lat. 56° 24'. E. long. 35° 14'.

STARK, a county of Ohio, containing the seven following townships, viz. Canton, with 845 inhabitants; Killback, with 532; Nimnitzkillen, with 385; Osnaburg, with 55; Planer, with 57; Sandly, with 198; and Tuscarawa, with 154; amounting in all to 2724.

STARKA, in Botany, received that name from the pen of professor Willdenow, in honour of the Rev. Mr. Starka, a clergyman at Grotziboura, in Silezia, who has paid great attention to the cryptogamic plants of that country, and is the author of an essay on *Bifusus Judikus*, in the first volume of Sims and Konig's Annals of Botany. — Willd. Sp. Pl. v. 3. 2216. Alt. Hort. Kew. v. 5. 118. - Clais and order, *Symgnesia Polygonum superflua*. Nat. Ord. Compositae distinctes. Linne. Corymbifera, Julia. Common Composite or Groat. Starka, imbricated, with numerous, linear-lanceolate, straight scales; the inner ones gradually longer; the innermost with elongated, smooth, very narrow points. Cor. compound, radiated. Florets of the disk not very numerous, perfect, tubular, funnel-shaped, with an equal, five-cleft, reflexed limb; those of the radius numerous, ligulate, emarginate, female, spreading, twice as long as the disk. *Stam.* in the perfect florets, Filaments five, capillary; anthers united into a tube, prominent in the mouth of each floret. *Pfl.* in both kinds of florets, German inerferly conical; style capillary, longer than the corolla; stigmas two, linear, deeply separated, revolute. *Peric.* none, except the permanent calyx. *Seeds* solitary to each floret of the disk and radius, inerferly conical. Down simple, sessile, capillary, smooth. *Recept* clothed with fine hairs, nearly equal to the feed-down.

1. S. umbellata. Umbel-flowered Starka. Willd. n. 1. Ait. n. 1. (Amelius umbellatus; Linn. Sp. Pl. 276. Amoen. Acad. v. 5. 407. Swartz Obs. 310. Solidago n. 1.) Browne Jan. 320. t. 35. f. 2.—Native of the cooler woods and mountains of Jamaica, a beautiful and uncommon plant. *Brown* Miller appears to have cultivated it in 1768. Linnaeus, justly unwilling to multiply genera, referred this plant to *Amelius*, at the same time remarking how very
very different it was from the A. Lyschnis. In this case the habit, supported by the character of the hairy, not chaffy or scaly, receptacles, fully authorizes a separation. The stem is herbaceous, erect, from two to three feet high, somewhat angular, clothed with dense white cottony down, intermixed with brown hairs; leafy in the lower part; forked at the summit, the central branch longest. Leaves opposite, flat, ovate, acute, finely and sharply serrated; tapering at the base; green and smooth, though covered when young with deciduous cottony down, on the upper side; always very white, soft, and densely woolly, beneath; somewhat triple-ribbed, with many branching veins. Flower-stalk feathery, at the top of each branch, simple, hairy and downy, an inch or two long, forming a sort of umbel, with a few lanceolate bracteas at its base. Calyx half an inch long, somewhat cottony. The flowers are yellow, an inch in diameter. Browne says the taste of the herb is aromatic, leaving a sweetness upon the palate, not at all in this clafs. He supposed it must be a fine vulnerary. Its cottony texture, no doubt, would contribute to stanch the blood of a fresh wound.

STARKENBACH, in Geography, a town of Bohemia, in the district of Koniggratz; 11 miles N.N.E. of Ciechlin.

STARKENBERG, a town of Prussia, in the province of Nacangen; 17 miles E.S.E. of Konigsberg.—Also, a town of France, in the department of the Sarre; 1 mile N. of Traarbach.

STARKS, a township of America, in the district of Maine and county of Somerset, on the W. side of Kennesaw river, containing 828 inhabitants; 35 miles N.W. of Augusta.

STARKSBOROUGH, a town on the flate of Vermont, in Addison county, containing 756 inhabitants; 12 miles E. of Ferrisburgh.

STARKSTADT, a town of Bohemia, in the circle of Koniggratz; 8 miles W. of Branau.

STARKLACKEN, a town of Prussia, in the province of Bartenland; 9 miles S. of Bartenfien.

STARLING, or STARE, in Ornithology. See Sturnus.

The common starling is about the size of the common black-bird; the weight of the male being about three ounces, and that of the female somewhat less; the bill, in old birds, is yellow; the whole plumage black, very repellent, with changeable blue, purple, and copper; each feather being marked with a pale yellow spot; the inner coverts are edged with yellow, and slightly glossed with green; the quill-feather and tail are dully; the former edged with yellow on the exterior side, the latter with dirty white; the legs are of a reddish-brown. These birds breed in hollow trees, eaves of hovelles, towers, cliffs, and high rocks over the sea; they lay four or five eggs of a pale greenish-ash colour; they feed on worms and insects, and, it is said, will get into pigeon-holes, and pick the eggs; in winter they assemble in large flocks; their flesh is to bitter, as to be scarcely edible; they are very docile, and may be taught to speak. Pennant.

Mr. Ray mentions a beautiful species, described by Bonituz under the name of the Indian starling, or fumus Indicus. This is of the size and shape of our common starling, but is variegated with a deep blue, a lead-colour, and a pale grey, and has on its head a very beautiful yellow crefl. It learns to imitate the human voices, and talks much better than the parrot, but is troublesome in being over noisy.

STARLING Colour, a particular colour of a horse. See Colour.

STARE, in Commerce, a corn measure in Italy. At Mantua, a staro of corn weighs 80 lbs. and 86 such measures are = 85 English bushels nearly, or 80.94 staro = 10 English quarters, and each staro = 2135 cubic inches. At Ferrara, 93.23 staro = 10 English quarters, and each staro = 1845 cubic inches. At Florence, 118.70 staro = 10 English quarters, and each staro = 1449 cubic inches. See Italian Dry Measures.

STARODUB, in Geography, a town of Russia, in the government of Novgorod Sieverkoe; 44 miles N. of Novgorod Sieverkoe. N. lat. 57° 35'. E. long. 33° 44'.

STAROSEOLO, a town of Russia, in the government of Mogilev; 20 miles N.N.W. of Rogatchev.

STAROSTE, in Modern History, a name given in Poland to the governors of cities and castles. They are appointed by the king to superintend his revenues, and to administer justice in his name. The district subject to the jurisdiction of each is called starosta. However, there are some starosts who have no jurisdiction.

STARSCH, in Geography, a town of Moravia, in the circle of Znyam; 15 miles N. of Budweis.

START BAY, a bay of the English Channel, on the coast of Devonshire, between Dartmouth and Start Point.

START POINT, a cape of England, on the S.W. coast of the county of Devon; 9 miles S. of Dartmouth. N. lat. 59° 13'. W. long. 1° 28'.

STARTING, among Brewers, the putting of new beer, or ale, to that which is decayed, to revive it again.

STARTING, in the Management. A horse is said to be flaring, skittish, or timorous, that takes every object he sees to be otherwise than it is; upon which he flies, flaps out, and flutters suddenly to one side, infomuch, that the rider cannot make him come near the place where the object is. This fault is more common to geldings than mares, horses. Such horses also as have bad eyes are most subject to it, as well as those who have been kept a long time in a stable without airing; but these last are easily cured of it. When you have a skittish horse, never beat him in his confinement, but make him advance gently, and with soft means, to the scare-crow that alarms him, till he recovers it, and gains assurance.

STARTZ, in Geography, a town of Moravia, in the circle of Znyam; 25 miles N. of Znyam.

STARTZOV, a bay or gulf of the Frozen ocean, on the coast of Russia. N. lat. 68° 16'. E. long. 40° 14'.

STARVEGUT BAY, a bay on the S.W. coast of Jamaica. N. lat. 17° 58'. W. long. 77° 45'.

STARTING to Death, a kind of punishment used by the people of Aragon some ages ago; and it is reported by Tavernier, that the chief ladies in the kingdom of Tonquin are at this day starved to death for adultery.

STARWITZ, in Geography, a town of Silesia, in the principality of Grottau; 3 miles N. of Pachtchau.

STARZEL, a river of Wurtemberg, which runs into the Neckar, 5 miles above Rotenburg.

STASAVITZ, a town of European Turkey, in Bofnia; 22 miles S. of Banjaluka.

STASFURT, a town of Wethphalia, in the duchy of Magdeburg; 20 miles S. of Magdeburg. N. lat. 51° 53'. E. long. 11° 45'.

STASIDA, a small island in the Mediterranean; 8 miles N.W. of Scarpanto. N. lat. 35° 53'. E. long. 26° 44'.

STASIS, in Ancient Geography, a town of Aetia, in the Pelopon; built upon a large rock.

STASIS, a word used by physicians to express a flagration of the humours. See STATE, in Geography, a town of Sweden, in Warmeland; 23 miles W. of Carlsbad.
STATE.

STATE, or ESTATE, an empire, kingdom, province, or extent of country under the same government. See ESTATE.

A state or nation, for in this place we consider the terms as synonymous, is a body politic, or a society of men united to promote their mutual safety and advantage by their union. From the very design that induces a number of men to form a society that has its common interests, and ought to act in concert, it is necessary that there shall be established a public authority, to order and direct what ought to be done by each in relation to the end of the association. This political authority is the sovereignty; and laws they, when there are laws, are from it.

It is evident, therefore, from the very act of the civil or political association, that each citizen subjects himself to the authority of the entire body, in every thing that relates to the common welfare. The authority of all over each member must, therefore, essentially belong to the body politic, or to the state; but the exercise of that authority may be placed in different hands, according as the society shall ordain. If the body of the nation keeps its own hands the empire, or the right of command, it is a popular government; or "democracy" if it refers it to a number of citizens, or to a senate, it establishes a "republic," an "oligarchy," or an "aristocracy;" or if it considers the government a single person, it is a "monarchy;" and this monarch may be limited or absolute. See SOCIETY, GOVERNMENT, and SOVEREIGNTY.

Every nation that governs itself, whatever may be the form of that government, without any dependence on a foreign power, is a "sovereign state." Its rights are the same as those of any other state: and if it be sovereign and independent, it must govern itself by its own authorities and laws. Indeed, there are many sovereign states. Those states may be reckoned in this class, which have nevertheless bound themselves to another more powerful by an equal alliance: and these unequal alliances may be infinitely varied. But whatever they are, provided the inferior ally refers to itself the sovereignty, or the right of governing its own body, it ought to be considered as an independent state, that keeps up correspontence with others, under the authority of the law of nations. Thus, a weak state seeks protection from one that is more powerful, and from gratitude secures the benefit of the law of nations. The laws are also of election, referring to itself the right of government and sovereignty. Thus also, though a weak state may pay tribute to a foreign power, and by so doing in some degree diminish its dignity, yet still its sovereignty may subsist entire. In some cases, sovereignties have been given in seft, and sovereigns have voluntarily rendered themselves feudatories to others; yet if the homage leaves independency and sovereignty in the administration of the state, and only means certain duties to the lord of the seft, or even a mere honorary acknowledgment, it does not prevent the seft, or the feudal prince, from being truly sovereign. Two sovereign states may also be subject to the same prince, without any dependence on each other, and each may retain all its national rights, free and independent. In short, several sovereign and independent states may unite themselves together by a perpetual confederacy, without each in particular ceasing to be a perfect state. They will form together a federal republic; the deliberations in common will offer no violence to the sovereignty of each member, though they may, in certain respects, put some constraint on the exercise of its power, in virtue of voluntary engagements. But a people that has passed under the dominion of another, can no longer form a state, and in a direct manner make use of the law of nations. Such were the people and kingdoms which the Romans rendered subject to their empire; most, even of those whom they honoured with the name of friends and allies, no longer formed states. Within themselves they were governed by their own laws and magistrates; but without, they were obliged in every thing to follow the orders of Rome; they dared not of themselves make either war or an alliance, and could not treat with nations. The preservation of a nation conflicts in the direction of the political associations of which it is formed; and the perfection of a nation is found in what renders it capable of obtaining the end of civil society. In a perfect state, when nothing necessary is wanting to arrive at that end. The end of civil society is procuring for the citizens whatever their necessities require, the conveniences and accommodations of life, and, in general, whatever constitutes happiness; with the peaceful possession of property, a method of obtaining justice with security, and, in short, a mutual defence against all violence from without. In order to form a just idea of the perfection of a state or nation, every thing must confine to promote these ends. The fundamental regulation that determines the manner in which the public authority is to be executed for the attainment of these ends, is what forms the "constitution of the state." The constitution is, in fact, nothing more than the establishment of the order in which a nation proposes to labour in common for obtaining those advantages with a view to which the political society was established. The laws are regulations established by public authority to be obeyed in society. All these ought to relate to the welfare of the state and of the citizens. The laws made directly with a view to the public welfare are the "fundamental laws," and in this class are the laws that regulate the body itself, and the being of society, the form of government, the manner in which the public authority is to be executed; and those, in a word, which together form the constitution of the state, are the "fundamental laws." The "civil laws" are those that regulate the conduct and behaviour of the citizens among themselves. The constitution and its laws are the basis of the public tranquillity, the firmest support of the public authority, and pledge of the liberty of the citizens. But this constitution is a vain phantom, and the civil laws are useless, if they are not religiously observed. The nation ought then to watch very attentively, in order to render them equally respected by those who govern, and by the people destined to obey. To attack the constitution of the state, and to violate its laws, is a capital crime against society; and if those guilty of it are invested with authority, they add to this crime a perfidious abuse of the power with which they are entrusted. From the principles here stated, we may infer, that a nation has a right to form, maintain, and perfect its constitution, and to regulate at pleasure every thing relating to the government, while no person has a right to hinder it. Government is established only for the sake of the nation, with a view to its safety and happiness. If any nation is dissatisfied with the public administration, it may reduce it to order, and reform the government. The nation may do this, but not any discontented and querulous malcontents. The body of a nation has a right to call to account those who abuse their power; but if the nation be silent, it is not the business of a small number of citizens to put the state in danger under the pretence of reforming it. If the nation be uneasy under its constitution, it has a right to change it.

If it be asked, what ought to be done if the people are divided?
STA

STA

divided? According to the common method of states, the opinion of the majority must pass, without dispute, for that of the whole nation; otherwise it would be impossible for the society ever to take any resolution. It appears then, for the same reason, that a nation may change the constitution of the state by a majority of votes, and whenever there is nothing in this change that can be considered as contrary to the act of the civil association, or to the intention of those united under it, all are bound to conform to the will of the majority, or to be quit of the form of government, to which alone it appeared that the people were willing to submit, on their entering into the bonds of society; if the greatest part of a free people, after the example of the Jews in the time of Samuel, are weary of liberty, and resolved to submit to the authority of an absolute prince, the citizens more jealous of that privilege, so invaluable to those who have enjoyed it, though obliged to suffer the majority to do as they please, are under no obligation at all to submit to the new government; they may leave a society, that seems to have dissolved itself, in order to be united under another form; and have a right to retire elsewhere, to fell their lands, and take with them all their effects.

After all it may be observed, that great changes in a state being delicate and very dangerous affairs, and that frequent changes being in their own nature prejudicial, a people ought to be very circumspect in doing it, and never be inclined to make innovations without the most prefling reasons, or an absolute necessity. The spirit of inconstancy which prevailed among the Athenians, was always contrary to the happiness of that republic, and was a length fatal to that liberty of which they were so jealous, without knowing how to enjoy it. Vattel's Law of Nations, b. i.

STATE, Civil. See CIVIL.

STATE, Free. See FREE.

STATE is also used for the policy or form of government of a nation. Hence, ministers of state, reasons of state, &c. See GOVERNMENT.

STATE, Council of, in Modern History, was projected by the states of Holland, Zealand, and Utrecht, in conjunction with William I. prince of Orange, and erected, in 1578, with ample authority. All affairs of state, the army, and revenue, were entrusted to the care of this council; but the states, growing jealous of this extraordinary power, reduced it gradually; and by a new instruction, in 1651, the disposition of military affairs, and the command of the army, were in part transferred to the states-general, with the advice of the council. In this council, the provinces were represented by such a number of deputies as bore some proportion to the quota of money which each contributed for the support of the whole. Groningen excepted. Guelderland had one. Holland three, Zealand two, Utrecht one, Friesland two, Overfjeld one, and Groningen two. These were all changed every three years, except the deputy from the nobility of Holland, and the two from Zealand, who enjoyed their posts for life. Here every member had a decisive voice, and presided for a week in his turn, without regard to the rank of the provinces. The governors or stadtholders of the provinces had a seat, but no decisive vote in this council, in which affairs were determined by a majority of voices. See Stadtholder.

STATE of a Diphed, the same with acme.

STATE WIND. See WIND.

STATELY, in the Manage. A horse is said to be stately, that goes with a proud, strutting gait.

STATEMENT, in Geography, an island belonging to the United States of America, and forming the county of Richmond, in the state of New York. It is situated below the bay of New York, and is the southern extremity of the state. It is of ancient date, having been represented by two members in the colonial legislature in 1691. The centre of Staten Island is about 11 miles S.W. of New York; it is about 14 miles long, and its greatest breadth is about 8 miles; the area is about 77 square miles, or 49,280 acres. It is bounded on the N. and W. by Newark bay and Brunswick river, E. and S. by Hudson river and the Atlantic ocean. Its southern extremity is in N. lat. 40° 39', and the western extremity 16° W. long. from New York.

The towns are, Castletown, containing 1301 inhabitants; Northfield, including 1595; Southfield 1007, and Weisfield 1444 inhabitants; the whole population being 5347, and the number of electors 500. The county of Richmond is hilly and broken, including some extensive tracts of good arable land. Its insular situation, and the benefit it affords to mariners, have given it celebrity, and several privileges to its inhabitants. The surrounding waters abound with a variety of fish. The quarantine ground for ships entering the port of New York lies in this county. It lends one member to the house of assembly.

STATELAND, an island at the extremity of South America, separated from Terra del Fuego by the strait of Le Maire. In the appearance of Staten Land, when Cook visited it in January 1769, he did not discover the wildness and horror ascribed to it in the account of lord Anson's voyage. On the N. side, Hawkeworth 1751, in his detail of this voyage (vol. ii. p. 64.), are the appearances of bays or harbours; and the land was destitute neither of wood nor verdure, nor was it covered with snow. The island seemed to be about 12 leagues in length, and 5 broad. On occasion of another voyage he visited it in January 1775, and gives the following account of it. (Second Voyage, vol. ii. p. 200.) Staten Land lies nearly E. by N. and W. by S., and is ten leagues long in that direction; and no where above three or four leagues broad. The coast is rocky, much indented, and seemed to form several bays or inlets. It shews a surface of craggy hills which rise to a vast height, especially near the west end. Except the craggy summits of the hills, the greater part was covered with trees and shrubs, or some sort of herbage, and there was little or no snow on it. The currents between Cape Desada and Cape Horn set from W. to E., that is, in the same direction as the coast; but they are by no means considerable. To the E. of the cape their strength is much increased, and their direction is N.E. towards Staten Land. They are rapid in Strait Le Maire, and along the S. coast of Staten Land, and let like a torrent round Cape St. John, where they take a N.W. direction, and continue to run very strong both within and without New Year's files. S. lat. 54° 49'. W. long. 65°.

STATE, an ancient silver coin, weighing four Attic drachms, and worth about three shillings or three shillings and a penny farthing. See DRACHM.

There was also a gold coin under this name: that of Cyzicus was much valued, having on one side the figure of a woman's head, and on the other that of the head of a lion; in weight it was equal to two drachms, and in value to twenty-eight silver drachms of Athens. The gold staters of Athens was equal in value to twenty drachms, and a drachm of gold was equal to about ten of silver.

The ancient gold piece, gold stater, or "Philippus," as it was called in compliment to Philip of Macedo, was a drachm; and there is reason to believe, that it passed for twenty silver drachms on its first appearance; but in later times for twenty-five Greek drachms, or Roman denarii. That the gold coins of Philip, called "Philippi," were di-

STATELAND,
drachmas, we know from ancient authors, and from the great number of them that still remain; and that the χρυσός, or chief gold coin of Greece, was of the same weight, is also evident from ancient authors. Being of twenty silver drachmas, it was anciently worth 1 s. 6d.; but valuing gold now at a medial price of 41. per ounce, it is intrinsically worth 1 l. at present. But we have larger gold coins than the χρυσός or didrachm. The ηχρυσός of Alexander, and of Lycurgus, weighs its double, or about two hundred and sixty-five grains, and palled for forty silver drachmas, or 17. 1s. 6d.; now worth 2l. Of Lycurgus, Antiochus III., and of some of the Egyptian monarchs, we have even the τριχρυσός, or quadruple χρυσός, weighing about five hundred and thirty grains, and current for eighty drachmas of silver, 1 gu., now worth 8l. sterling. We have also minuter coins, such as the τετραχρυσός, or half the χρυσός, of Hiero I. of Syracuse, and of Pyrrhus, which weighed three drachmas, and palled for ten silver drachmas, or 7s. 6d.; now worth 10s.;—also, the τετραχρυσός, or quarter of the Philipus, of Philip, Alexander, and Lycurgus, weighing forty-five grains, and palled for five drachmas of silver, 1 gu., now worth intrinsically 5s.; and also gold coins of Greece still smaller, and which could not have palled for more than two drachmas of silver.

STATERA ROMANA, or sterleyard, a name given to the Roman balance.

STATES, a term applied to the several orders, or classes, of a people, aslemmed to consult of matters of the public good. See Estate.

STATES-GENERAL, the name of an assembly, consisting, under the former government, of the deputies of the Seven United Provinces.

In this assembly, the deputies of each province, of what number soever they were, had only one voice, and were esteemed as but one person, the votes being given by provinces. Each province prefixed at the assembly in its turn, according to the order settled among them; Guelderland prefixed first, then Holland, &c.

This assembly was the representative of the sovereignty of the Union, which reigned properly in the general assembly of the states themselves of all the several provinces; but a sort of ordinary assembly of seven or eight hundred persons, it was resolved, after the departure of the Earl of Leicester, in order to avoid expense, and the confusion of so numerous a body, that the provincial estates should, for the future, be ordinarily represented by their deputies, under the name of the States-General; who were always to reside at the Hague, and who alone were called states-general.

STATES-GENERAL of France, assemblies which were first called A.D. 1492, and were held occasionally from that period to the year 1614, when they were discontinued, till they were summoned again at an interesting period, viz. in the year 1789. (See France.) These states-general, however, were very different from the ancient assemblies of the French nation under the kings of the first and second race. There is no point with respect to which the French antiquaries are more generally agreed, than in maintaining that the states-general had no suffrage in the palling of laws, and possessed no proper jurisdiction. The whole tenor of the French history confirms this opinion. The form of proceeding in the states-general was this; the king addressed himself to the whole body assembled in one place, and laid before them affairs on account of which he had summoned them. The deputies of each of the three orders, of nobles, of clergy, and of the third estate, met apart, and prepared their "cahier," or memorial, containing their answer to the propositions which had been made to them, together with the representations which they thought proper to lay before the king. These answers and representations were considered by the king in his council, and generally gave rise to an ordinance. These ordinances were not addressed to the three estates in common. Sometimes the king addressed an ordinance to each of the estates in particular. Sometimes he mentioned the assembly of the three estates. Sometimes mention is made of a general assembly of the estates which suggested the propriety of enacting the law. Thus the states-general had only the privilege of advising and recommending; the legislative authority resided in the king alone.

STATES of Holland, an assembly consisting of the deputies of the council, or colleges of each city; in which resided the sovereignty of that province.

Originally, none but the nobility, and the five principal cities, had seats, or voices, in the states. Afterwards they were the deputies of eighteen cities. The nobility had the fifth voices, which were pronounced by the grand peniency, as peniency of their order. The other provinces of the Union had likewise their states, representing their sovereignty, deputies from which made what they called the States-general.

STATESBURG, in Geography, a post-town of South Carolina, and the capital of Clermont county, on the E. tide of Beech creek, which unite with Sharks creek, and discharge itself into the Waceree, a few miles below the town. It contains 10 or 12 houses, a court-house and gaol; 7 miles S. by E. from Camden.

STATES-LAND, a township of Hancock county, in the district of Maine, containing 87 inhabitants.

STATESVILLE, a post-town of Iredell county, in North Carolina; 441 miles from Washington.

STATHEL, in Agriculture, a term sometimes employed to signify any sort of fladle for either corn, hay, straw, or any other kind of farm produce. See STADDLE and STAND.

STATHENI, in Ancient Geography, a people of India, in the number of those who were subjugated by Alexander.

STATHEUSIS, formed of σταθες, I stand, a word used by the old writers to express the torrefaction, or roasting of some medicines before a slow fire, as is done frequently at present with rhubarb, &c.

STATHEUSIS. See STATHOLDER.

STATICAL BAROSCOPE. See BAROSCOPE and BAROMETER.

Statistical is sometimes applied in a peculiar sense to the experiments made as to the quantity of perpiration, and other excretions of the human body.

We have a very particular account of some experiments of this kind in the Philosophical Transactions, No. 427, or Abr. vol. ix. p. 475, made by Dr. John Lining of Charles Town, in South Carolina.

STATICAL Hygroscope. See HYGROSCOPE.

STATICE, in Botany, a name adopted from the Greeks, whole στατίξα is reported to have been so called from ταστικα, to hop, or ares, because of its astringent quality. What the ancient plant may have been, can scarcely be guessed with any probability. The modern application of the name to our Thrift, or Sea-Gilliflower, seems to have originated with Dalechamp, whom Tournefort followed. Hence it has become appropriated to a fine and extensive genus, whose wiry and entangled stems, so well formed to impede the progress of a foot passenger, may literally almost justify its present use.—Linn. Gen. 153. Schreb. 205. Willd. Sp. Pl. v. 1. 1523. Mart. Mill. Dict. v. 4. Sm. Fl. C Brit.
STATICE.

Gen. Ch. Cal. Involutcus different in the different species. Perianth inferior, of one leaf, funnel-shaped; its tube constricted; limb undivided, plaited, membranous, dry, and permanent. Cor. funnel-shaped, of five petals, tapering downwards, combined at the base, dilated upwards, obtuse, spreading. Stam. Filaments five, awl-shaped, shorter than the petals, and inserted into their claws; anthers incumbent. Pist. Germen very minute; stigmas five, thread-shaped, spreading; stigma acute. Peric. Capsule oblong, somewhat cylindrical, membranaceous, with five points, of one cell, splitting at the base only into five valves, clothed with the permanent calyx, and crowned with its flimsy border. Seed solitary, elliptic-oblong. Eff. Ch. Calyx of one leaf, undivided, with a plaited flimsy border. Petals five. Capsule superior, of one cell, of five valves at the base. Seed solitary.

Ob. Limonium of Tournefort, the numerous recently distinguished or discovered species of which now compose the bulk of the genus before us, was characterized by its disfigured, not capitate, flowers.

The species of Statice in the Species Plantarum of Linnaeus are 14; in the last edition of Syll. Veg. 22. Willdenow has 57, to which five are added in the Prodr. Fl. Grec.; and one in Pursh. Three are natives of Britain. They are nearly all perennial, herbaceous, rarely shrubby; natives chiefly of Europe or Africa, two only being found in North America. Their habit is rigid. Leaves simple, mostly radical, generally entire and undivided. Flowers copious, retaining most of their colour and beauty when dried. We shall particularize all the British, as well as the new species, interfering some of the most beautiful or remarkable ones besides.

S. Armeria. Common Thrift, or Sea-Gilliflower. Linn. Sp. Fl. 304. Wild. n. 1. Fl. Brit. n. 2. Engl. Bot. t. 224. (Corps. plurimus; Loh. ic. 452; Ger. Em. 602.)—Stalks simple, capitate. Leaves linear. Awns of the calyx minute.—Native of muddy sea-fluxes, marine rocks, or moist boggy situations on the loftiest mountains, throughout Europe, as well as of the sea-coast of North America, flowering in July and August. Light-foot well denominates it, for this reason, "the most humble and moist lofty of plants." It also bears the smoke of London better than most plants, and from its thriving in almost any situation, has obtained the name of Thrift. It often serves for edgings in country, as well as town gardens. The woody root bears thick tufts of lax, linear, channelled, smooth, deep-green leaves. The stalks are about a span high, simple, round, each invested, at their first protrusion, by a tubular membrane, soon torn from its base, and carried up along with the terminal round head, of numerous, pink, inodorous flowers, whose base is surrounded with an involucrum of many leaves, in three rows. The permanent calyx is of a pale shining brown, or nearly white, its points tipped with five minute, scarcely rough, awns. We are not satisfied that the larger plant, made the leading variety in Willdenow and Aiton, and figured likewise in Lobel's Icones 452, may not be a different species; perhaps the following.

S. Albancz. Garlick-like Thrift. Cavan. Ic. v. 2. 6. t. 109. Wild. n. 3. Sm. Fl. Grec. Sibth. t. 394, unpublished.—Stalk simple, capitate. Leaves linear-lanceolate, somewhat three-ribbed. Awns of the calyx rigid, rough.—Found by Cavanilles on various mountains of Spain, and by Sibthorp on Mount Athos and Hyemetus. The herbage is larger than the leaf; the leaves more or less lanceolate. Heads of flowers hardly so large, entirely white in the Greek, as well as Spanish, specimens; the calyx having in those of Dr. Sibthorp a hairy tube, not described by Cavanilles: its awns are elongated and rough.

S. Limonium. Common Sea-Lavender Thrift. Linn. Sp. Fl. 394. Wild. n. 6. Fl. Brit. n. 2. Engl. Bot. t. 192. Fl. Dan. t. 93. (Limonium, et L. Pentanum; Ger. Em. 411.)—Stalk panicled, round. Leaves obovate-lanceolate, smooth, without ribs, tipped with a decurrent awn.—Common about muddy sea-fluxes throughout Europe, from Sweden to Greece, flowering in July and August. (See Limonium.) This species varies greatly in size and luxuriance, or perhaps some of its reputed varieties ought to be considered as distinct. Usually its leaves are three or four inches long and one broad, tapering downwards, leathery, somewhat waved, very smooth, rather glaucous. Stalk near a span high, hard and rigid, panicled, bracteate, its branches ending in close imbricated spikes of hand-to-meet blue flowers, whose calyx is pale pink in a recent flate, white when dry, deciduous of awns; its tube closely enveloped in a fount, feathering, membranous-edged involucrum, of a fiddle leaf.

S. caroliniana. Carolina Sea-Lavender Thrift. Walt. Carol. 118. Pursh n. 2. "Stalk round. Panicule much branched, divaricated. Calyx acute. Leaves lanceolate-oblong, bluish, smooth, flat-edged."—In salt-marshes along the sea-coast, from New Jersey to Carolina, flowering in August and September. Flowers blue. Pursh. We are not certain of having seen this species, which Linnaeus appears to have confounded with the last. Mr. Walter observed the separation of the capsule into five valves at the base; a character of Jullien's Plumbaginies. See that article.

S. bellidiformis. Daily-leaved Thrift. Sm. Prodr. Fl. Grec. Sibth. n. 733. Fl. Grec. t. 295, unpublished.—Stalk panicled, round. Leaves obovate-lanulate, abrupt, smooth. Calyx bluish, without awns.—Gathered by Dr. Sibthorp, on the shores of Rhodes, and several islands in the Archipelago. The root is woody, crowned with large tufts of spreading, green, abrupt or emarginate leaves, an inch or inch and half long, convex at the edges, very smooth. Stalk a foot high, panicled copiously nearly from top to bottom, rather zigzag. Flowers purple, loosely spurred. Calyx with a hairy tube, and white limb, with five brown ribs. Petals emarginate.

S. globularifolus. Globularia-leaved Thrift. Desfont. Atlant. v. 1. 274, by the description. Sm. Prodr. Fl. Grec. Sibth. n. 734. Fl. Grec. t. 296, unpublished. (Limonium medium, globularia folio; Barrel. Ic. t. 793, 794.)—Stalk panicled, round; with level-topped branches. Leaves obovato-lanulate, pointed, smooth. Calyx acute. —Native of Barbary and Sicily, by the sea-faede. The leaves are more glaucous than in the last, somewhat bordered, acute, and tipped with a sharp point. Branches of the panicle shorter, more dense and level-topped. Flowers rather smaller, and of a lighter purple. Calyx hairy, and similarly coloured, but the segments of its limb much narrower, more taper and acute. The common flower-stalk does not begin to branch so near the base, nor is it so fount.

STATICE.

turned upwards. Calyx bluntish. Leaves spathulate, obtuse, pointless, smooth, glaucous.—Native of the coast of Barbary. Flowered in August 1811, in the garden of Mr. W. Pringle at Sydenham. Mr. Aiton marks it as introduced in 1804. This differs from the leaf in having blunt leaves, without points, in which respect it also differs from S. limonium, and a reputed variety thereof, found on the coast of Brittany, which leaf is perhaps Barrarer’s t. 790, and very nearly accords with our present plant, in its crowded spikes of flowers twice the size of the leaf, and a much less branched stalk. We have not been able to ascertain how far this and Vahl’s auriculatula, Wild. n. 12, are distinct. Specimens from Narbonne, supposed to be the latter, agree in every thing with the figure of spathulata, except in having a point to the leaf.

S. laticolla. Broad-leaved Thrift. Sm. Tr. of Linn. Soc. v. 1. t. 350. Wild. n. 9. Ait. n. 7. (Limonium folio Eunala, fabellis tenusfima ramosissima, floribus parvis caruleis ; Gerber’s M.S.) —Stalk panicled, very much branched, rough. Leaves downy, with minutely flarly hairs. Calyx somewhat pointed, without awns. —Native of Russian Tartary, on the banks of the Don, near Aphi. It flowered in Sinn gardens, under the care of Mr. Hoy, in 1788, as mentioned in the Linnean Tranfections, so that the date of 1791 in Hort. Kew. is an error, though the name of Mr. Bell, as the introducer of the plant, is probably right. This species is distinguished by the great size of its oblong leaves, a foot or more in length, borderless with flarly tufts of soft hairs, and the vast profusion of its small blue flowers, which compose a spreading, rather level-topped, panicled, often two feet wide. It is a hardy perennial, flowering from May to July. Willdenow gives as a synonym S. corysia, Pallais Ind. Fl. Taur. and remarks that the lower branches are barren, as in S. reticulata and others. This is not very evident in our specimens, though it may possibly be so.

S. oleifolia. Olive-leaved Thrift. Sm. Prodr. Fl. Gracc. n. 735, excluding probably the synonym of Willdenow. (Parvum Limonium parvum oleofolium; Lob. t. 295. Limonium parvum; Ger. Em. 411.) —Stalk panicled, round; its lower branches barren. Leaves oblong-spatulate, obtuse, smooth, with scarcely any point. —Native of the sea-coasts of the south of France, Italy, and Greece. The roots are woody and tufted. Leaves an inch or inch and half long, not above a quarter of an inch broad in any part; tapering at the base; minutely dotted on both sides; a little hooked, or reflexed, but not awned; at the extremity. Stems a foot high, or more or less, roughish; their branches copious, zigzag and somewhat divaricated, about half of them naked and barren; the upper ones bearing level-topped, rather lax, spikes of slender flowers, all turned one way. Tube of the calyx slender, hairy; the segments of its limb ovate, acute, awnless.

S. dichotoma. Many-forked Thrift. Cavan. l. c. v. 1. t. 37. t. 50. Sm. Prodr. Fl. Gracc. n. 736. (Limonium minus oleifolium, var. pisi ; Barrrel. l. c. t. 790.) —Stalk erect, panicled; its branches rough with points; the lower ones barren, in many capillary segments. Leaves obovate, smooth. —Native of Spain, about two miles from Madrid, according to Cavanilles. Dr. Sibthorp found it in Greece. The leaves are four times as large as the leaf, and perfectly obtuse. Stems eighteen inches high; its lower branches repeated and minutely forked, almonlike with S. reticulata, but not prostrate. Inflorescence like the leaf. Calyx with a hairy tube. Flowers pale blue. Willdenow quotes Barreller’s t. 790 for his L. oleofolia; a species whose branchlets are described as angular and winged, and which, therefore, does not answer to Scopoli’s oleofolium. Del. Infub. v. 1. t. 10, nor are we able to determine what Willdenow intended. S. reticulata. Matted Thrift or Sea-Lavender. Linn. Sp. Pl. 594. Wild. n. 16. Fl. Brit. n. 3. Engl. Bot. t. 538. Hill Fl. Brit. t. 35. f. 2. —Stalk prostrate, panicled, zigzag; its branches rough with points; the lower ones barren. Leaves wedge-shaped, rather acute, without points. —Native of falt-marshes on the north coast of Norfolk, flowering copiously in July and August. It is also found in the south of Europe. This is smaller than the last, and differs in having the stems quite prostrate, their branchlets much flouter, matted and entangled together. Flowers light purple, few in each spike. Calyx hairy below. Willdenow makes the preceding a variety of this, nor can we be positive of the contrary.

S. palmari. Humble Frosted Thrift. Sm. Prodr. Fl. Gracc. n. 737. Fl. Gracc. t. 207, unpublished. —Rough with hoary dots. Stalk panicled, round, erect, and rather close. Leaves spathulate, obtuse. —Gathered by Dr. Sibthorp on the seacoast of Afla Minor. The roots is woody, crowned with many tufts of numerous spreading leaves about an inch long, frosted as it were, and rough with tubercles, like the whole herbage. Stems many, three or four inches high, composed of four or five alternate, erect, simple, lax spikes of handsome pink flowers, without any branch or forked branches. The calyx is smooth, brown, with short ovate segments.

S. echinoides. Bugle-leaved Thrift. Linn. Sp. Pl. 394, excluding Magnol’s synonym. Wild. n. 17. Ait. n. 13? Fl. Gracc. t. 298, unpublished. —Rough with hoary dots. Stalk panicled, round, jointed, very much branched, zigzag, divaricated. Leaves spathulate. —Native of the shores of Cyprus and Crete. The roots is very strong and woody, crowned with many rote-like tufts of frosted leaves, much like the last. The flowers, however, are very different, a foot or more in height, bulky, repeatedly branched, stout, and strongly divaricated, almost at right angles. Spikes very zigzag and lax. Flowers light purple. Calyx with a hairy tube, and white obtuse limb, whose segments are very shallow. Linnneas confounded this with the following, which he appears to have known from Magnol’s work only.

S. ariflata. Awned Annual Thrift. Sm. Prodr. Fl. Gracc. n. 739. Fl. Gracc. t. 299, unpublished. (Limonium minus annuum, bullatis foliis, vel echinoides ; Magn. Montp. 107. t. 156. Tourn. Infl. 346.) —Stalk panicled, round, dotted; its branches loosely spiked. Leaves oblong, round, rough. Calyx of the fruit awned. —Native of the sea-shores of the south of France, and island of Cyprus. The root is simple, small, and annual. Leaves several, radical, an inch or two long, green, rough with tubercles. Stalks several, from six to twelve inches high, erect, branching from near the bottom into numerous long, slender, spreading, lax spikes of small pink flowers. Calyx with a smooth tube; its membranous limb so delicate, that it soon leaves the strong brown rib, in the form of naked awns.

S. speciosa. Plantain-leaved Thrift. Linn. Sp. Pl. 395. Wild. n. 13. Ait. n. 14. Curt. Mag. t. 656. (S. n. 15; Gmel. Sib. v. 2. 221. t. 91. f. 1.) —Stalk panicled; its branches angular and somewhat winged. Flowers crowded. Bracts dilated, pointed, longer than the blunt crenate calyx. Leaves obovate or lanceolate, pointed. —Frequent throughout Siberia, in open, dry, hilly places. Gmelin. Sometimes seen in our gardens, but seldom long preferred. The root is marked, as before, with a smooth tuberoth to the touch, usually about two inches long and one broad. Stalk from six to eighteen inches high, erect;
STATICE.

Simpie, naked, and almost round, in the lower part; but terminating in a large, angular-branched, dense panicle, of handsome pink flowers. General and partial bractee ovate with a sharp point, the latter most dilated and membranous at the edges. Tube of the calyx hairy, concealed, like the flat-tish involucrum, by the bractees; its limb white, membranous, obtuse, crenate, not lobed, nor awned.

S. rofafa. Curr. Mag. t. 59. appears to us, without any doubt, a variety of this with narrow leaves; there being in reality no material difference in the bractees.

S. arboresc. Tree Thrift. — Stem arborescent, leafy. Leaves obovate, stalked. Flower-flasks panicked; their branches angular and winged. Flowers crowded. Bractees ovate, sheathing, much shorter than the involucrum.—Gathered on the maritime rocks at Buracao and Rambla in the isle of Teneriffe, by Mr. Maffon, whole specimen, given to the younger Linnaeus, is marked "Statice arboresc. of Selandier!" but we find nothing published under this name.

The Spaniards call the plant Siganisporia del mar. The stem is said to be arborecente, fix feet high. The branches are round, woody, one-third of an inch in diameter, scarred with the crowded bases of old footflasks, resembling thin annular filipulas. Leaves fix or eight at the end of each branch, spreading every way, two or three inches long, and about half as broad, obtuse, smooth; wavy at the edges; tapering at the base into a rigid angular footflask, dilated and clasping the stem at the bottom. Flower-flasks terminal, solitary, root or more in length, compressed and winged, bearing a very large compound corymbous panicle, of innumerable crowded flowers, whose partial flasks are dilated into a wedge-shaped, leafy, two-lobed form. Bractees short, ovate, membranous, the partial ones in pairs, sheathing the base of the involucrum, which is twice their length, involute, coriaceous and ribbed, resembling that of S. Limonium and its allies. Tube of the calyx smooth, concealed in the involucrum; limb of a delicate light permanent blue, in the dried specimen, spreading, with five red ribs, and as many shallow lobes. We can discover nothing of the colour of the corolla.

This noble plant would be a great acquisition to our greenhouse.

S. Echinus. Prickly Mountain Thrift. Linn. Sp. Pl. 395. Willd. n. 20. Fl. Grac. t. 300, unpublished. (Echinus, id ef Tragacantha altera; Alpin. Exot. 57. t. 56. Limonium cetipetorum, foliis aculeatis; Buxh. Cent. 2. 18. t. 10.)—Branches clothed with awl-shaped, spiny leaves. Flowers somewhat spiked.—Found by Buxbaum in the deserts of Media, flowering in July. Dr. Sibthorp gathered it on the Sphacitei mountains of Crete, as well as on the Bithynian Olympus. The long and woody black root is crowned with dense tufted leafy flms and branches, two or three inches high. Leaves about an inch long, spreading every way, rigid, linear, channelled, smooth, entire, with a spinous point. Flowers of a bright pink, very beautiful, three or four together, in terminal, solitary, nearly fifele, spikes. Invoucurnm of two spreading pointed leaves. Calyx white, with five brown ribs, a smooth tube, and a pentagonal, scarcely lobed, border. Such indeed is the alpine plant, found by Alpinus and Sibthorp. The flower-flask in the figure of Buxbaum is elongated, naked, and somewhat branched, a span long; but the Linnean specimen, intermediate between the two, prove this to be a mere variety, owing to situation. It is pity this elegant species is unknown in gardens.

S. purpurata. Purple Cape Thrift. Linn. Mant. 59. Willd. n. 22. Thurb. Prod. 54. (S. peregrina; Berg. Cap. 801.)—Stem shrubby, leafy. Leaves obovate-wedge-shaped, three-ribbed, stalked, pointed, smooth. Panicle level-topped; its branches roughish, somewhat angular, without wings.—Native of the Cape of Good Hope. The habit of this plant approaches that of our last species but one, S. arboresc., but its stipe is less. The stem is shrubby, with round, smooth, woody branches, leafy towards their extremities. Leaves scattered, rounded, obtuse or emarginate, with a small point; smooth on both sides, with three brown equal ribs; tapering down gradually into a rigid footflask, whose dilated membranous, sheathing base surrounds the stem. Each leaf is about two inches long; the footflask about half as much. Panicle corymbose and level-topped; its branches quite defilite of wings, rough with minute points; the ultimate ones zigzag and most angular. Bractees roundish-ovate, acute, with a membranous edge. Flowers not very numerous. Calyx with a hairy tube, and broad, membranous, purple border, which is very slightly angular rather than lobed. Corolla purple. Bergius's description hardly answers to the Linnean plant, except perhaps what he lays concerning a variety. S. schiedeis has no resemblance to karputata.

S. rofafa. Rose-coloured African Thrift.—Stem shrubby, leafy. Leaves obovate-oblong, single-ribbed, stalked, pointed, rough on both sides. Branches of the panicle rough, somewhat angular, without wings. Flowers crowded.—We are obliged to Sir Samuel Young, bart. of Formosa, Berks, for specimens of this beautiful species, gathered at St. Helen's bay, on the coast of Africa. Its stem, shrubby habit, and leafy branches, agree with the last; but the roughness of the whole plant, and particularly both sides of the leaves, with minute tubular points, the want of lateral ribs in the foliage, and the far more abundant, crowded flowers, whose permanent calyx is roser-coloured, rather than purple, induce us to consider it as distinct. The tubular riblets involucrum, with two short sheathing membranous-edged bractees at its base, is the same in both these species.

S. monopetala. Sicilian Shrubby Thrift. Linn. Sp. Pl. 396. Willd. n. 27. Ait. n. 20. (Limonium linumaria, &c.; Bocc. Sic. t. 16, 17.)—Stem shrubby, leafy. Leaves lanceolate, fleshy, fleshy, with sheathing flasks. Flowers diffusely spiked. Corolla monopetalous; its tube longer than the calyx.—Native of uncultivated ground in Sicily, as well as the south of France. It is not an unfrequent greenhouse shrub, flowering in July and August. Boccone says the red woody root is sometimes thicker than a man's leg. The flms are bulbous, but diffuse, unless artificially supported. Leaves numerous, obtuse, an inch or two long, various in breadth, thick, ribles, glaucous and minutely scaly all over, tapering down into a footflask, whole base is cylindrical and sheathing. Flowers large, pink, in solitary or aggregate lax spikes. Invoucurnm very hard and tight, nearly concealing the calyx and its small border. Claws of the petals combined.

S. sinuata. Scallop-leaved Thrift. Linn. Sp. Pl. 396. Willd. n. 34. Ait. n. 22. Curt. Mag. t. 71. Fl. Grac. t. 301, unpublished. (Limonium foliis foliati; Ger. 412.)—Stem herbaceous, winged. Radical leaves falcate; those of the stem awl-shaped, decurrent, three in a whorl. Calyx undivided, without awns.—Native of Sicily, Barbary, and Palestine. Dr. Sibthorp found it very frequent on the inundated shores of the Greek islands, and suspected it might be the real \\nu\\nu\\nu\\nu\\nu\\n. The modern Greeks call it \"evdoukia.\" In gardens it has been known ever since the days of Parkinson, but seldom endures long, even in a greenhouse. The numerous radical leaves are pinnailed, with numerous rounded lobes, green, obtuse, and hairy, three or four inches long. Stems de-
cumbent, a span long, branched, with leafy wings, and
whorls of narrowly acute leaves, about an inch in length.
Flowers crowded, in level-topped hairy tufts, all turned
upwards. Leaves of the involucrum three-pointed.
Limb of the calyx cup-shaped, undivided, of a delicate lilac-
purple, elegantly contrarcted with the pale yellow mono-
petalous corolla. The latter, however, soon passes away,
the calyx only retaining its form and colour when dry.
Martyn, in his Hist. Plant. Rat. t. 48, exhibits a variety
of this plant, whose leaves are but partially finnated.

**S. canescens.** Wedge-shaped Thrift. (S. finnata; Linn.
Sp. P. 397. Limonium caucubis alatis, alpeil folis
manibus asperis, calycibus acuto floribus flavoCentibus; Shaw
Afr. n. 367.)—Stems herbaceous, winged, leafless.
Leaves radical, somewhat finnated. Calyx acutely five-leaflet,
awned.—Gathered by Shaw in Barbary, where, as he tells
us, the Arabs call it El Khaddak; and by Haifeliquit in
Palestine. We cannot but consider this as a distinct species,
on account of its nearly smooth herbage, want of flimen-leaves,
and the greatly dilated wedge-shaped bracteat, much more
conspicuous than in the lath. The involucrum moreover is
of a much firmer texture with rigid, recurved, spinous
points; but above all the yellowish, not purple, limb of the
calyx has five acute lobes, the strong ribs of which, soon de-
nated, as in our S. arifata, become recurved brilliantly awns.

**S. lobata.** Lobed Spinosus Thrift. Linn. Suppl. 187.
Willd. n. 35.—Stems herbaceous, without wings. Leaves
radical; finnated. Calyx undivided, without awns.—Na-
tive of Barbary. This species is hardly known, except in the
Linncean herbarium. The specimen came from Moro-
cco. The root is simple, long and taper, apparently an-
nual. Leaves all radical, an inch and half long, hairy,
much like those of S. finnata. Stalks round, three or four
inches long, decumbent, panicled, with a spiky-shaped leaf
or two at their divisions. Bracteatas wedge-shaped and de-
current, as in the lath, but much smaller, and rough at the
edge with hooked prickles. Leaves of the involucrum
rough with long, spinous, spreading points. Limb of the
calyx white or yellowish, like the lath; but entire and
without awns, like S. finnata.

**S. muricata.** Curled Thrift. Linn. Suppl. 187.
Willd. n. 47.—Stem branched, winged with a triplicate
crisped border. Leaves radical, ovate, pointed. Flowers
spiked, crowded, all turned one way.—Native of the coast of Barbary, flowering
in July. Sometimes kept in greenhouses. The partly
decumbent flimen are much branched, and remarkable for
their crisped, not very broad, wings. Leaves on longish
footstalks, ovate, but tapering at the base, slightly wavy
at the margin, rather glaucous or scaly. Flowers blue-
purple, crowded, in aggregate level-topped spikes. Bracteatas,
as well as involucrum, reddish, obtuse,pointed, concave,
not keeled; their margins broad and membranous. Limb
of the calyx scarcely pentagonal, neither lobed nor awned.
A very distinct species, unlike any of the rest.

**STATICE.** In Gardening, comprehends plants of the hardy,
herbaceous, and under-shrubby kinds, of which the species
cultivated are, the thrift, or sea-gillyflower (S. armeria); the
sea-thrift, or sea-lavender (S. linorum); the heart-
leaved sea-lavender (S. cordata); the matted sea-lavender (S. reticulata); the rough-leaved sea-lavender (S. echioides);
the plantain-leaved sea-lavender (S. speciosa); the Tart-
tarian sea-lavender (S. tartareca); the triangular-leafed
sea-lavender (S. spinifolia); the narrow-leaved shrubby sea-
lavender (S. stethroica); the broad-leaved shrubby sea-
lavender (S. monopetalus); the cut-leaved sea-lavender
(S. ferulacea); and the scollop-leaved sea-lavender (S. finnata).

In the first fort there are several varieties: as with red
flowers, with scarlet flowers, with white flowers; great
thrift with red flowers, with white flowers; and small fea-
pink, with flesh-coloured flowers.

The second species has also several varieties: as common
great sea-lavender, great late-flowering sea-lavender, olive-
leaved sea-lavender, deep blue-flowered sea-lavender, and
white-flowered sea-lavender.

In the twelfth or last fort there are two varieties, which
differ in their leaves, flimen, and flowers.

**Method of Culture.—** All the sorts of these plants are capa-
bile of being increased by planting or by the roots. This,
with the first kind, should be performed in the autumn,
or very early spring season, planting them immediately as
edgings, or in the borders: they should not, however, be
parted too small. And when planted out as edgings, a quan-
tity of slips should be obtained in these edgings from old
plants, by planting or dividing the off-sits of their roots,
each slip being furnished with roots and tops; then, having
made up the edge of the bed or border even and firm, plant-
ing them either with a dibble in one range, two or three
inches distance in the row; or to form once a close edging,
so near as to touch one another, or in a small trench or
close, as in planting box-edgings. These edgings should,
every summer, immediately after flowering, be trimmed
with garden-hoes, or a knife, to cut off all the decayed
flower-talcs close to the bottom; likewise to trim in any
projecting irregularity of the edging, at the sides or top;
also, when it spreads considerably out of the bounds, it should
be cut in evenly, on each side, in due proportion; per-
forming those trimmings in moist weather, and not too late
in the autumn, otherwise the drought of summer, or the cold
of winter, will be apt to injure them when newly cut, and
cause them to have a shabby disagreeable appearance.

When these edgings grow considerably out of bounds, or
become very irregular, it is necessary to take them up, slit
the plants small, and immediately replant them as before,
in a neat regular edging. They sometimes require replanting
every three or four years in this manner.

The second sorts may likewise be increased by parting
the roots in the autumn or spring, preferring some mould
to be set on them and planting them out again immediately, being
placed in an east border, where the soil is loamy.

They may also be raised from seeds obtained from abroad,
fowing them on a similar border, keeping the plants clean;
and when of sufficient growth, planting them out in pots.
It is the common practice, in treating the second fort, ac-
cording to Martyn, to consider it as a greenhouse plant;
and it appears to the greatest advantage in a pot, as it is
much disposed to throw up new flowering-flomen. By hav-
ing several pots, some plants will be in flower throughout
the summer: on this account, and for the fineness of its
large blue calyx, it is a plant that merits attention. The
echioides is also a greenhouse plant.

The eighth, ninth, tenth forts, &c. may be increased by
planting cuttings of the young shoots, in July, in a shady
border, watering them frequently. When the plants have
a little growth, they should be taken up, and placed in
separate pots, filled with light loamy mould, putting them
in the shade till re-rooted. The plants of these sorts must
be removed into shelter in the autumn; but they only re-
quire protection from hard frosts, of course may be placed
with myrtles, and other hardy greenhouse plants, where
they often continue to flower a great part of winter, and
make a pretty variety. These sorts afford ornament among
other potted more hardy greenhouse plants, and produce a
pleasing diversity. All the other common sorts are useful
in increasing the variety, when planted out in the common
ground,
ground, in a rather funny situation, where they generally lack the longest.

**Staticks,** Staticks, formed of Στιξ, I weigh, a branch of mathematics, which considers weight or gravity, and the motion of bodies arising from it.

Those who define mechanics the science of motion, make statics a subordinate part of it; eis, that part which considers the motion of bodies arising from gravity.

Others make them two distinct doctrines, refining mechanics to the doctrine of motion and weight, in reference to the structure and power of machines; and statics to the doctrine of motion, considered merely as arising from the weight of bodies, without any immediate respect to machines. On which footing, statics should be the doctrine or theory of motion; and mechanics, the application of it to machines.

For the laws of statics, see Gravity, Desert, &c.

**Staticks,** Statics, in Medicine, a kind of epilepsies, or persons seized with epilepsies.

Staticks differ from catalepsies, in that these last have no sense of external objects, nor remember any thing that passes at the time of the paroxysm; whereas the statics are all the while taken up with some very strong, lively idea, which they remember well enough when out of the fit.

**Staticula,** among the Romans, those little figures with which it was usual to adorn their drinking cups, called joppis.

**Staticuli,** among the Romans, a kind of dancing pantomimes. See Pantomime.

**Station,** in Geometry, &c. a place pitched upon to make an observation, take a triangle, or the like.

An inaccessible height, or distance, is only to be taken by making two stations, from two places whose distances are known. In making maps of provinces, &c. stations are fixed on all the eminences, &c. of the country, and angles taken thence to the several towns, villages, &c.

In surveying, the instrument is to be adjusted by the needle, to answer the points of the horizon at every station; the distance from the last station to be measured, and an angle to be taken to the next station; which includes the whole breadth of surveying.

In levelling, the instrument is rectified, that is, it is placed level at each station, and observations made forwards and backwards.

We have a method of measuring distances at one station in the Philosophical Transactions, No 7, by means of a telescope. But the practice of this method does not answer to the theory.

**Station,** Line of, in Perspective. See Line.

**Station,** in Acronomy, the position or appearance of a planet, in the same point of the zodiac, for several days. As the earth, whence we view the motions of the planets, is out of the centre of their orbits, the planets appear to proceed irregularly; being sometimes seen to go forwards, that is, from west to east, which is called their direction; and sometimes to go backwards, or from east to west, which is called their retrogradation.

Now between these two stations there must be an intermediate one, in which the planet neither appears to go backwards nor forwards, but to stand still, and keep the same place in her orbit; which is called her station.

**Station,** in British History. The stations, or stations, fortresses erected along the line of Severus's wall, were so called from their stability, and the stated residence of garrisons. They were also called ephires, a name which many of them still bear. These were by far the largest, strongest, and most magni-

STA

Station, Statio, in Church History, is applied to the fall of the fourth and sixth days of the week, that is, Wednesday and Friday; which many among the ancients observed with much devotion, till three of the clock in the afternoon. St. Peter of Alexandria, in his Canonicall Epistle, can. 15, observes, that it was appointed, conformably to ancient tradition, to fall weekly on those days; on Wednesday, in memory of the council the Jews took to put our Saviour to death; and on Friday, on account of his passion. Some regard to which is still had by the church of England. See Abstinence.

Station is also used in the church of Rome, for a church where indulgences are to be had on certain days.

It was St. Gregory that fixed the stations at Rome, i.e. the churches where the office was to be performed each day of Lent, and on solemn fast-days. These stations he marked down in his Sacramentary, as they now stand in the Roman Missal; appropriating them chiefly to the patriarchal and titular churches; but though the stations were fixed, the archdeacon did not fail, at each station, to publish to the people the following station.

Station is also a ceremony in the Romish church, in which the priests or canons go out of the choir to sing an anthem before the crucifix, or the image of our Lady. This ceremony is ascribed to St. Cyril.

Station, Statio, ranx, in the Ancient Music, was sometimes used for any fixed pitch, or degree of sound, whether produced by intonation or semitone.

Station-Line, in Surveying. See Line and Surveying.

Stationa, in Ancient Geography, a town of Italy, in the interior of Etruria, according to Strabo.

Stationarium, were men, thus called in the middle ages, who trafficked in books, made large fortunes by lending them out to be read, at exorbitant prices, not in volumes, but in detached parts, according to the estimation in which the author was held.

Stationary, in Astronomy, the state of a planet when it seems to remain immovable in the same point of the zodiac. The planets having sometimes a progressive, and sometimes a retrograde motion, there will be some point in which they appear stationary. Now a planet will be seen stationary, when the line, that joins the earth's and planet's centre, is confluently directed to the same point in the heavens, that is, when it keeps parallel to itself. For all right lines drawn from any point of the earth's orbit, parallel to one another, do all point to the same star; the distance of those lines being insensible, in comparison of that of the fixed stars.

Saturn is seen stationary at the distance of somewhat more than a quadrant from the sun; Jupiter at the distance of 52°; and Mars at a much greater distance; Venus at 47°, and Mercury at 28°.

Saturn is stationary eight days, Jupiter four, Mars two, Venus one and a half, and Mercury a half; though the several stations are not always equal; because the orbits of the planets are not circles, which have the sun in their centre.

Stationary Fevers, an hypothetical term, used by Sydenham to denote those fevers which continue to prevail through a certain number of seafasts, as connected with some particular constitution of the atmosphere, according to his supposition; and giving a particular epidemic character to the maladies of those seafasts; and as contrasted with those casual and short occurrences of particular diffeases, which are now and then intermixed with the prevalent epidemics, and which he denominated intercurrent fevers. (See Sydenham, Observat. Medicæ circa Morb. Acut. Historiam et Curat. sect. i. c. 2., and sect. vi. c. 1.) Although he was able to trace several successive changes in epidemic constitutions, or stationary fevers, at different periods of his practice; he is compelled to admit, that these changes could not be ascribed to any sensible variations of the atmosphere, such as heat and cold, dryness and humidity; and adopted, therefore, the idea of occult and inexplicable contamination in some occult and inexplicable contamination of the air by certain effluvia from the bowels of the earth. See Sydenham.

Stativa, among the Romans, a standing camp kept for the defence of the frontiers of the empire. These camps gave rise to a great many towns, which took their names from the legion stationed there.

Statius, Publius Papinius, in Biography, an eminent Roman poet, was born at Naples, in which city his father was settled as a teacher of oratory, and was in great reputation both for his lectures and poetry, in which he gained several prizes. Statius was born probably about the year A.D. 61. He early displayed a lively disposition and good talents, and soon became a votary of the muses with so much success, that during his father's life he obtained the crown in the poetical contests of his native place. He was thrice a victor in the poetical games celebrated at Alba. The poems which he addressed to several of the principal persons in Rome, are proofs of the friendship which he contrived with men of rank in that city; and a piece, which he recited in the quinquennial games instituted by Nero, and renewed by Domitian, procured for him a golden crown from that emperor, and the honour of admission to his table. He was exquisitely at a contest in the Roman games, on which occasion he recited a part of his principal work, the Thebaid. According to Juvenal, he was heard with delight by a crowd of auditors in other public recitations of this poem: the fatality at the same time intimating, that notwithstanding this applause, the author might have starved, had he not sold his "Agave," apparently a new composition, to a celebrated actor, a favourite of Domitian. He possessed a small estate and country house near the site of the ancient Alba, and lived in a decent state of mediocrity. Having no children of his own, he adopted a son, whose death he tenderly laments in one of his miscellaneous poems. The time of his own death is not known; but it is thought to have been about the year 96, when he was only 35 years of age. He is not even mentioned by any contemporary poet, except Juvenal. Martial, who celebrates many other poets, takes not the least notice of him. The existing works of Statius consist of the "Sylvae," or miscellaneous pieces, in five books; the "Thebaid," an epic poem, in twelve books; and two books of an unfinished poem, entitled "Achilles," "They all," says his biographer, "display a considerable share of genius and real talent, but are vitiated by the false taste which then began to infect Latin poetry, and gave a turn to turgid and unnatural thoughts and expressions. Several pieces in the "Sylvae" are, however, pleasing and elegant.

His principal work, the "Thebaid," holds no mean rank among epic poems, and once it was a great favourite among the remains of antiquity. For this preference it was indebted to its swelling sentiments, verging to bombast, and to the savage and sanguinary character of its incidents, which fudged the times of chivalrous turbulence. But with these faults it exhibits strokes of the real sublime, and considerable force and novelty in natural description, especially in the families." The best editions are those of Calpur Barthus, 4to. 1664; of Vossius, Lug. Bat. 8vo. 1671; and
and the Delphin, 2 vols. 1689. Markland’s edition of the “Silvano” is highly esteemed.

**STATO della Chiesa, State of the Church, or Papal dominion, is given to the dominions of the pope in the central part of Italy. These dominions were bounded on the N. by the Venetian States, on the E. by the Adriatic and part of the kingdom of Naples, on the S. by the Mediterranean, and on the W. by the Mediterranean, the duchy of Tuscany, and the duchy of Modena; and consisted of several states or provinces. See Ecclesiastical State.**

The peculiar power of the popes is traced back to the age of Pepin and Charlemagne; and the forged collection of papal receipts, published in the 9th century under the name of Iulianus, led to successive accumulations of dominion. The small territory, granted in the eighth century, was increased by the acquisition of Benevento in the eleventh, after which there was a pause; and the popes themselves were constrained to reside at Avignon. In 1513 Bologna was acquired by Julius II.; the marquise of Ancona followed in 1532; Ferrara in 1598; and Urbino in 1626. But since the French revolution, the temporal power of the pope was annihilated by Bonaparte (see Italy); and again restored after the expulsion of the French emperor. When the temporal power predominates, not great industry can be expected, and the soil is not likely to derive much accession to its natural fertility from cultivation. The principal, and, indeed, almost the only exports from the Papal states, are superior kind of alum, prepared from a whitish argillaceous rock at Tufa, near Civita Vecchia, from which place also is exported punica (which see). The chief city of the papal territory is Rome (which see); and its revenue has been computed at about 350,000l. sterling; but by exertions in foreign countries it is laid to have been raised to 500,000l. subject, however, to a large debt, being 8 per cent. interest; and this strikingly evinces a defect of industry and prosperity. See Ecclesiastical State, Italy, and Popes.

**Statuto de Gli Prestiti, a name given to a part of Tuscany, which was ceded to Philip II. king of Spain, and belongs to Naples. It is situated on the coast of the Mediterranean, and confines of the towns of Orbitello, Porto Hercule, the principality of Fiuminana, and the island of Elba, with a few villages. By the peace signed at Florence, between the king of Naples and the French republic, this country was given to France. See Naples and Tuscany.**

**STATORES, among the Romans, made a part of the emperor’s life guard.**

**STATURAL, Statuaria, a branch of sculpture, employed in the making of statues.**

Statuary is one of those arts in which the ancients surpassed the moderns; indeed it was much more popular and more cultivated among the former than the latter. It is disputed between statuary and painting, which of the two is the most difficult, and the most artful. See Sculpture.

The invention of statuary was at first very coarse. Leon Battista Alberti, who has an express treatise on statues, imagines, that it took its rise from something casually observed in the productions of nature, that, with a little help, seemed dipole to represent the figure of some animal. The common story is, that a maid, full of the idea of her lover, may by the influence of her father’s implements, who was a potter. This, at least, is pretty certain, that earth was the first matter upon which statuary was practised.

**Statuary is also used for the artificer who makes statues. Phidias was the greatest statuary among the ancients; and Michael Angelo among the moderns.**

**Statuary Column. See Column.**

**Statuary Fountain. See Fountain.**

**Statuary Marble, among our artificers, the name of the softer white marble usually wrought into statues, the same with the Parian marble of the ancients.**

**Statue, Statua, a piece of sculpture in full relief, representing a human figure.**

Daviler more scientiﬁcally deﬁnes statue, a representation in high relief, and insulare, of some person distinguished by his birth, merit, or great actions; placed as an ornament in a fine building, or exposed in a public place, to preserve the memory of his worth.

In strictness, the term statue is only applied to figures on foot; the word being formed from the Latin statum, the size of the body; or from stas, to stand. Statues are formed with the chisel, of several matters, as stone, marble, plaster, &c.

They are also cast of various kinds of metal, particularly gold, silver, brass, and lead. For the method of casting statues, see Foundry of Statues.

Darius, the son of Artabanus, who lived not only before the siege of Troy, but even before the expedition of the Argonauts, among many other notable contrivances ascribed to him, is said to have been the inventor of statues. And yet it is certain, there were statuaries before him; only it was he who ﬁrst found how to give them action and motion, and to make them appear as if alive. Before him, they made them with the feet joined together, never intending to express any action. He ﬁrst loosened the feet of his, and gave them the attitudes of people walking and acting. The Phoenicians are said to have been the ﬁrst who erected statues to the gods. The Greeks succeeded in their statues beyond the Romans, both the workmanship and the fancy of the Roman statues being inferior to the Grecian. Indeed we have very few remaining that have escaped the injuries of time.

Statues are usually distinguished into four general kinds. The ﬁrst are those less than the life; of which kind we have several statues of men, of kings, and of gods themselves. The second, those equal to the life; in which manner it was that the ancients, at the public expense, used to make statues of persons eminent for virtue, learning, or the services they had done. The third, those that exceed the life; among which, those which usurp the life once and an half, were for kings and emperors; and those double the life, for heroes. The fourth kind were those that exceeded the life twice, thrice, or even more; and were called colossal.

Every statue resembling the person it is intended to represent, is called statue iconica. See Sculpture.

**Statute, Allegorical, that which, under a human ﬁgure, or other symbol, represents something of another kind, as a part of the earth, a sea, a plant, an element, a temperament, a colour, &c.**

**Statue, Caryatic. See Caryatides.**

**Statue, Colossal. See Colossus.**

**Statue, Cupid, those which are represented in chariots drawn by bigs, or quadrige, that is, by two or four horses: of which kind there were several in the circuses, hippodromes, &c. or in cars, as we see some, with triumphal arches, on antique medals.**

**Statue, Equestrian, that which represents some illustrious person on horseback; as that famous one of Marcus Aurelius at Rome, and that of king Charles I. at Charing-Crofts.**

**Statue, Greek, denotes a ﬁgure that is naked and antiqua,
tique, it being in this manner the Greeks represented their deities, athletes of the Olympic games, and heroes. The reason of this nudity, by which the Greek statues are distinguished, is, that those who exercised wrestling, in which the Greek youth placed their chief glory, always performed naked.

The statues of heroes were particularly called Achillia statues, by reason of the great number of figures of that prince in most of the cities of Greece.

Status, Hydraulix, any figure placed as an ornament of a fountain, or grotto, or that does the office of a jet d'eau, a cock, spout, or the like, by any of its parts, or by any attribute it holds. The like is to be understood of any animal serving for the same use.

Status, Pedestial, a statue standing on foot; as that of king Charles II. in the Royal Exchange; and that of king James II. in the Privy-Gardens.

Status, Persian, See Persian.

Status, Roman, is an appellation given to such as are clothed; and which receive various names from their various dressers.

Those of emperors, with long gowns over their armour, were called statue paludata; those of captains and cavaliers, with coats of arms, thoracata; those of soldiers, with cuirasses, loricata; those of senators and augurs, trabata; those of magistrates, with long robes, togata; those of the people, with a plain tunic, tunica; and lastly, those of women, with long trains, folate.

The Romans had another division of statues, into divine, which were those consecrated to the gods; as Jupiter, Mars, Apollo, &c.; heroes, which were those of the demi-gods; as Hercules, &c.; and Augusti, which were those of the emperors; as those of Caesar and Augustus, under the pontific of the Capitol.

Status, Foundery of. See Foundery.

Status, Pedestal of. See Pedestal.

Status, Plinth of. See Plinth.

Status, Repairing a. See Repair.

Status, the site, or height of man; derived from the Latin statua, of stare, to stand.

The stature, or pitch, of a man, is found admirably well adapted to the circumstances of his existence. See Dwarf and Giant.

It is a common opinion, and has been so ever since Homer's time, that people in the earliest ages of the world much surpassed the moderns in stature; and, it is true, we read of men, both in sacred and profane history, whose pitch appears surprising; but then, it is true, they were, even then, esteemed giants.

The ordinary stature of men, Dr. Derham observes, is, in all probability, the fame now as at the beginning; as may be gathered from the monuments, mummies, &c. still remaining. The oldest monument in the world is that of Cheops, in the first pyramid of Egypt, which, Mr. Greaves observes, scarcely exceeds the measure of our ordinary coffins. The cavity, he says, is only 648 feet long, 2218 feet wide, and 2580 feet deep: from which dimensions, and those of several elongated bodies observed by him in Egypt, that accurate writer concludes, there is no decay in nature; but that the men of this age are of the same stature as those three thousand years ago.

To these, we have after and later influences to add from Hakewell: the tombs at Pisa, which are some hundreds of years old, are yet no longer than ours. The fame may be laid of Athelstan's in Malmbury church; and of Sheba's in Paul's, of the year 695, &c.

The like evidence we have from the ancient armour,

Vol. XXXIV.
Statute-Staple is a sort of statute-merchant, relating to merchants and merchandizes of the staple; which fee.

The staple-Staple is of two kinds; proper and improper.
The proper is a bond of record, acknowledged before the mayor of the staple, in the presence of one or more constables of the staple; by virtue of which the creditor may forthwith have execution of the body, lands, and goods, of the debtor, on non-payment.

This and the statute-merchant are both securities for debts, originally permitted only among traders for the benefit of commerce; by which the lands of the debtor are conveyed to the creditor, till out of the rents and profits of them his debt may be satisfied; and during such time as the creditor holds the lands, he is tenant by statute-merchant, or statute-Staple.

Improper is a bond of record, or recognizance, founded upon the statute 23 Hen.VIII. cap. 6. of the nature of a proper statute-Staple as to the force and execution of it, and acknowledged before one of the chief justices; or, in their absence, before the mayor of the staple, and recorder of London; which extends the benefit of the mercantile transactiion, already mentioned, to all the king's subjects in general.

STATUTO MERCATORIO, a writ for the imprisoning him that has forfeited a statute-merchant bond, until the debt be satisfied; and of these writs there is one against lay persons, and another against persons ecclesiastical.

Statuto Stapula, a writ that lies to take the body to prison, and seize upon the land and goods of one who hath forfeited the bond called statute-Staple.

STATUTUM de Laborariis, an ancient writ for the apprehending such labourers as refuses to work according to the statute.

STAVANGER, in Geography, a sea-port town of Norway, in Christiantown, situated on a bay of the North sea; anciently the fee of a bishop, but removed, after the town was burnt in the year 1688, to Christiantown; 86 miles S. of Bergen. N. lat. 58° 50'. E. long. 5° 44'.

STAVANI, in Ancient Geography, a people of European Sarmatia, according to Ptolemy; who also gives the same name to a people in the northern part of Aria.

STAVELOT, in Geography. See STABLO.

STAVENAU, a town of Brandenburg, in the Mark of Pregnitz; 7 miles N.W. of Perleberg.

STAVENHAGEN, a town of the duchy of Mecklenburg; 24 miles E. of Gyllow. N. lat. 53° 40'. E. long. 11° 24'.

STAVEN, a town of Holland, and the most ancient of Friesland, supposed to have been built one year before the commencement of the Christian era, and to have taken its name from an ancient idol, worshipped by the inhabitants, called "Staan." Great part of the ancient town having been destroyed by the sea, the inhabitants rebuilt it in the place where it now stands, as being least exposed. It was anciently a very rich, powerful, and populous city, with the best harbour in that country. The ancient kings of Friesland built it their ordinary residence, the palace built by Richolde, the first king, about the year 450. Radbode VI. after he had conquered all the country as far as Utrecht, called his conquests the Kingdom of Staveren, which flourished the flourishing state of the town at that time, and was the occasion of its being included in the league of the German Hanse towns. It was surrounded with walls and ditches, about the year 339, by Obidalde VI. duke of Friesland. It is since reduced very much from its ancient grandeur, the harbour being choked up; however, there remains enough of its former splendour to make it a considerable
town; and they still carry on some trade, especially in fishing, and in paissage-boats over the pools and lakes of the neighbourhood. In 1796, the town was taken by the British fleet; 40 miles N. of Amsterdam. N. lat. 52° 56'. E. long. 10° 46'.

STAVERN. See Fredriksvorn.

STAVERS. See Stuvera.

STAVES. Flag. See Flag-Staves.

STAVE, Lewes. See Lewelling-Staves.

STAVES, Tp. See Tip-Staves.

STAVESACRE. Staphiasioria, in Botany; for the characters, see Delphinium.

Staveacre, Delphinium hispoidagnus, grows in Provence, Languedoc, and many other southern parts of Europe.

The seeds, which are the only part of the plant directed for medicinal use, are usually imported here from Italy; they are large, rough, of an irregular triangular figure, and of a blackish colour on the outside, but yellowish within; their shell is disaggregable, and somewhat lefled; to the taste they are very bitter, acrid, and nauseous. Their virtues are extracted partially by water, and completely by rectified spirits.

These seeds seem to have been known to the ancients, by whom they were employed as a mastrictory: for, on being chewed the excite a copious flow of saliva, and on this account were recommended in tooth-aches, and other painful affections of the face and gums. The ancients also prescribed them with a view to their emetic and cathartic effects in doses of twenty or fifteen grains; but the deleterious narcotic qualities of staveacre were discovered to be so powerful as to forbid its internal use. Schultz, only by keeping it some time in his mouth to relieve a tooth-ache, was for a time deprived of his senses, and Hillefeld has related, that a dog, by taking five scruples of these seeds, became convulsed, and soon died. Staveacre is now, therefore, confined to external use in some kinds of cutaneous eruption, but more especially for destroying lice and other insects; and by its efficacy in this way, this plant, in most of the European languages, is distinguished by the name of louse-wort.

Stave, a castle of Germany, in the principality of Nassau, Saarbruck Ufingen.—Alfo, a castle of Germany, in the principality of Anspach, with a citadel; 90 miles S.E. of Anspach.

STAFFEN, a town of the Brugia, on the Mehlbach; 24 miles N.E. of Bâle. N. lat. 48° 54'. E. long. 7° 48'.

STAFFENBURG, a town of Upper Hesse; 5 miles N.E. of Gießen. N. lat. 50° 40'. E. long. 8° 45'.

STAVIGNETTI, a town of Walachia; 42 miles E.E. of Ierapoli.

STAUNTON, a post-town of America, in the state of Virginia, and capital of Augusta county; situated on the E. side of Middle river, a water of Patowmac, N. of Maddison's cove. It contains about 160 houses, mostly constructed of stone, a court-house and gaol; 100 miles S.W. by S. of Winchester. —Alfo, one of the principal branches of Roanoke river, which rises on the western side of the Blue Ridge, where it has the name of Roanoke, but when it has passed through the ridge, it takes the name of Staunton, and preserves to it its confuseness with Dan, there refusing the name of Roanoke. It might be made navigable for 100 miles from its mouth. It receives several streams.

Staunton's Island, a small island near the east coast of China. N. lat. 36° 47'. E. long. 128° 13'.

STAVRER HOVED, a cape of Denmark, on the east coast of the island of Fyen. N. lat. 55° 29'. E. long. 10° 46'.

STAVURI, in Ancient Geography, a people of Asia, in the environs of Hyrcania. Pliny.

STAUROLITE, Granatite of Saussure and Werner, and Staurotide of Huy, in Mineralogy, a stone of the glistening genus according to Kirwan, of a reddish or blackish-brown colour, which seems always crystallized. Its crystals are of an hexahedral prismatiform form, four faces of which are the largest, meeting in pairs, and forming two obtuse angles, measuring 120°. The prism is either entire or truncated on the obtuse angles. It is not uncommon to find two crystals penetrating each other obliquely, or at right angles, so as to form a cross; sometimes even three prisms are thus arranged, forming a triple cross, whence its name of "Croftone."

Its surface is smooth or uneven, and its lustre varies considerably. Internally it is more or less shining, with a lustre between vitreous and resinous. Its fracture, parallel to the axis, is imperfect lamellar, and in the opposite direction it is small-grained uneven, passing to conchoidal. It is brittle, and somewhat harder than quartz. Sp. gr. 3.38. Exposed to the blowpipe, it undergoes no other change besides that of fritting a little on its surface. Its component parts, according to an analysis by Vaucufile, are

- 33. Silex.
- 44. Alumine.
- 3.84. Lime.
- 1. Oxyd of manganese.

This mineral is found in St. Gothard, in Switzerland, in small crystals, imbedded in micaceous schistus, and accompanied with cyanite; in Brittany, near Quimper, in middle-sized crystals, imbedded in a micaceous clay, apparently produced by the decomposition of some primitive rock; also at St. Iago de Conisffelas, in a primitive rock. Aikin.

STAUROPHORI, Σταυρόφοροι, compounded of σταυρός, a cross, and φόρος, I carry, in Church History, certain ecclesiastics, whose business it was to carry the cross in processions.

STAUROPHYLAX, Σταυροφυλακη, derived from σταυρός, a cross, and φυλακη, I keep, a dignified officer in the church of Constantinople, to whose care the keeping of the cross, found by St. Helena, was committed.

STAUROPOL, in Geography, a town of Russia, in the government of Simbirsk, on the Volga; 44 miles S.E. of Simbirsk. N. lat. 53° 44'. E. long. 48° 48'. —Alfo, a town of Russia, in the government of Cazacow, on the Volga; 86 miles W.N.W. of Ekaterinosgrad. N. lat. 44° 56'. E. long. 41° 57'.

STAVROS, or STAuros, anciently Stagira, a town of European Turkey, in Macedonia, the native place of Aristotle; situated in the gulf of Coatefa; 46 miles E.E. of Saloniki.

STAUROTIDE, in Mineralogy, the name given by Huy to grautite. See Staurolite.

STAUSEE, Fort, in Geography, an American fort, just above the falls of the Niagara, and eight miles above Queen's Town.
STAUSTADT, a town of Switzerland, in the canton
of Unterwalden; 6 miles S.E. of Lucerne.

STAXIGO HARBOR, a bay of Scotland, on the east
coast of the county of Caithness; 1 mile N. of Nobs Head.

STAXIS, a word used by the ancient physicians to ex-
press a distillation of the blood in drops from the nose.

A fluxis, in the doctrine of crises, is justly condemned
as indicating a weakness and decay of strength in nature;
whereas, on the contrary, free and copious discharges of
blood from the nose are esteemed good indications, and often
make happy crises.

STAY, in Sea Language, a strong rope employed
to support the masts on the fore-part, by extending from
their upper end at the mast-head towards the fore-part of
the ship, as the hounds are extended to the right and left,
and behind it.

The stays are denominated from the masts, as the lower
stays, topmast stays, top-gallant stays, flag-staff or royal
stays, &c.

Back-stays, breast, shifting, and standing, are stays which
support the topmasts and top-gallant-masts from aft: they
reach from the heads of the topmast and top-gallant-mast
to the channel on each side of the ship, and affix the hounds,
when strained by a press of sail. The shifting back-stays
chain according to the action of the wind upon the sails,
whether aft or upon the quarter. Bob-stays are stays used
to confine the bowspirit down upon the foremast, and counteract
the force of the stays which draw it upwards. Stay-fall
stays are those on which the stay-falls are extended. The
jib-stay is similar to the stay-fall stays, and extends the jib.
The martingale-stay supports the jib-boom, as the bob-stays
support the bowspirit. Preventer-spring-stays are subsidiary
stays to support their respective stays, and supply their
places, in case of any accident. The practice of placing
the spring-stays before the foremost crosstrees, and of
bringing the catheadspins and futtock-hounds to the mast,
is now freely forbidden in the navy, as the placing of the
spring-stay before the foremost crosstrees was with a view
to separate it from the standing stay: it is for the future to
be effected, by placing the collars five or six feet apart on
the bowspirit. Static-stays are ropes used for hoisting or
lowering burdens in or out of ships. Stay-rope have four
frands, with a heart running through the middle, which
keeps the rope true; and when hawser-laid as a rope, pre-
vents it from tretching, and the frands have each their
proper bearing. The stays are made of five yarn, spun
from the beit topt hemp. Twenty threads a-hook make a
rope three inches in circumference, and fo in proportion for
any size. The yarn is warped to the length and size for
the stay wanted. The frands are warped long enough for
one frand to make two, when hauled about and hung upon
the back-hook. By this an eye is left for the upper end of
the stay to go through and form a collar, to go over the
mast-head. For stays of nine inches in circumference, each
frand should be 3/4 inches, and fo in proportion. The
heart must be near the face of the frand, or the rope will
not lie round and true. Particular attention should be paid
to making the stays, as on them the safety of the mast, &c.
greatly depends. Main, fore, and mizen-topmast, and some
top-gallant-mast-stays, are cable-laid.

The stay of the fore-mast, called the fore-stay, reaches
from the mast-head towards the bowspirit-end; the main-
stay extends over the fore-castle to the ship's stern; and the
mizen-stay is stretched down to that part of the main-mast
which lies immediately above the quarter-deck; the fore-
topmast-stay comes also to the end of the bowspirit, a little
beyond the fore-stay; the main-topmast-stay is attached
to the head or hounds of the fore-mast; and the mizen-topmast-
stay comes also to the hounds of the main-mast; the fore-
top-gallant-stay comes to the outer end of the jib-boom;
and the main-top-gallant-stay is extended to the head of
the fore-topmast.

STAY a Ship, To, or bring her on the Stays, is to manage
her tackle and sails, so that she cannot make any way
forwards, which is done in order to her tacking about.

STAY, in the Manage. To stay, or furlain your horse,
is to hold the bridle firm and high. We likewise stay or
furlain a horse with the in-leg, or in-heel, when he makes
his course go before his shoulders upon a volley; as also when
we hinder him to traverse, and ride him equally, keeping
him always subjects, so that his course cannot fly out, and
he cannot lose either his cadence, or his ground, but marks
all his times equal.

STAY-Sail, in a Ship, a fort of triangular sail extended
upon a stay. See SAIL.

STAY-Sail-Stay-Tackle. See TACKLE.

STAY-Tackle Pendants. See PENDANTS.

STAYNER, Sir Richard, in Biography, was the gall-
 surrender and during the protectorate;
and, in conjunction with captain Smith, took a Dutch East
India ship of 8oo tons burden, having on board four chefs
of silver. In 1676 he was appointed to the command of
three frigates, and with this small squadron he fell in with
the Spanish flotilla, confining of eight sail, of which he
captured two, burnt one, sunk another, and drove two
on shore. The treasure captured on this occasion amounted to
six hundred thousand pounds sterling, so that captain
Stayer returned to England not only crowned with glory,
but laden with wealth. In the following year he again
failed with the fleet, under the chief command of Blake, for
the purpose of intercepting the Spanish West India fleet,
which had taken shelter in the bay of Santa Cruz. On re
connoitering the force and position of the enemy, the Eng
lish admiral found it impossible to bring off the enemy's
ships, though he thought they might be destroyed. Stayer
was immediately detached to begin the attack, and being
supported by Blake with the remainder of the fleet, the
Spaniards were, in a very few hours, driven out of their
ships and breast-works. The former were infanty taken
possession of by the English, and, as they could not be
brought off, they were all set on fire, and burnt to the
water's edge. "The whole action," says lord Clarendon,
"was so miraculous, that all men, who knew the place,
 wondered that any sober people, with whatever courage
endowed, would ever have undertaken it; and they could
hardly persuade themselves to believe what they had done!
while the Spaniards comforted themselves with the belief
that they were devils, and not men, who had destroyed
them in such a manner." Cromwell thought it highly of the
ducal of Stayer, that he immediately con-
ferred on him the honour of knighthood. On the restora-
tion, sir R. Stayer had a command under Montague,
and afterwards the earl of Sandwich, was again knighted,
and was constituted rear-admiral of the fleet. He first hoisted
his flag in the Swiftsure, and afterwards in the Mary.
After this, the nation being at peace, no opportunity was
offered to this brave man of adding to those services which
he had already rendered his country; and it is thought he
died very soon after. Campbell's Lives of the Admirals,
vol. iv.

ST CLAIR, in Geography. See CLAIR.—Also a
township in Butler county, in the state of Ohio, containing

1180
STEADMAN's Creek, a river of America, in New
York, which runs into the Niagara, above Fort Schlosser.

STEADY, a word of command at sea, given by the
pilot to the man at the helm, in a fair wind, to keep the
ship steady in her course, without deviating to the right or
left, or making angles (or gyres, as they call them), in and
out. The helmsman accordingly answers steady; thus de-
noting his attention and obedience to the pilot's orders.

STEAL, in Agriculture. See STALE.

STEALING on Horses. See FORCIBLE ABDUCTION.

STEALING, in Law. See LARCENY.

STEAM, in a general sense, is a term used to signify
the visible clouds and air arising from the condensation
of aqueous vapour.

In those arts and manufactures where the vapour of water
is employed, such as steam-engines, the term steam is used
for water in its elastic form, at or above the temperature
of 212°, and when it is invisible. It is in this form that
we can properly call it steam; as we shall shew, that in the
visible misty form in which we see it in the atmosphere, both
in the form of clouds, and as it passes from a warm medium
into a colder one, it is not steam but water in minute glo-
bules.

Some have confused the word steam to the vapour of wa-
ter not less than 212°, as if water did not assume the elastic
form at a lower temperature; conceiving it to exert the full
force of steam the moment it arrives at that point, and to
be wholly converted into water when reduced below the
same. Nothing, however, can be more absurd than this
notion: steam can exist at the lowest known temperature.
At 50° below the cypther of Fahrenheit, if the barometer
could shew it, the presence of ice would afford an elastic
fluid of some force. We want no other proof of this fact
than the experiments of different philosophers to ascertain
the force of aqueous vapour, answering to different tem-
peratures; and before we proceed further on our subject,
it may not be amiss to give the table of these facts, formed
by Mr. John Dalton of Manchester. In order to make
these experiments, Mr. Dalton took a barometer of the
common size. The mercury was first boiled, to free it
from air. He then put a little water into the tube, and
poured it out again, leaving its sides wet; and next intro-
duced the mercury, inverting the tube so as to exclude the
air. The water, being the lightest fluid, rose above the
surface of the mercury about one-eighth of an inch. He
then surrounded the tube, from the top downwards, with
another tube, 14 inches long and 2 inches diameter; form-
ing a cavity between the tubes, capable of holding water of
different temperatures. The temperature of this water was
constantly marked by a thermometer placed in it; and the
elasticity of the vapour, in the upper part of the barometer,
was constantly marked by the height of the mercury. The
outer tube being of glass, the whole could be seen. This
apparatus was used for all the temperatures below 155°.
For the higher temperatures, as high as 212°, he used an
outer tube of tin, with a siphon barometer.

These results he found to agree with similar experiments
made with the air-pump. The air-pump was provided with
a mercurial gauge of considerable extent. Some water was
first made to boil in a Florence flask, in which a thermometer
was placed. In this state it was put under the receiver,
and then the air being withdrawn, the steam alone affected
the barometer; the thermometer, at the same time, marking
the temperature.

From these facts Mr. Dalton constructed his table. The
altitudes of the mercury, answering to the degrees of tem-
perature, he found not to have a constant ratio; nor did
they vary by any regular progression. When the degrees
were in arithmetical progression, the columns of mercury
answering thereto were not in the same, but something ap-
proaching to a geometrical series. The increase, although
not strictly geometrical, of the ratios themselves diminished
regularly, which enabled him to calculate with sufficient
exactness those degrees which he could not ascertain by
experiment. We seldom find any of nature's laws attended
with any thing so indefinite; and Mr. Dalton very pro-
perly observes, that the defect is not in nature, but in the
imperfect scale of our thermometers, which, M. de Luc
and others have shewn, do not mark equal increments of
heat.


STEAM.

In answer to some references which may be required, we have thought proper to add a third column to this table, shewing the weight of aqueous vapour contained in a cubic foot of space, when a sufficient quantity of water is present at the given temperature. This column has been formed on the fact, that when the force of vapour is 30 inches, the aqueous vapour in a cubic foot of space is equal to 253 grains. And since the density must be as the pressure; therefore, as 30 inches is to 253 grains, so is the force of vapour of any other degree to the number of grains in the cubic foot at the same.

This table, from 30° to 212°, was the result of careful experiment. Those below and above were determined by calculation, and will doubtless be much more correct than by experiment, from the great difficulty and uncertainty which the high and low temperatures would occasion. For a more detailed account of Mr. Dalton’s experiments, see the Manchester Trans. vols. vi. and vii.

These will be found a valuable reference in all practical applications of steam, and will not be of less importance in ascertaining the processes of evaporation, as well as in forming the arts of life, and the natural evaporation in the air. With a view to assist our conception of the nature of steam, or of the elastic vapour of water, we shall consider a number of facts, which may be very proper to commit to memory.

1. A cubic inch of water forms a cubic foot of steam, when its temperature is equal to 30 inches of mercury.

2. One pound of Newcastle coal converts seven pounds of boiling water into steam.

3. The time required to convert a given quantity of boiling water into steam, is six times that required to raise it from the freezing to the boiling point; or from 32° to 212°, supposing the supply of heat to be uniform.

4. When a quantity of water is exposed to a given temperature, the quantity of steam formed in a given time will be as the surface, all other things being equal. The quantity will also be jointly as the force of vapour anfwering to each degree of heat, and the surface.

The depth of water evaporated, in a given time, will be as the force of vapour, whatever the surface, if the mass be uniformly of the same temperature.

When the force of vapour is 30 inches, and the temperature at 212°, this degree being just preferred only, the depth evaporated is 1.5 inch in one hour. This will be near the truth for this temperature. For lower temperatures, the rules given with the table will point it out.

5. When a quantity of water is raised to the boiling point, or 212°, it requires as much heat to give it the elastic form as would raise the same weight of water 900° higher. If its volume were not changed by the heat, that is, if it could be prevented from expanding, its temperature would become 1112°, with the same quantity of caloric. Thus, agreeably to fact the 30°, the heat required to convert water of 212° into steam, is six times that required to raise the temperature from 32° to 212°.

6. The same weight of water, in the form of steam, contains the same quantity of heat, whatever may be its temperature or density; that is, the temperature at which the steam is formed, added to the degrees required to give it the elastic form, is always a constant quantity. The meaning of this is, that if a given weight of aqueous vapour, at 100° for instance, were compressed till its elasticity became equal to that at 212°, no heat being allowed to escape, its temperature would become 212° by the condensation; and it would, of course, contain the same heat as steam formed at the same temperature, viz. 212° + 900°, as mentioned in the last fact.

In viewing the second column of the table, and comparing it with the temperature in the first column, we shall be far from concluding that all the steam in the cylinder of a steam-engine is condensed by the bell mouth employed. Owing to the circumstance of the rapid decrease of the force of vapour from the boiling point, some have been led to imagine that there is no medium between steam at 212° and liquid water. By referring to the table, we shall see that, by a decrease of temperature from 212° to 180°, the column of 30 inches is reduced to 15. This column is again bisected or reduced to 7.5, by the temperature falling to 150°. At 125°, the steam exerts a force equal to 3.75 inches of mercury; and this will be reduced to 1.875, at the temperature of 100°.

We here see the importance of Mr. Watt’s discovery of condensing his steam in a separate vessel. The spring of the residual vapour in his cylinder, after condensation, is only equal to the force of vapour answering to the temperature of his condenser, while the cylinder itself is kept at 212° nearly.

In the old method of condensing in the cylinder, so much cold water would be added as would reduce the temperature as low as Mr. Watt’s condenser, in order to produce as perfect a vacuum; and on filling the cylinder again the next time, it would require to be raised to its original heat, at the expense of fresh steam. The effect of cold water in condensing steam, whether in the cylinder or a separate vessel, may be easily known by calculation, and the aid of the preceding table.

Let $C =$ the capacity of the vessel containing steam in cubic feet.

$S =$ the weight of a cubic foot of steam.

$q =$ the weight of condensing water.

$T =$ its temperature.

$b =$ the degrees of heat to convert water into steam.

$d =$ the temperature of the steam.

$t =$ the resulting temperature, supposing $b$ and $d$ to be sensible heat before the experiment, and $t$ the same afterwards.

$n =$ capacity of steam for heat, water being $t$.

Then, according to a theorem for finding the resulting temperature by mixing bodies of different temperatures together, $t = \frac{qT + (b + d)Cs}{q + Cs}$. In this, will come out as if the steam in the vessel, after mixture, were condensed into water; when, in fact, the heat is divided between the remaining steam and the water, one part giving the whole a common temperature, and the other in a latent form giving elasticity to the vapour. But, according to fact the 6th, as before given, this steam contains as much heat above its own temperature as would raise it to 212°; hence the real temperature added to the latent heat will be equal to $t$.

The conclusion from these facts will be, that $\frac{b + d}{t} = \text{f}$, and $\text{f} = \frac{p}{b + d}$. If we now
STEAM.

Now refer to the table with this force of vapour, we shall find the temperature after condensation. To illustrate this theorem by an example, let

\[ C = 1 \text{ cubic foot.} \]
\[ S = 253 \text{ grains, the weight of a cubic foot of steam.} \]
\[ q = 253 \text{ grains of water.} \]
\[ T = 60. \]
\[ b = 900. \]
\[ d = 212. \]
\[ s = .9. \]

\[ \frac{q + (b + d) Sn}{q + Cs} = \frac{253 \times 60 + (900 + 212) \times 253 \times .9}{253 + 253 \times .9} = 558. \]

Then \( b + d \) and \( f \) of mercury. Now, the temperature answering to this force of vapour, in the table, is equal to 177°.5. The quantity of steam of this density will be \( \frac{30}{558} \), or \( \frac{1118}{558} \), as found, and \( s = .9 \), to be equal to fifteen inches of mercury. Hence, if the capacity of the steam-vessel be known, and the degree of condensation at the same time be given, the supply of cold water for that purpose may be ascertained. This will be \( q = \frac{b + d - t}{s} C S n. \)

We have before hinted at the vulgar idea of there being no medium between steam at 212° and liquid water. A doctrine strongly favourable to such an opinion is at present held by several philosophers of eminence. The elastic form of water, at all temperatures below 212°, is supposed to be a solution of water in air. Does any thing like this appear to be the case in the detail of Mr. Dalton’s experiments, to determine the force of vapour of steam at different temperatures? We would ask, where was the air to diffuse the water above the column of mercury, in which water and mercury alone existed? It is admitted on all hands, that steam at 212° can exist independent of air, and where have we become acquainted with any rule, that aqueous vapour cannot exist in a separate state at other temperatures? This is certainly the case with respect to water; and it is highly probable, that a portion of all the solid and liquid matter on the globe exists in the elastic form, in proportion to the temperature. What is the smell we perceive from melted metals, and at a much lower temperature with some of the metals? This is very conspicuously observed in heating copper-plates and fleet-lead. The odour of cast-iron is particularly flaming.

There can be no doubt that elastic mercury exists in the space above the mercury in a barometer, since the condensed mercury is seen frequently to coat the interior surface.

These appearances would be oftener observed, if it were not for the difficulty with which evaporation takes place, from the body affording the vapour being surrounded with vapour of its own and others. The presence of any elastic fluid mechanically refills further evaporation, to a degree more than is conceived. If water be exposed to a vacuum, a quantity of vapour depending upon the temperature would in a little time occupy the space; the first portion would project itself with great rapidity, and the last very slowly. The temperature being raised, would cause successive portions to rise, the limit being what we have shewn in the table. If at any temperature the vapour, already suspended over the water, be removed by a current or by an air-pump, the processes would be greatly facilitated, as we observe in the drying of the ground in a brisk wind. This shews that the vapour of water refills evaporation more than the air itself; perhaps in the same medium, its retarding power increases as the density. The advocates for the solution of water in air have said, that the capacity of air for moisture is inversely as the density, whether this difference of density arises from the nature of the gas, or from rarefaction. It ought very properly to be asked, at what degree of rarefaction is the dissolved water a maximum? The most probable anwer would be, at the limit of rarefaction. This is contrary to all laws of solution. If air can chemically combine with water, every particle of air may combine with a particle of water; and the quantity of water in a given space would be the greatest, when the air was the densest. If we had no direct proof that a given space will contain the same quantity of water, whether air be present or not, the hypothesis of the chemical solution of water in air could not be defended.

We have seen that the quantity of water in a given space is as the force of vapour in inches of mercury, because the density must be as the pressure. Mr. Dalton has ascertained by experiment, that the rate of evaporation, at a given temperature, is as the force of vapour at the same.

This fact leads to the conclusion, that since the density is also as the force of vapour, the velocity of diffusion through the air is the same at all temperatures. Since, however, the atmosphere always contains some moisture, the next evaporating power will be as the difference between that force of vapour answering to the temperature at which dew would begin to fall, and the temperature to which the evaporating substance is exposed. That point in the atmosphere where dew falls, is called by Mr. Dalton the dew-point. The manner of finding this is as follows: Take a tall cylindrical bottle, about one foot high and three inches in diameter; or, if this is not at hand, a common decanter. Fill it with water so much colder than the air, that the bottle may appear misty, when it is put into it. If no appearance of this kind is observed, the water is not cold enough; and ice, or some freezing mixture, must be added to it. The bottle, when filled, must contain a thermometer. When the dew appears upon it, wipe it off with a clean dry cloth; and continue to do so till no more dew appears. Then observe at what degree the thermometer stands in the bottle, which will never be greater than the temperature of the air, which must also be noted. Then find in the table the force of vapour at the temperature of the dew-point, and also the force of vapour answering to the temperature of the atmosphere, or that of the mass which is the source of the vapour. The difference between these two columns of mercury will be expressive of the rate of evaporation.

In order to obtain absolute data for these proceedes, we shall make use of Mr. Dalton’s facts, which were derived from careful and judicious experiments. He exposed water to different temperatures, to observe the weight evaporated in a given time. These vessels were of a cylindrical form, one being 34 inches in diameter, and the other 4 inches. The latter vessel, when the water in it was just made to boil, loft from 35 to 45 grains per minute; this difference being occasioned by a greater or lesser current of air passing over it. The quantities evaporated at different temperatures were found to agree exactly with the force of vapour. 

Vol. XXXIV.
From a vessel of six inches in diameter, he found that at 212° the mean quantity evaporated in one minute was 154 grains. Then since the mean of the small vessel was about 40, if the quantity be as the surface, we ought to have

\[
\frac{154}{40} = \frac{5}{6},
\]

which is very near; for if the small vessel had been 3.05, then the squares would have been in the ratio of 154 to 40.

Mr. Dalton has constructed a table on these data, which, from its great utility in all inquiries relating to the moisture in the atmosphere, cannot fail to be acceptable.

**Table**, showing the Force of Vapour, and the full evaporating Force for every Degree of Temperature from 20° to 85°, expressed in Grains of Water raised per Minute, supposing no Moisture in the Atmosphere at the Time.

</table>

In order to apply this table to practice, in finding the rate of evaporation at any time, suppose the dew-point found, as above directed, to be 25°, and the temperature of the air at the same time 70°. We find in this table, that the mean rate of evaporation at 45° is 1.62 grains in a minute, the rate at 70° being 3.72. Then 3.7 - 1.62 = 2.08 grains, the quantity evaporated in a minute, under such circumstances. If the example were to ascertain the rate of any artificial evaporation, the temperature of the mass exposed must be taken, instead of the temperature of the air. It must also be observed, that if a brisk wind prevails, the grains evaporated must be taken from the column marked "greater extreme." If there be no wind, look at the "lesser extreme" column; and in a moderate breeze, take the "mean" column. By this means we are enabled to ascertain, at any time, not only the rate of evaporation, but the quantity of water contained in a cubic foot of space.

From the decrease of temperature in the upper regions of the atmosphere, and the greater decrease of the force of vapour at those temperatures, the greatest parts of the water which rises from the earth will be precipitated at a very small height.

If the temperature were taken by a thermometer, the degrees of which should be equal increments of heat, aqueous vapour at any temperature would become of half this density,
STEAM.

flying, by a decrease of temperature equal to 25°. And since, at the intervals of every six miles above the surface of the earth, the pressure, and of course the force of vapour, is halved; the quantity of water in a cubic foot of space must diminish very fast with the height. At the temperature of 50°, when the atmosphere contains as much moisture as the temperature will admit, it contains only 3.5 grains in a cubic foot; and if the temperature upward were to vary no more than 25° for every six miles, at 20 miles high, there would be little more than one grain of water in a cubic foot of space. But the temperature is known to vary much more rapidly; and hence we should have much less water in the same space, on account of the condensation resulting from this greater decrease. Still, however, some portion of water must exist in the very limits of our atmosphere, in a state of steam or vapour of some density; and this vapour is still within the limits of fact the 4th, before given, 8vs. If such vapour were compressed till its density was equal to 253 grains in the cubic foot, its temperature would be 214°, whatever might be its temperature previous to its compression. The same thing, as Mr. Dalton has very ingeniously supposed, would be the case with the air itself; that is, if the rarefied part of our atmosphere were condensed to the density of that at the surface, its temperature would also become the same. This change of temperature in elastic fluids, by rarefaction or condensation, is evidently owing to a change in their specific heat. We have lately heard of a fact, which has excited the curiosity of some philosophers, and surprised others, which is as follows. When steam, of very considerable density from pre-
fusion, is made to issue from the mouth of a pipe, a person may place his finger close to the aperture, without feeling any unpleasant effect from the heat. The sensible heat of this steam, which would otherwise escape, is absorbed by the sudden change of specific heat, by the expansion of the steam. This fact is very analogous to an experiment which has been long known. When the bulb of a thermometer is placed within the nozzle of a pair of bellows, and a blast sent through them, the mercury rises above the common temperature; but if the bulb be placed at a little distance from the nozzle, the mercury falls below the common temperature. In the first instance, the air was compressed, and the heat given out; in the second, heat was absorbed, and consequently the temperature lowered. The cold produced by the exhaustion of the receiver of the air-pump is to be explained in the same way.

The change of temperature of the atmosphere is doubt-
less more regular at considerable elevations, than near the surface; hence the air in which we live is frequently in a strong evaporating state, while condensation is taking place in the superior regions. This gives rise to numerous clouds, which are nothing more than water in small globules, having lost their elastic form by condensation. The changes of temperature, which take place from the various currents arising from the action of the sun upon the earth, materially and constantly change these appearances; sometimes causing the disappearance of opaque clouds, and at other times darkening the air by sudden condensation. We can but, therefore, regard the water in the air as existing in two states, namely, in the liquid and in the elastic state, between which there can be no medium: for evaporation or condensation must be the result of the slightest change of temperature; we may conclude, that one of these processes will commence with the change, and will progressively go on till as much water is either precipitated or taken up as the temperature will admit. Evaporation, as we have before observed, can never be instantaneous; even if the air did not mechanically refill it, the presence of the vapour already formed would have that effect. Although there appears to be no medium between water and steam, the actual precipitation of the water is progressive, and is more or less rapid at different times. The clouds which appear to be suspended in the atmosphere are constituted by an assemblage of small globules of real water, which in vacuo would be precipitated with a rapidity agreeing with the laws of falling bodies; but in consequence of the resistance of air, their descent is retarded, being dependent upon the ratio between their surface and solidity.

There are good reasons for supposing that these globules are prevented from uniting by the presence of electricity, as we know that they must repel one another when they are similarly electrified. On the contrary, when particles are intermixed having contrary states of electricity, the condensation will be much facilitated, as we perceive in rain immediately succeeding thunder. In all those situations where steam undergoes condensation, we do not see water immediately precipitated. The milky appearance is caused by small globules of real water falling towards the earth with a small but progressive velocity. If the change of temperature causing the condensation be very slow, the globules are extremely small in the first instance, and are with more difficulty united. This is doubtless the case with all bodies which are perfect liquids. Globules of mercury are united with greater difficulty the smaller they are. The state in which mercury exists in liquid form, is in these minute globules produced by the mechanical action in mixing it. If boiling water is poured upon mercurial ointment, the fat is separated and floats upon the water; this may be poured off, and the mercury will be left in minute globules, which are united with great difficulty. It occupies a much greater space than when united, having the appearance of froth. Such is the state of water forming the white fleecy clouds which we frequently observe at a great height; the dense dark-coloured clouds being composed of larger globules, which seldom remain long before they are more completely formed into drops of rain.

The clouds, therefore, are not to be considered as absolutely suspended, but as water in globules of different magnitudes, falling with a velocity in the inverse ratio of their magnitudes. There is nothing hypothetical in this idea, since it is within the limits of calculation to ascertain the magnitude even of particles of lead falling through any assignable space in a given time. We cannot demonstrate the principle better than by solving the following problem.

What must be the diameter of a globule of water, to be capable of falling one inch in a second, after it has acquired an uniform velocity.

Let \( e \) = the specific gravity of the air through which the steam falls, water being 1.

\( \rho = 3.1416, \&c. \)

\( g \) = the space a body falls in one second by gravity.

\( v \) = the velocity.

\( s \) = the diameter of the globule which is required.

Then, since the particle will cease to be accelerated when the resistance is equal to its weight, the velocity at that point will be \( v \), which it will uniformly retain, all other things remaining equal. The space fallen through to give \( v \), will be \( \frac{v^2}{2g} \); this, multiplied by \( \rho s^2 \), will give the \( \frac{4}{3} \pi s^3 \) content.
STEAM.

content of the cylinder of air; and \( \frac{\rho \cdot v \cdot a}{8g} \) = the weight of the cylinder. This would be equal to the resistence, if the surface presented to the refisting medium had been a plane perpendicular to the direction. The resistence of such a surface to that of the spherical one, is as 1 to 2.

Hence the resistence will be \( \frac{\rho \cdot v \cdot a}{16g} \).

The weight of a globule of water of the diameter \( a \), will be \( \frac{1}{6} \cdot \rho \cdot a^3 = \frac{\rho \cdot v \cdot a^3}{16g} \). Then, since \( r = 1 \) inch, \( g = 194 \) inches, \( \epsilon = .0018 \), \( \rho = 3.1416 \),

\[ \frac{a}{6} \cdot \frac{3}{8} \cdot \frac{1}{194} \cdot \frac{1}{0.0018} \cdot \frac{3.1416}{194} = .0000461 \text{ of a grain, and in weight only .0000461 of a grain.} \]

When we consider how inconceivably small the atoms of water must be, it will be easy to conceive globules of water much smaller than the above calculation gives.

We are quite aware of the difficulties attendant on the belt theory of clouds and rain. If the view we have given is supported by facts and observation, which at present appears to be the case, we may expect it to stand on firmer grounds than has hitherto been the fate of numerous hypotheses, as it is free from any thing gratuitous or hypothetical.

Steam is at present applied to many economical purposes, as well as in various manufactures, independent of its important office in the steam-engine.

In dyeing, bleaching, and many other similar departments, it is used to communicate heat to water, instead of having separate fire-places and boilers. The vessels to contain hot water, which were formerly separate pans or boilers, are now supplied from one principal close boiler, similar to those used for steam-engines, by separate steam-pipes. When the economy of the steam is considered an object, the pipes for conveying the steam should be cased with wood, or otherwise covered with some bad conductor of heat, which will not be affected by the heat of 212 degrees.

The boiler, which supplies the steam, should be placed lower than any reservoir of water which it has to heat, as in that cafe the water, which may sometimes condense in the pipes, may run back into the boiler. This affords a little economy, by favoring the degrees of heat between the hot water and the cold, with which the boiler is supplied. Another advantage is in the pipes not being liable to be choked by the coagulating water not being allowed to get out of the way of the steam. For heating water in brewhouses, walk-houses, dyeing-vats, &c. the steam-pipe comes directly into the water, the steam passing into the flame making a loud noise, like the rapid cracking of a whip. For heating large baths and buildings, the steam is condensed in the pipes which pass round the bath or around the rooms, and the water should in this case run back into the boiler. The pipes, or other metallic vessels in which the steam is condensed for the purpose of warming rooms, should be coated with paint, the blacker the better. This is found to give heat much more rapidly than the metallic surface, and in a still greater excess above a polished metallic surface.

When steam is employed for the purpose of heating water, the supply for a given quantity of water will be easily calculated by the data already given.

Let \( L \) = the heat required to convert water into steam at 500 degrees.

\( W \) = the weight of the water to be heated by steam.

\( T \) = its temperature.

\( t \) = the temperature to which it is required to be heated.

\( S \) = the weight of steam required.

\( b \) = the temperature of the steam.

Then 
\[ \frac{L}{W} \cdot S + \frac{T}{S + W} \text{, and } S = \frac{L + b - t}{b - t}. \]

A simple rule for finding the quantity of steam required to raise a given weight to any given temperature arises out of this formula. Multiply the water to be warmed by the difference of temperature between the cold water and that to which it is to be raised for a dividend. Then to the temperature of the steam add 500, and from the sum take the required temperature of the water. This half remainder being made a divisor to the above dividend, the quotient will be the quantity of steam, in the same terms as the water.

What quantity of steam at 212 degrees will raise 100 gallons of water at 60 degrees to 212 degrees? 
\[ (212 - 60) \cdot 100 = 152 = \frac{900}{9} \]

17 gallons of water, formed into steam. This quantity of steam from a boiler containing about 27 cubic feet, with a fire applied to the boil advantage, will be fulfilled in 2 hours and 16 minutes, supposing no heat to be lost by the heated mass being exposed. The coal consumed for this purpose will be about 23 or 24 lbs., depending on its quality.

The theorem above given will apply to any temperature above 212 degrees, when the steam is under greater pressure than 20 inches of mercury. It will also appear from the table of the force of vapour, that any degree of heat short of endangering the vessels, may be given by steam under different degrees of pressure. Such means are at present employed for evaporating water from sugar, salt, and other fluids requiring a greater degree than 212 degrees. It will be equally obvious, that an uniform heat may be kept up below 212 degrees, by adjusting the steam-cock through which the medium to be heated is supplied. In giving heats above 212 degrees, the vessels should be completely steam-tight, and very strong. The boiler should have a safety-valve, which should always be kept clean and free to act.

Steam is employed to great advantage for culinary purposes. It is made to communicate with vessels in the form of boilers, as a substitute for having fires under them, which is a great advantage, both in the economy of fuel, and in avoiding at the same time the nuisance of ashes and smoke.

The most convenient application of steam for culinary purposes is, when it directly acts upon the substance to be heated. This has been generally effected by placing the substance, whether meat or vegetables, in a vessel without water, and allowing the steam to enter and condense upon it. The most convenient apparatus of this kind we have yet heard of, consists of a cast-iron plate about 30 inches or three feet square, standing horizontally in a receve in the wall, like a table. Round the edge of this plate is a groove, about half an inch wide and two inches deep. Into this groove fits an inverted tin-veil, like a dish-cover. This is capable of being elevated and depressed by a pulley and chain, having a counterpoise,
STEAM.

terpoles, in order to expose the table at any time. The steam comes under the table and enters in the centre. The dishes to receive the heat are placed on any part within the groove, the steam being common to all. The water resulting from the condensation runs into the groove, and at a point short of the top runs off. The water which remains forms a complete water-lute, to prevent the escape of steam. The table being placed in a recfex, like a common stone hearth, a small flue is placed over it to take away any steam that may escape when the cover is lifted up.

The great quantity of hot water required in a scullery should be one flue connected up to the bottom of the cylinder, by which the latter is kept constantly full. The hot-water cylinder is closed firmly at the top, and therefore, when the air is allowed to escape, the water rises to the top. If now a pipe be connected with the top, coming down to where it is to be drawn off, and any portion be drawn out here, as much will come in at the bottom of the cylinder from the re protector above. So far we have described this cylinder without its steam-vessel. Within this cylinder, and about the middle, is a distinct vessel, nearly of the width of the cylinder; but having a free space round the inner vessel about an inch wide. The depth of the inner vessel must be about one-sixth that of the outer one. This inner vessel must have no connection with the outer one, and must be so water-tight, that although it is surrounded with the water of the outer one, none should get in. The inner vessel is on one flue connected the pipe with a steam-boiler, having another pipe to allow the condensed water to run off, which may be preferred as distilled water, and is valuable for many purposes. The heat arising from the condensation is communicated to the water in the outer vessel, the hottest being at the top, where the mouth of the exit-pipe is placed. When, therefore, a portion of hot water is drawn from the cock, the pipe of which comes from the top of the vessel immediately under the cover, an equal quantity comes in at the bottom from the re protector. This is the apparatus is the invention of an ingenious person, a citizen of Derby, and is at present in use in his kitchen.

When steam is properly applied to the warming of baths, the economy is so great, that if it were known, these exquisite luxuries would soon become more fashionable. The steam is condensed in pipes about two or three inches in diameter, which are placed round the bottom of the bath. These pipes are concealed in a recex, which is afterwards covered by thin stone plinths, perforated with holes to allow the water to circulate.

We shall point out the economy of these baths, by giving some facts of a bath in common use. Its size is about 10 feet square, and its depth such as to contain about 520 cubic feet. The steam at 212°, to first raise it from 32° to 96°, will be found by the above theorem to be as much as will condense it into 33 cubic feet of water. This will be produced by 30 lbs. of coal, including that required to raise the 33 cubic feet of water from 32° to 212°, which is always about 3th of what will afterwards make it into steam.

Supposing the bath to have double doors, and a small skylight instead of common windows, it will be found, when the outer air is 45°, that the bath will not cool more than 4° in 24 hours. To reheat this every day, will require only 3th of what was required to raise it from 32°. This will be about 23.5 lbs. Supposing the whole water of the water to be changed by a regular inlet and outlet every 14 days, then the weekly supply of coal for such a bath will be about 350 lbs.

It is suggested by Dr. Darwin, that the art of boiling vegetables of all kinds in steam instead of water, might probably be managed to advantage, as a greater degree of heat might be thus given them, by contriving to increase the heat of the steam after it has left the water; and thus the vegetable mucilage in roots and seeds, as in potatoes and flour-puddings, as well as in their leaves, stems, and flower-cups, might be removed, probably more nutritive, and perhaps more palatable; but that many of the leaves of vegetables, as the fumus of cabbage-fsprouts, lose their green colour by being boiled in steam, and look like blanched vegetables. This etiolation of some vegetables by steam is probably owing to its dissolving their colouring matter, which may then become decomposed, and may render them less agreeable to those who choose by the eye rather than the palate; which green colour is, however, heightened by boiling them in some hard waters which contain an un decided lime or soda, or by a slight admixture of common salt with soft water; an effect which is owing to the evaporation of a part of the marine acid, and to the remaining alkali which was the basis of it, when applied to blueish vegetables converting them into green, as in the common experiment of adding salt of tartar to syrup of violets, or according to the custom of some cooks who add a little potash, or fixed vegetable alkali, to the water in which young peas are boiled, to make them green, and afterwards a very little sugar to sweeten them. And the same effect of making vegetables green, when boiled in another kind of hard water, is probably produced by the lime which abounds in them, and which, like the vegetable alkali, when the aerial acid which was united with it evaporates, is said to convert bluish vegetable colours into green ones.

Steam has likewise lately been applied in gardening to the purpose of forcing plants of different kinds in the winter season, in order to have their produce at an early period, as to the cucumber, and some other vegetables of a somewhat similar nature; but the exact manner of its application in this instance, so far as we know, has not yet been communicated to the public; it is, however, by some mode of fluxes, pipes, and other contrivances for conveying and containing it, so as to allow its heat to be uninterrupted, equally, and regularly afforded to the roots of the plants which it is designed to push forward into the fruiting state. It is said to have been used in some instances in different parts of Lancashire with great success. But how far the expense and advantage of such a method may admit of and encourage its being introduced into general practice, have not, probably, yet been well or fully ascertained. If it should be found capable of perfectly succeeding in this use, on more full and correct experience, it will, however, constitute not only a neat and clean, but an elegant mode of forcing plants into fruit at early seasons.

It has been found that subterranean steam often affect the surface of the earth in a particular manner, and promote or retard vegetation more than almost any thing else.

Steam-Engine, or Fire-Engine, a machine very generally employed in this country as a first mover of other engines and machines, its mechanical force or moving power being obtained from the expansion or contraction of the steam of boiling water. Until of late years this machine was called the fire-engine, because it is in reality excited by the fire which carries the water to boil.
STEAM-ENGINE.

The steam-engine is an invention highly creditable to human genius and industry, and is amongst the most valuable applications of philosophical principles to the arts of life. The invention of a ship, with all her accoutrements, and the degree of knowledge requisite to conduct her through a distant voyage, are more striking instances of the power of the mind of man, and of his enterprising disposition; whether we consider the number of sciences which must be applied to practice in the construction and management of a vessel; or the advantages which mankind have derived from such an invention, and the improvements which it has occasioned in the state of civilization, by uniting, in a great degree, all the inhabitants of the globe in one society, who mutually supply each other's wants, and who all contribute their share to the general flock of knowledge.

The steam-engine follows next to the ship in the scale of inventions; but in an English Cyclopaedia it will take the lead, from the circumstance of its being wholly invented, and brought into general use, by our own countrymen, within the space of a single century; and also as having been the principal means of effecting those great improvements which have taken place in all our national manufactories within the last thirty years; and the increase of our commerce which has ensued.

The art of navigation is the result of the combined ingenuity and experience of all nations, from the earliest period of history to the present time; and the successive and almost imperceptible improvements by which it arrived at its present state of perfection, have many of them been the productions of accident, and for which we do not exactly know to whom we are indebted. But the steam-engine is the invention of a few individuals, all of them Englishmen; and brought into general use within a century. In the first beginning it was the result of reflection, and the production of a very ingenious mind; and every alteration in its construction and principle was also the result of philosophical enquiry.

General Principle of the Steam-Engine.—The force of the steam-engine is derived from the property of water to expand itself, in an amazing degree, when heated above the temperature at which it becomes changed into the state of vapour, which being an exceedingly elastic fluid, can be retained within the close vessel or boiler to which the heat is applied, even when it has an expansive force sufficient to make it fill, if left at liberty, 20 or 30 times the space in which it is confined. In this state the steam will exert a proportionate force or preffure to burst open the sides of the vessel in which it is retained; which force may be applied either to expel or raise up water from any vessel into which the confined steam is admitted, or to give motion to a moveable piston, which is so accurately fitted to the interior capacity of such vessel, as not to permit the escape of the steam between them.

Another source of the power of the steam-engine is the facility with which steam of a great expansive force can be cooled by the application of cold water, and condensed into the small quantity of water from which it was originally produced. A partial vacuum can thus be made, in a very large vessel, in an instant, and even in the same vessel, which was a moment before, filled with confined steam, exceeding $212^\circ$ Fahrenheit's thermometer. The preffure of the atmosphere which tends to fill up this vacuum, can be made to produce the ascent of water into the vessel to any height less than twenty-four or twenty-five feet. Or the preffure of the atmosphere may be made to give motion to a piston, by admitting the atmospheric air to press upon one side of the piston, whilst there is a vacant space formed by the condensation of the steam which filled the cylinder on the other.

Notwithstanding the great variety of different constructions of the steam-engine, they all derive their force from one of these two principles, or from the combination of the two; but before entering upon any description of the manner in which these forces are applied, it is necessary to have clear ideas of the nature of steam, and of the law by which it expands by heat, in order to form a precise judgment of what praises in the interior part of a steam-engine when it is at work. In the common acceptance of the word steam, it is that hot white vapour which we see every day rising in a cloud from a tea-kettle or boiling-pot; but this is not exactly the state of the steam employed in an engine; it is there perfectly transparent, and is more or less hot than boiling water, according as it is retained under a lesser or greater degree of preffure. The ordinary preffure of the atmosphere, bearing upon the surface of water, will retain it in a state of fluidity, until it is heated to what is generally called the boiling point, and is marked $212^\circ$ in Fahrenheit's thermometer. If the heat is increased above that degree, and if the water is unconfined, except by the preffure of the atmosphere, the water immediately assumes the aeriform state, and flies off in elastic vapour, which we call steam; but if the same water is relieved from the preffure of the atmosphere by enclosing it in a close vessel, and exhausting the air from it, a certain portion of steam or vapour will rise from the same at any temperature, even when it is as low as freezing; and if this vapour is conveyed off from the vessel as fast as it rises, the water, although cold, will boil, and such vapour will rise as fast as the boiling kettle does in the open air. If the vapour is retained in the vessel, it will only accumulate, until it has acquired a certain degree of elastic force to press upon the surface of the water, which will then cease to yield any more vapour, until the heat is further increased, or that the vapour is drawn off to relieve the water from the preffure which confined and retained it in its fluid state. On the other hand, water which is retained in a close vessel, under a greater degree of preffure than that occasioned by the pressure of the atmosphere, will not boil or rise in vapour, until it becomes heated to a higher temperature than $212^\circ$. It is even probable, that water might be compressed to that degree, that it would not boil until heated red-hot; but this would require such an enormous strength in the vessel which should contain the steam, that it is far beyond the practicability of an experiment.

In this manner the reader is to bear in mind, that vapour or steam, when confined in close vessels, is always more or less elastic, in proportion to the degree of heat which is applied to it; or, in other words, that the temperature of the steam is an exact index of the elastic or expansive force with which it presses upon the surface of the water, and against the interior surface of the vessel which contains it.

The following tables shew the law by which the expansive force increases with the increase of the temperature. They were made from the experiments of Mr. John Dalton, which he published at length in the "Memoirs of the Literary and Philosophical Society of Manchester," and experiments have been also made in France by M. Betanier. The preffures in the following tables, do not differ from those in the preceding table so much as to affect the results in any great degree, when applied to practice, in calculating the force of steam-engines. These experiments were made by enclosing water in a clove vessel, from which the air was carefully exhausted, so as to make a vacuum. A thermometer was applied, so as to indicate the
STEAM ENGINE.

The temperature of the interior of the vessel; also there was a communication made from the vessel to the lower part of a fihon barometer tube, that is, an inverted glass fihon filled with mercury, from one leg of which the pressure of the atmosphere was excluded, and the other leg communicated with the interior of the vessel. In this way, when there was a vacuum in the vessel, the surface of the mercury in the two legs of the fihon would stand at the same level, because it would not be pressed upon at all on either side; but when any vapour was raised in the vessel, it would press upon the interior surface thereof, and also upon the surface of the mercury in one of the legs of the inverted fihon; and as the surface of the mercury in the other leg would not be pressed upon at all, the mercury would mount in one leg and descend in the other, and the difference of the level between the two being measured, would express the elastic force of the vapour, which was found to increase with the increase of the heat, according to the second column of the table. For the convenience of estimating the force of the vapour, we have added the third and fourth columns to Mr. Dalton's table. The third, to express the pressure by the altitude of a column of water, instead of mercury; and the fourth column to show the pressure upon each square inch of the surface upon which the vapour acts, in pounds anywhere and decimals. The table also shows, in the third and fourth columns, the difference of pressure between the vapour and atmospheric air in three different terms, viz., in the column of mercury, column of water, and in pounds on the square inch.

In the first table, which is for every 10° of temperature up to 212°, or the heat of boiling water when in the open air, the three last columns shew how high the pressure of the atmospheric air, when the barometer is at 30 inches, will force up mercury or water in a tube, which at the upper end communicates with the vessel containing the vapour, and the lower end is immersed in the mercury or water. And in the second table, which is for the degrees of heat above 212°, the same columns shew how high the boiling force of the vapour will cause mercury or water to mount up in a tube, which at the lower end communicates with the vessel containing the steam, and the upper end is open to the atmospheric air.

History of Invention of the Steam-Engine.—The great elastic force of steam has been long known in the instrument called the aëolipile (see that article); and its property of condensation was also experienced in the use of the same instrument: the manner commonly practised for filling the ball with water being to plunge it into cold water, when heated and filled with steam; by which means the steam is condensed, and forms a vacuum sufficient to draw the water into the ball, although the orifice is so small that water could not be introduced by any other means. At the same time, the true principles of its action were fo little understood, that the steam which issued from it, when placed on the fire, was supposed to be air produced by the decomposition of the water; and nearly all the old philosophers, who have described this instrument, proposed to employ it for blowing furnaces. The first idea of employing this force of steam to produce motion was by Branca, a philosopher of Rome, who contrived a great number of different kinds of mills to be worked by the steam coming from a large aëolipile, and blowing against the floats or vanes of a wheel. We are obliged to this author for a number of other ingenious inventions, which he dedicated to M. Cacci, governor of Loretto, in 1258, and published his work (Le Machine) at Rome the year following. The representation of his fire-machine is given in the twenty-fifth plate; but the force which he could have thus obtained from steam would have been found altogether insconsiderable, if he had ever put it in practice.

The first real steam-engine was invented by the marquis of Worcester; but it was only for raising water, and that by the expansive force of steam alone. The next engine was by captain Savery, and operated, both by the expansive force and the pressure of the atmosphere, to fill up the vacuum which was produced by the condensation of the steam, after it had ceased to operate by its expansion. These actions were employed alternately to raise water. The third inventor, Newcomen, abandoned the force of expansion, and only employed the condensation of the steam to obtain a vacuum, and cause the pressure of the atmosphere to act, unbalanced upon a piston, fitted into a cylinder; and as the force was thus exerted upon a moveable piston, his machine is capable of being applied to give motion to pumps or other machines, whereas his predecessors were obliged to confine themselves to the raising of water. Soon after this invention, engines were proposed with pistons to be actuated by the expansive force of the steam only, without the vacuum. Lastly, Mr. James Watt invented the engines now in general use, which are actuated both by the pressure of steam, and the vacuum acting at the same time upon the opposite surface of the piston.

We owe too much to these inventors, as well as many others, to pass over their discoveries with such flight notice; and shall, therefore, give a detailed history of the progress of this valuable invention, drawn from the best authorities we have been able to obtain.

The Marquis of Worcester's Steam-Engine.—The earliest description
STEAM-ENGINE.

It must be also further considered, that these projects were published at a time when true science was beginning to take place of empiricism.

The Century of Inventions appeared about three years after the establishment of the Royal Society, during the time of Mr. Boyle, Dr. Hooke, Dr. Wallis, sir Christopher Wren, sir Isaac Newton, and others equally skilled in calculations, as in the inventive parts of mechanics.

Under all these circumstances, it is not astonishing that the marquis’s propositions in general should meet with a cool reception, or that this celebrated invention should be condemned to obscurity, amongst the other wonders with which it was accompanied.

We do not wish to be misunderstood, that all the marquis’s propositions, except the fire-engine, are of the same nature as No. 99; on the contrary, several have been re-invented, and proved true, since the marquis’s time; for example, short-hand telegraphs, floating baths, carriages from which the horses can be disengaged if unruly, combination locks, secret eutectheons for locks, candle-moulds, etc. It is also probable that others may be brought to perfection; yet the greater part is so much in the style of the wonderful, that it is to be wished that the marquis had published nothing but No. 63, which at once would have rendered his name immortal, and without any tarnish or alloy to the glory of so great an invention.

Captain Savery’s Steam-Engine.—The next attempt upon record is that of captain Thomas Savery, a commissioner of the sick and wounded, who, in the year 1698, obtained a patent for a new invention for raising water, and occupying motion to all sorts of mill-work, by the impelling force of fire. This patent bears date the 25th July, in the tenth year of the reign of William III., that is 1698. The patent states that the invention will be of great use for draining of mines, serving towns with water, and for working all sorts of mills.

In June 1699, he shewed a working model of his engine to the Royal Society, and in their Transactions for that year, vis. No. 275, vol. xxi. there is the following register:

“Mr. Savery, June 14th, 1699, entertained the Royal Society with shewing a small model of his engine for raising water by the help of fire, which he set to work before them; the experiment succeeded according to expectation, and to their satisfaction.”

The above is accompanied with a copper-plate figure, with references by way of description, from which it appears, that the engine then shewn by captain Savery was for raising water not only by the expansive force of steam, like the marquis of Worcester’s, but also by the condensation of steam, the water being first raised by the pressure of the atmosphere to a given height from the well into the engine, and then forced out of the engine up the remaining height by the expansive force of steam, in the same manner as proposed by the marquis. This action was performed alternately in two receivers, so that while the vacuum formed in one was drawing up from the well, the preasure of the steam in the other was forcing up water into the reservoir; but both receivers being supplied by one suction-pipe and one forcing-pipe, the engine could be made to keep a continual airflow, or so nearly so as to suffer very little interruption.

The inventor afterwards published an account of his engine in a small book, entitled “The Miner’s Friend, or Engine to raise Water by Fire described, and the Manner of fixing it in Mines, with an Account of the several Utensils applicable unto, and an Answer to the Objections made against it,” printed at London in 1704, by Thomas Savery.
STEAM-ENGINE.

man. This little book was separately addressed to king William III., to whom the engine had been shewn at Hampton Court, to the Royal Society, and also to the Mine Adventurers of England, who were invited to adopt the invention.

This engine displays much ingenuity, and is almost as perfect in its contrivance as the same kind of engine has ever been made since that time: we have on that account copied the principal figure, and copied Savery's own description, as given by Dr. Harris, in his Lexicon Technicum. See Plate I. Steam-Engines, fig. 1.

Captain Savery's Description of his Fire-Engine.—A denotes two furnaces, whole fire-places are marked B 1 and B 2, and their common funnel or chimney C.

In these two furnaces are placed two vessels of copper, which I call boilers, the one a larger, as L, the other a smaller, as D.

These boilers have each a gauge-pipe, as G and N, of which G goes within eight inches of the bottom of the small boiler, but N reaches only half way down into the great boiler.

By these pipes, before the engine can work, you must fill the small boiler quite full, and the great boiler two-thirds full of water. Then light the fire under the large boiler at B 1, and make the water therein boil, by which means the steam of it being quite confined must needs be wonderfully compressed, and therefore will, on the opening of a way for it to issue out (which is done by pushing the handle Z of the regulator from you), rush with a great force through the steam-pipe O 1, into the receiver P 1, driving all the air before it, and forcing it up into the force pipe through the clack R 1, as you will perceive by the noise and rattling of the clack; and when all the air is thus driven out, the receiver P 1 will be very much heated by the steam. When you find it is thoroughly emptied, and is grown very hot, as you may both see and feel, then pull the handle Z of the regulator towards you, by which means you will stop the steam-pipe O 1, so that no more steam can yet come into the receiver P 1, but you will open a way for it to pass into O 2, and by that means fill the other receiver P 2 with the steam, as the other was before.

While this is doing, let some cold water be poured on the first-mentioned receiver P 1, by which means the steam in it being cooled and condensed, and contracted into a very little room, and consequently prelling but very little (if at all) on the valve or cock R 1, at the bottom of the receiver P 1, there is nothing there to counterbalance the preffure of the atmosphere on the surface of the water, in the lower part of the sucking-pipe T, wherefore it will be preffed up, and ascend into, and fill the receiver P 1, driving up before it, as it rises, the clack or valve R 3, which afterwards falling down again and shutting close, hinders the descent of the water that way.

Then (the receiver P 2 being in the mean time emptied of its air) push the handle of the regulator from you, and the force of the steam coming from the boiler, will act upon the surface of the water contained in the receiver P 1, where it forces or preffes hard upon it, and still increases its elasticity or spring until it exceeds the weight of the column of water in the receiver and pipe S, which then it will necessarily drive up through the passage Q R 1, Q O 1, into the force-pipe S, and at last discharge it out at the top, as is represented in the figure.

After the same manner, though alternately, is the receiver P 1 filled and emptied of water, and by this means a regular stream is kept continually running out at the top of the force-pipe S, and so the water is raised very easily from the bottom of the mine, &c. to the place where it is designed to be discharged.

"Only I should add, that after the engine begins to work, and the water is riven into and hath filled the force-pipe S, then it fills also the little ciffern X, and by that means feeds the pipe Y Y, which I call the-feeding-pipe, and which can be turned sideways over either of the receivers, and be then be open: by this cold water is conveyed down from the force-pipe to fall upon the outsides of the receivers when thoroughly heated by the steam, in order to condense the steam within, and make them suck (as it is usually called) the water out of the well up into the receiver.

"Also a little above the ciffern goes the pipe E, to convey water from the force-pipe into the leffer boiler D, for the purpose of replenishing the great boiler L, when the water in it begins to be almost consumed. Now when there is need of doing this, turn the cock E, so that there can be no communication between the force-pipe S and the leffer boiler D; and putting in a little fire under the small boiler B 2, the water shall there grow presently hot; and when it boils, its own steam, which hath no vent out, prelling on its surface, will force the water up the pipe H, through X, into the great boiler L, and so long will it run till the surface of the water in the boiler D gets to be as low and at the bottom of the pipe H, and then the steam and water will run together, and by its noise, and rattling of the clack L, will give him that works the engine sufficient assurance that the small boiler hath emptied and discharged itself into the greater one L, and carried in as much water as is then necessary; after which, by turning the cock E again, you may let new cold water out of S into the leffer boiler D, as before, and thus there will be a continual motion and a continual supply of the engine, without fear of decay or disorder.

"Also, to know when the great boiler wants replenishing or not, you need only turn the gaug-box N, and if water come out there is no need to replenish it, but if steam come only, you may conclude there is want of water; and the like will the cock G do in reference to the leffer boiler D, shewing when it is necessary to supply that with fresh water from S; so that in working the engine there is very little skill or labour required; it is only to be injured by either a stupid or wilful neglect.

The engine above described does not differ essentially from that represented in the print in the Philological Transations, but it is more nearly put into form, and improved in some of the minor particulars. For instance, the original engine had only one boiler, and there was none of supplying it with water, to replace the waste occasioned by the evaporation of the steam, without stopping the action of the engine whenever the boiler was emptied to such a degree, as to r ilk the burning of the vellis. And after the boiler was replenished, the engine could not begin to work again, until that water which was introduced cold was made to boil.

The engine which we have just described from the Miner's Friend has a subfdary boiler, in which a quantity of water is reduced to a boiling heat in a few minutes for supplying the great boiler, and the power of the steam raised in the subfdary boiler is employed to force the water contained in it into the other, or great boiler, which actuates the engine; by this means the transposition of the feeding water is not only infantly performed, but being at a boiling heat, it is immediately ready to produce steam for carrying on the work. There is also another great improvement in the construction of this engine. His steam engine was worked by four separate cocks, which the operator was obliged to turn
STEAM-ENGINE.

turn separately at every change of stroke; and if he turned them wrong, he was not only liable to damage the engine, but he prevented its effect, and lost a part of the operation; whereas in this second engine the communications are made by the double sliding-valve, or regulator, as it has since been called. This is a brass plate, shaped like a fan, and moving on a centre within the boiler, so as to slide horizontally in contact with the under surface of the cover of the boiler, to which it is accurately fitted by grinding, and thus at pleasure opens or shuts the orifices or entries to the steam-pipes of the two receivers alternately. This regulator acts with less friction than that of a cock of equal bore; and by the motion of a single handle backwards, at once opens the proper steam-pipe from one receiver, and closes that which belongs to the other receiver.

The contrivance of the regulator has since proved of more consequence, as having been universally adopted in the cylinder engines.

Captain Savery, in the Miner’s Friend, above referred to, in addition to the description of his engine, enumerates the following uses to which it may be applied, and which he describes rather fully, as follows: viz. 1st. To raise water for turning all sorts of mills; 2dly, supplying palaces, noblemen’s and gentlemen’s houses with water, and giving the means of extinguishing fires therein, by the water so raised; 3dly, the supplying cities and towns with water; 4thly, draining swamps and marshes; 5thly, for ships; 6thly, for draining mines of water; and 7thly, for preventing dams in the said mines.

Dr. Harris, in his account of the fire-engine, speaks of captain Savery as one that he was acquainted with, and as a person of great merit and ingenuity. He first mentions another machine of Savery’s, for rowing a ship in a calm by paddle-wheels placed at the vessel’s side, of which the captain published an account in 1698; and it is worthy of remark, that the same kind of wheels, when actuated by improved steam-engines, is the only method, amongst an infinite number of others, which at present has been found to answer for rowing vessels. Dr. Harris, in proceeding to the fire-engine, says, “The other engine is for raising water by the force of fire, in which he has shewn as great ingenuity, depth of thought, and true mechanic skill, as ever discovered itself in any design of this nature.” Notwithstanding this, Dr. Defaguiers has endeavoured to take away all the merit of the invention of the fire-engine from captain Savery, as if he had merely copied it from the marquis of Worcester.

The account given by Dr. Defaguiers has been so frequently copied by different writers, that it is generally considered as correct; and we therefore think it a piece of justice to the memory of captain Savery, to set his pretensions in a clearer light than has been generally done. The doctor says, “Captain Savery having read the marquis of Worcester’s book, was the first who put in practice the raising water by fire, which he proposed for the draining of mines. His engine is described in Harris’s Lexicon, (see the word Engine,) which, being compared with the marquis of Worcester’s description, will easily appear to have been taken from the book, with captain Savery denied it; and the better to conceal the matter, bought up all the marquis of Worcester’s books that he could purchase in Paternoster-Row, and elsewhere, and burned them in the presence of the gentleman, his friend, who told me this. He said that he found out the power of steam by chance, and invented the following story to make people believe it; viz. that, having drank a flaks of Florence at a tavern, and thrown the empty flaks upon the fire, he called for a basin of water to wash his hands; and perceiving that the little wine left in the flaks had filled up the flaks with steam, he took the flaks by the neck, and plunged the neck of it under the surface of the water in the basin, and the water of the basin was immediately driven up into the flaks by the pressure of the air. Now he never made such an experiment then nor designedly afterwards, which I thus prove — that in the experiment published about half a flaks of wine in a flaks, which I laid upon the fire till it boiled into flaks; then putting on a thick glove to prevent the neck of the flaks from burning me, I plunged the mouth of the flaks under the water that filled a basin, but the pressure of the atmosphere was so strong, that it beat the flaks out of my hand with violence, and threw it up to the ceiling. As this must also have happened to captain Savery, if ever he had made the experiment, he would not have failed to have told such a remarkable incident, which would have embellished his story.”

This conclusion of the doctor’s is altogether unphilosophical, and does not at all invalidate captain Savery’s account. We know that the marquis of Worcester gave no hint concerning the contrivability or sudden condensation of steam, upon which all the merit of the modern engine depends. The marquis of Worcester’s engine was actuated wholly by the elastic power of steam, which he either found out, or proved by the bursting of a cannon, in part filled with water; but he gave not the least hint that steam so expanded is capable of being again so far contracted in an instant, as to leave the space it occupied in a vessel in a great measure a vacuum. This grand discovery was referred to captain Savery, and his account of its accidental origin is not at all improbable. The captain tells us in the Miner’s Friend, that he did not bring his design to bear, until after a great number of fatiguing inquiries; and he actually erected several machines before he obtained his patent in July 1698. Many objections were made against the grant of that patent being passed; but in the hearing of these objections, the discovery of the marquis of Worcester’s prior claim was not mentioned; and, indeed, it is certain that the account given in the Century of Inventions could not instruct a person who was not sufficiently acquainted with the properties of steam to be able to invent the machine himself.

Defaguiers seems to have been too hasty in concluding that the captain had never made such an experiment as that of the wine-flask, because, in the single instance in which he tried it himself, he found the effect of the condensation took place in a much higher degree than reported by the captain. It is not difficult to conceive that a very small difference in the heat of the steam which filled the flask, and other circumstances, might create the whole of the difference in the result. And, on the whole, there is no reason to hesitate in believing that the captain actually took his hint of the condensation of steam from such an accident, and being of a very mechanical genius, he would naturally turn his thoughts towards the consideration of such a power; and the most obvious application of it would be to a machine on a construction similar to that described by the marquis. Or, if he really had been acquainted with, and considered the marquis of Worcester’s engine, he would easily see that the new principle of condensation might, with great advantage, be combined with the former, and thereby produce an effect more powerful than either of them could do alone. The only thing in the doctor’s account which cannot now be disproved is, that captain Savery destroyed the marquis of Worcester’s books. Even if this is true, it may be accounted for that the captain must, first or last, have become acquainted with what had been before made public by the marquis of Wor-
STEAM-ENGINE.

eater; and after having in his books spoken of his invention, and his new power or cause of motion, and finding the marquis's inventions to be but little known, he might be tempted, in order to secure the whole credit and expected advantage to himself, to buy up the marquis's books and burn them. But the grounds for this assertion are very slight, and will never prevent the conclusion, that the great principle of obtaining force from the prehure of the atmosphere, by the condensation of the steam of boiling water, was a discovery for which we are indebted to captain Savery, who had also the merit of first reducing it to practice in a most complete manner, in combination with the prior discovery of the marquis.

M. AMONTONS' FIRE-WHEEL.—The French writers who have treated of the steam-engine, seldom fail to mention Papin and M. Amontons as the first inventors of the method of raising water by steam, and speak of Savery as a person who put their ideas in execution, and brought them to perfection: we think it right on this account to relate what was done by M. Amontons and Papin, although the attempts of the latter to employ the force of steam are not entitled to any notice, either from their originality, or from their real merit. It is probable, that the news of the patent granted to Savery in 1698, for raising water, and occasioning motion to mill-work by the impelling force of fire, excited the attention of the French academicians, before the means by which it was to be accomplished were made public, so as to be known abroad, and that they were thus induced to attempt the same thing. For in June 1699, which is the same month that captain Savery flew his machine at work before the Royal Society, M. Amontons delivered a memoir to the Royal Academy of Sciences at Paris, entitled “A commodious Way of Substituting the Action of Fire instead of Men and Horses to move Machines.”

This may be regarded as the first attempt to produce a circular motion by the means of fire, otherwise than by the aëolipile, or the fly of a smoke-jack: but as the motion of M. Amontons' wheel was to be produced by the alternate dilatation and contraction of air, and not of the steam of boiling water, it is nothing in common with Savery's machine, except that the first cause of motion is that of fire.

M. Amontons' fire-wheel, as he called it, consists of a number of close buckets, or chambers, placed in the circumference of a hollow wheel, and communicating with each other by valves opening in one direction; and a sufficient quantity of water is put into these buckets to fill about one half of the number: another circle of similar buckets, but of larger dimensions, are placed on the outside of the circle of the former buckets; these large buckets contain air, and each one has a pipe conducted from them to one of the water-buckets which are nearer to the centre: a part of the circumference of the wheel, which is about the level of the centre, is exposed to the fire of a furnace, so that each air-bucket that passes will be heated; and also the lower part of the wheel is immered in a cistern of cold water, so as to cool the same bucket again. The action of the machine may easily be understood. The air contained in the large bucket which is opposite the fire becomes heated and expanded, and by the pipe of communication it is forced into that water-bucket which is at the lower side of the wheel, and preffing upon the surface of the water therein, causes it to mount up through the other chambers, in the direction in which the valves open from one chamber to the next; the water, being thus accumulated in the chambers at one side of the wheel, will give it a preponderating power to turn round upon its axis. This motion brings another air-bucket opposite to the fire, and the air therein expands in its turn, and again elevates the water in the interior chambers as much as it had been heated by the motion of the wheel; a continual succession is thus kept up, and the air-buckets which have passed the fire descend into the cold water, and the air is thereby cooled and reduced to its former bulk. By the communication with the water-buckets, the prehure of the expanded air is removed from within them, and puts them in a state of contraction to repeat their action.

This machine is ingenious, and if a better application of fire, by rareifying water into steam, had not been discovered, it is possible that the invention of M. Amontons might have been further prosecuted. From his computations it would appear, that the machine he proposed would act with a considerabler power; but as he exhibited no working model, or actual trial, it was never proved that the machine, if put into practice, would be capable of producing anything near the effect promised by his calculations. Leopold, in his "Theatrum Hydraulicum," 1724, proposed an improved form of this fire-wheel; and steam-engines have been since made with mercury, or fluid metal, contained within a hollow wheel, which is to be always kept on one side with the mercury by the force of the steam; they have not been found to equal other modes of applying the force of steam. Such of our readers as are curious to know more of the construction of M. Amontons' machine, can consult the original memoir; and they will also find a full account of it, with a figure, in Martin and Chamber's Abridgment of the Philosophical History and Memoirs of the Royal Academy of Sciences at Paris, vol. I.

Papin's Pretensions to the Invention of the Steam-Engine.—M. Papin, to whom the French attribute the invention of the steam-engine, was a doctor of physick, and professor of mathematics at Marburg, in Germany, and in 1680 he was elected a fellow of the Royal Society of London. In the following year, and whilst in London, he invented and published a method of dissolving bones, and other animal solids, in water, by confining them in close vessels, which he called digesters, and which he made sufficiently strong to retain the steam and prevent all evaporation, so as to acquire a great degree of heat. About the same time Dr. Hooke, the most inquisitive experimental philosopher of that inquisitive age, observed that water could not be made to acquire above a certain temperature in the open air, and that as soon as it begins to boil, its temperature remains fixed, and an increas of heat only produces a more violent ebullition, and a more rapid waffe. Papin's experiments with his digester rendered the elastic power of steam very familiar to him, and when he left England, and settled as professor of mathematics at Marburg, he made many attempts to employ this force in mechanics, and even for raising water.

By his own account, it appears that he had made some experiments with this view in 1698, by order of Charles, landgrave of Hesse, but without effecting anything. This is all the reason the French have to consider him as the first inventor of the steam-engine. Nine years after Savery's patent he published an account of his invention, in a tract, entitled "Ars nova ad aquam ignis admiculum efficacissime elevandam"—"A New Method of raising Water by the Force of Fire," printed at Cael, 1707. This machine, which is described in Belidor's "Architecture Hydraulique," vol. ii. does not essentially differ from that of the marquis of Worcester; but is far less perfect than Savery's: it works wholly by the repellent power of steam; the only advantage is, that the receiver being made cylindrical, the steam is separated from the cold water by a floating piston, and that the water is made to flow in some degree coolantly, by being thrown into a large air-vessel. In this publication, Papin admits
STEAM-ENGINE.

admits that he had seen a draft of Savery's engine, but says, that in the year 1698 he made a great number of experiments, by order of his serene highness Charles, landgrave of Hesse, in order to raise water by the force of fire, which he communicated to several persons, and particularly to M. Leibnitz, who answered, that the same thought had occurred to himself. He also acknowledged that captain Savery was about that time working upon the same subject in England, and that Savery had first published the fruit of his researches; that from 1698 the affair had lain dormant till the year 1705, when he received a letter from M. Leibnitz, then in London, which contained a draft of captain Savery's engine, and defied Papin's opinion upon it. He showed this draft to the landgrave, he ordered Papin to refuse the work, and perfect the inventions which he had begun; and which Papin then published, not with a view to make it suppos'd that captain Savery had taken the thoughts from him, but to show the world its obligation to the landgrave, in having first formed a design so useful, and in having brought it to its present degree of perfection; and he labours much to show that his engine is preferable to that of captain Savery. Although we must allow Dr. Papin to compliment his patron and himself upon the successe they met with, after encountering many unforeseen difficulties and experiments, which succeeded, as he tells us, quite contrary to their expectations; yet it cannot be denied that the experiments put in 1698 were the first, because the marquis of Worcester's publication was earlier by no less than thirty-five years; nor were they probable to have been so early as Savery's beginning, since we cannot suppos'd that he would be at the expense of a patent, without some previous experiments to confirm his speculations, or that he could bring his engine to the degree of perfection in which he exhibited it to the Royal Society on the 14th of June, 1699, in less than a year, at a period when workmen were not ready or skilful in the execution of such machines.

We have copied the figure of Papin's engine from Belidor, that our readers may be able to compare it with captain Savery's, and judge of the authority upon which M. Boffill has laid in his Hydromatique, that the first notion of the steam-engine was certainly owing to Dr. Papin, who had not only invented the digester, but had, in 1695, published a little performance describing a machine for raising water, in which the pistons are moved by the vapour of boiling water, alternately dilated and condensed. Now the fact is, that Papin's publication on the steam-engine was in 1705, in which is contained the invention to Savery. He had occasionally before that published several inventions in the Acta Eruditorum, in which cylinders and pistons were to be employed, but they were not intended to be worked by steam, but by gunpowder and air, as we shall shew hereafter.

Description of Papin's Engine.—The intention of Papin's steam-engine was to turn a water-well by a stream of water issuing with violence from an aperture or jet, the force of steam being employed to throw the water into an air-veisel, from which it was to issue by the re-action of the compressed air. A vessel of wood, $A$, (6) in which the lower axis is supposed to be 36 inches, and the letter axis 20 inches, is placed in a furnace, so that the fire can surround every part: this veisel or boiler, which is made of copper, should be two-thirds full of water, which is introduced by a tube $B$; a fiphon, $C D$, communicates from the boiler $A$ to a cylinder $G H$, of 20 inches in diameter, and about the same in height, which performs the office of the barrel of a pump, and which moves a copper'piston, $S T$, made hollow within, so that it may float upon the water: the base of this cylinder, which has no bottom, is joined to the extremity of a curved tube, $I K O$, which goes through the bottom of another cylinder, $M N$, of three feet in height, and 23 inches diameter, which is closed at all parts, so that the air cannot enter. A veisel $Y$, made like a funnel at the top, is adapted to the tube $I K O$, and serves to introduce water into the body of the pump $G H$, beneath the piston $S T$, which water can never rise above the piston. A cock at $E$ alternately opens and shuts the communication through the fiphon $C D$, between the boiler $A$, and the body of the pump $G H$. When the communication is open, the steam formed in $A$ passes into the upper part of the body of the pump, and preffes the piston, which displaces the water: this water cannot return into the veisel $Y$, because a valve at $R$ prevents it; it therefore rises by the tube $I K O$, and discharges itself into the cylinder $M N$, where it fills a part of the space occupied by the air contained in that cylinder, which, in consequence, acquires a great elaticity.

As soon as the piston is arrived at the bottom of the body of the pump, the cock $F$ is to be shut, to stop the passage of the steam, and another cock, $P$, at the top of the body of the pump, is to be opened, to permit the escape of the steam which has performed its office; then the weight of the water with which the veisel $Y$ is always filled, opens the valve $R$, and introduces itself into the body of the pump $G H$, and makes the piston $S T$ to rise up again: the water contained in the tube $K O$ is to be removed, because a valve at $K$ prevents it from descending. When the water which is introduced into the body of the pump is come to an equilibrium with the water in the veisel $Y$, the cock $P$ is to be shut, and $E$ is to be opened; the steam comes again to press on the piston, which it forces to descend, and, as in the former instance, expels the water through the tube $K O$ into the cylinder $M N$, where it cannot introduce itself without surmounting the resistance arising from the elaticity of the air of which it comes to occupy the space.

The cylinder $M N$, which is three feet high, can contain about 86 cubic feet of water, or about 2.86 cubic feet at every foot in height; therefore, when it is filled to within two feet of the top, the air will be reduced to occupy only one-third of the space in which it was at first shut up, and it will have acquired an elaticity capable of making it subtant a column of water of 64 feet, in addition to the 32 feet with which it is in equilibrium in its ordinary state of compresion; under these circumstances, if the cock $Q$ is opened, the water will fly out, at the first instant, with the same velocity as if it was 64 feet high in the cylinder $M N$; but by degrees, as the water passes out, it will be driven with less velocity, because the air occupying a greater space, its elaticity diminishes; but according to Papin's statement, there should always be at least a foot of water in the cylinder, and the air, in its smallest condensation, should not occupy more than one-third of the space which it occupies in its natural state; and in that case it will have a sufficient pressure to sustain a column of 16 feet of water.

M. Papin's machine is, on the whole, far inferior to the engine of captain Savery, and it wants the advantage of the grand principle of condensation, and is only a return to the marquis of Worcester's idea: it cannot therefore be called an improvement on Savery's, although it must be allowed that the separation of the hot steam from the cold water by a diaphragm, piston, or float, is a considerable improvement on the marquis of Worcester's, and would be also an advantageous addition to Savery's, if the condensing water could be as well applied to run down the outside of a cylindrical veisel as an oval one.

Long after Papin's publication, some English engineers made this addition to captain Savery's engine, and attempted
STEAM-ENGINE.

to introduce it in opposition to the cylinder or atmospheric engines, for which we shall hereafter speak; but the consumption of fuel was too great to balance the advantage of simplicity in the structure of the engine.

Captain Savery must have been employed a considerable time with his machine prior to the 14th of June 1699, and even previous to his patent, as may be inferred from his Miner's Friend, printed in the year 1702, where, in his address to the Royal Society, he says, that since the time he exhibited his model to them, "I have met with great difficulties and expence to instruct handicraft artificers to form my engines according to my desire; but my workmen, after much experience, are become such masters of the thing, that they oblige themselves to deliver what engines they make me exactly tight, and fit for service, and as such I dare warrant them to every body that has occasion for them."

In his address to the gentlemen adventurers in the mines of England, he says, that the frequent disorders and cumber-omenes of water-engines then in use "encouraged me to invent engines to work by this new force; that though I was obliged to encounter the oddity and almost insuperable difficulties, I spared neither time, pains, nor money, till I had about completed them."

Application of Savery's Engines, and its Defects.—Respecting the real use which was made of Captain Savery's invention, it appears that a number of small engines were erected, under the authority of the patent, for the supply of noblemen's and gentlemen's seats in different parts of England, and for such purposes they succeeded very well; but for the supply of towns, and the drainage of mines, where large quantities of water, and great perpendicular preffures were required, they were not well adapted. With respect to the raising water for turning mills, an application wheroe really suggested itself to the ingenious inventor, we do not think it was ever attempted, for at that period there were scarcely any mills which could have supported the expense of the erection, and maintenance of such engines, even where coals were cheap.

For the drainage of fields they were not well adapted, because the height to which water is most generally required to be raised in such cases is small, and the quantity very great; on this account several engines would always be wanted for one drainage, and a great part of the power would be lost, because the perpendicular height would be very much less than the height to which the atmosphere would raise the water. To ships we may conjecture that they never were applied, and this reduces their use to a very small compass.

The principal reasons why they could not be so generally employed in mines as the captain was led to expect, and which he laboured to bring about, was, that the working part of the engine must necessarily be placed from 2: to 26 feet above the bottom of the mine; and if, by any accident, the water should happen to rise above that level, the engine would be drowned and irrecoverably lost, without some other engines to recover it.

As the power of suction in this engine cannot extend more than 26 feet, the rest of the perpendicular lift must be obtained by the expansive force of the steam; and for every 33 or 34 feet of altitude of this column, a preffure equal to the atmosphere must be exerted on the inside of the boiler and receivers, tending to burst them open.

It is not uncommon, in the calculation of engines, to force the water by steam of more than three atmospheres' preffure, or about 67 feet above the engine; and this limits the whole power of an engine, on Savery's plan, to about 90 feet.

On this account it would require a separate engine for every 14 fathoms of the depth of a mine, and they must raise from one to another; but if any one engine is disregarded, the rest must stop likewise.

Another difficulty was in the quantity of water which could be raised with safety; the size of his largest boiler did not exceed 30 inches diameter, and the capacity of the receiver could be but small; and, therefore, the generality of mines would require more than one engine at the same level. The charge, trouble, and difficulty, attending such a number, would naturally prevent their introduction, even in cases where they would really have been of great service. Add to this, the consumption of fuel in Savery's engines was enormous, compared with the modern engines; and they were always in danger of blowing up, particularly when they were employed to raise water to any considerable height.

Suppose, for instance, the water is to be raised 100 feet; 25 may be done by suction, and the remaining 75 feet must be lifted by the force of the steam. To effect this, the preffure within the vessel must be more than three atmospheres; and it will be seen by our table, that every square inch of the interior surface of the boiler and receiver will be preffed with a force of more than 35 pounds, tending to burst them open. This moderate height will, therefore, require very strong vessels, and all the joints must be made with the greatest care; for although it is true that the preffure is much less than is usual in pumps, and other hydraulic machines, in which there is a greater column of water, yet there is much greater danger of the vessels being burst by steam of such great elasticity, than by an equal preffure of a column of water; because the force of the steam is always liable to be suddenly increased to a very great extent, on any acccident of the heat; and that tends to weaken the vessels, particularly the boiler, which sooner or later must be reduced in thickness at the bottom, and will then burst.

According to Mr. Dalton's experiments, from which we have formed our tables of the expansive force of steam, it must be heated to a temperature of 287° of Fahrenheit's thermometer, before it can overcome a column of water of 75 feet in altitude; and as this steam must come immediately in contact with the surface of the cold water in the receiver, which is perhaps as low as 40°, the condensation of the steam is excessive for some time, and must cool, until the surface of the water acquires nearly the same temperature as the steam; which, however, it will soon do, because the heat is transmitted downward very slowly in fluids. When the surface of the water is sufficiently heated, the steam, which before was condensed as frost as it came in contact with the water, will begin to preff upon the water; and as the heat and elasticity increase, it will lift the column. But when it has expelled all of the water from the receiver, a new course of condensation is produced, from the cold surface of that part of the receiver which was before filled with the cold water; and this condensation will be much more rapid than the former, because the vessel, being necessarily made of metal, will transmit the heat more rapidly than the water did, and delay the process of forcing out the water until the interior surface of the receiver is made as hot as the steam. Captain Savery seems to have been fully aware of this, as he says in the "Miner's Friend," that you may see on the outside of the receiver how the water goes out, and that as far as it is transparent; or as far as the steam is contained within the vessel, so far it is dry without, and so hot as fercerly to endure the least touch of the hand; but as far as the water is, the said vessel will be cold and wet where any water has fallen on it, which cold and moisture
STEAM-ENGINE.

vanish as fast as the steam, in its descent, takes the place of the water. Also, he says, the force of the steam presses upon the surface of the water, which surface, being only heated by the steam, it does not condense.

Improvement upon Savery's Engine.—The rapid condensation which must take place, when steam of a great elastic force is brought into immediate contact with the water, is an insuperable bar to the raising of water to any considerable height, on Savery's plan. The most obvious improvement was to employ a cylindrical receiver, with a floating piston, in the manner of Papin's; but this was only a partial remedy, because the condensation from the sides of the vessel still took place; and it was not until the piston was made to fit exactly into the cylindrical receiver, and the water kept out of it altogether, that the steam-engine was rendered an efficient machine. But this change, which was invented by Newcomen, introduces much complexity into the work. It becomes necessary to have a separate receiver, with a piston, or, in other words, a pump, to raise the water, and also machinery to communicate the motion of the steam-piston to that of the pump. The simplicity of Savery's engine, and the certainty of its action, rendered it very desirable to obviate its defects so far that it could be employed for mines, even after the more perfect engines were introduced. To avoid returning to the description of Savery's engine, we shall give a brief account of these attempts, before proceeding to the other engines.

The first improvement of Savery's engine was to introduce a small jet of cold water into the inside of the receiver, to perform the condensation, instead of throwing cold water upon the outside of the receiver; by this means a more perfect condensation is obtained, and with less waste of cold water than by the original plan. The water is conveyed by a small pipe, which branches out from the great forcing-pipe, and enters into the receiver, where it turns down, and terminates with a ball, perforated in all directions, like the spout of a watering-pot, so as to disperse the water in a shower within the receiver. A cock is placed to stop the communication at pleasure; and this cock is opened to admit the cold water, when the steam is to be condensed. But it must be observed, that water cannot enter through this cock into the receiver the first instant that it is opened, because the prelude of the water in the force-pipe must be less than that of the steam within the receiver, and, therefore, the injection will not commence until after the steam-cock is shut, and then the condensation, or loss of heat, which always takes place within the receiver from the coldness of the water, will very soon diminish the heat, and consequently the prelude of the steam far off, that it will no longer balance the prelude of the fame column of water, which it had just before lifted into the force-pipe. This being the case, the injection-water begins to run, and falls in a shower through the steam contained in the receiver. The sudden effect of this shower to produce the condensation is really surprising. The injection, being a portion of the fame water which has just before quitted the receiver, must have the same temperature as that which was then in contact with the steam; and the difference in the rapidity of the condensation arises only from the dispersion of the water into drops. When the cold water is contained in the lower part of the vessel, the surface only of the water is exposed to the steam, and soon becomes so heated that it will not condense with that great rapidity which it does at first. On the other hand, a quantity of water dispersed in drops will be completely exposed to the steam, and will take up therefrom, in an instant, as much heat as will reduce the temperature of the steam, and increase the heat of the injection-water, until they approach to an equality of temperature. This being the case, it will easily be seen that the degree of condensation which can be obtained within the receiver will be in a ratio to the coldness and quantity of the injection-water; but the quantity required for injection is far less than when applied on the outside of the receiver, because the receiver will not transmit the heat of the steam through it so quickly, but the water must run down the outside of the receiver, and descend into the well, without being much warmed, and without having extracted much heat from the steam within.

The next improvement in Savery's engine was the addition of the safety-valve to the boiler. This was invented by Papin for his digester, to permit the steam to escape from the boiler into the open air, when it arrives at such a degree of prelude as to endanger the rupture of the vessels. The safety-valve, which is shown in the figure of Papin's engine, fig. 2, is nothing more than a valve opening outwards, and well fitted to close an aperture which is made in the top of the boiler, and is kept shut by a weight or a lever, which is loaded with a weight capable of lifting upon the lever in the manner of a yard; so that the prelude of the weight upon the valve can be regulated at pleasure, according to the strength of steam which is required: but, in all cases, it must be loaded so as to permit the steam to lift it up and escape, when it arrives at a prelude which would endanger the boiler or receiver. With a view to strengthen the boiler, hoops and internal radiating bars were tried, according to the idea of the marquis of Worcester; but this was found of very little service, because, on account of the condensation of the steam, it is much better to divide the mine into engines of from 70 to 80 feet high, according to captain Savery's first proposition, than to attempt using steam of that degree of elasticity, which will require any such precaution.

In the Philosophical Transactions, No. 461, there is an account of a new way of producing steam of a great prelude. The boiler consists of an inverted conical vessel of iron, to the base or upper part of which a close and strong copper-head or hemispheric is joined by rivets all round; this has a copper base, or base, in a reverberatory furnace, to receive a sufficient heat from the flame, without injuring it. The water is introduced into this boiler in a number of small streams, or jets, which are injected into it by a pipe, which descends through the cover, or spherical top, of the boiler; and in the middle of the cone several spouts are fixed, radiating from it like the arms of a wheel: the pipe must be carried up above the boiler, so as to have a column of a sufficient height to overcome the prelude of the steam, and also enter into the boiler with a considerable force; and by the radiating spouts it is dispersed in a shower upon the interior surface of the iron cone, and is thus converted into steam, which flies up to the copper-head, and is carried off by a pipe to the engine. The inventor proposed to make the tube with the radiating spouts to revolve, for the purpose of distributing the water more completely; but he probably never tried the experiment, or he would have found that the boiler would have been soon destroyed by the rapid oxidation of the iron which must take place from throwing water upon it when red-hot; and copper would have melted. In 1719, Dr. Defagurier made an engine on Savery's plan in an improved form. He says, that in considering Savery's engine with Dr. Graveande, they thought there was a great waste of steam, by its constantly acting upon the receivers without intermission, the steam becoming useless until it had heated the surface of the water in the receiver, and also to a certain depth below the surface; but
STEAM-ENGINE.

if it were so contrived, that after the steam had press'd up one receiver full of water, instead of being thrown into another, it should be confined in the boiler till the receiver was refil'd by the atmosphere, and thus turn'd upon the water, the steam would have acquired so much force from its confinement, that it would press suddenly upon the surface of the water, and discharge a considerable portion of it even before it had heated the surface. In pursuance of this idea, they had a model made which could either be used with one or two receivers, and found, on experiment, that one receiver could be discharged three times in the same time that two could be discharged once. They also learned that captain Savery had made an engine at Kenfonington with only one receiver, which acted very well. Delfaguliers then made several engines with a spherical boiler, provided with a safety-valve, and a receiver of about one-fifth of the capacity of the boiler, and of a cylindrical figure, tall, and of small diameter in proportion. The steam and the injection-water were alternately admitted into the receiver at top through a double-panagled cock, the handle of which being turned towards the boiler, admitted steam; or, being turned towards the force-pipe, admitted the jet of cold water; but only one of these paf-fagled cocks were turned at a time. The small chamber from the force-pipe which conveyed the injection-water to the double-panagled cock, had another cock in it to adjust the aperture, and regulate the quantity of water which should flow into the receiver. The suction-pipe and force-pipe were the same as Savery's; but the valves were conveniently situated, so as to be readily accessible when they required repairs. Dr. Delfaguliers tells us that he made seven of these engines: the first was for the czar Peter the Great, for his garden at St. Petersburgh, where it was set up. The boiler of this engine was spherical (as they were all in Italy where the steam was so much stronger than air), and held between five and fix hogheads; the receiver held one hoghead, and was filled and emptied four times in a minute. The water was drawn up by suction, or the preffure of the atmosphere, twenty-nine feet high out of the well, and then preffured up eleven feet higher. The pipes were all of copper, but foldered to the suction-piece with soft folder, which held very well for that height; but he did not venture either upon a greater quantity for that height, or a greater height for any quantity of water above the boiler. It is a curious experiment to see the behaviour of water as it leaves the boiler. The steam must have been greater, and the steam of the same force would have had a greater surface to act upon, which might have burst the boiler, or would have required it to be made much thicker.

Another engine of this sort, which he put up for a friend in 1730, drew up the water twenty-nine feet from the well, and then it was forced up by the preffure of the steam twenty-four feet higher, into a cistern holding about thirty tons, placed at the top of a tower, in order to run down again through a pipe or conduit, and play several jets in the garden. But sometimes no jets being played, the water was discharged at the height of fix or eight feet out of the force-pipes to fill the ponds and water-meadows in dry weather, which it did with a less strength of steam than what drove the water into the tower; or if the same steam was kept up, it would make eight or nine strokes in a minute, instead of about fix, as when the water was driven up into the cistern. Upon the safety-valve there was a feet of the yard, the place of whose weight showed the strength of the steam, and how high it was capable of raising water; but when the weight was at the very end of the feet of the yard, the steam, being then very strong, would lift it up and go out at the valve, rather than damage the boiler. Twenty-five years after this engine was made, a man, who was entirely ignorant of the nature of the engine, without any instructions, undertook to work it; and having hung the weight at the farther end of the yard, in order to collect more steam, to make his work the quicker, as also a very heavy plumber's iron upon the end of the yard, the steam not being able to lift the safety-valve, the feet of the yard, loaded with all this unusual weight, burst the boiler with a great explosion, and killed the poor man who stood near with the pieces that flew about.

These accounts shew how high, and in what quantity, this kind of fire-engine can safely raise the water. About as much fire as a common large parlour-fire was sufficient to work this engine, and raise fifteen tons per hour; so that if the cistern was kept full, the jets could be made to play to entertain friends at any time, and then a man being sent to light the fire under the boiler, the engine would raise water to supply the jets before the cistern was empty.

M. De Moura, of Portugal, sent an engine to the Royal Society upon the principle of Savery's, but provided with apparatus to make it self-acting, and to open and shut the valves at the proper instant. The receiver, boiler, steam-pipe, and injection-cocks, are the same as we have before described, together with the force-pipes, and their valves. What is peculiar to this engine is, a float within the receiver, composed of a light ball of copper, which is not loose therein, but fastened to the end of an arm or lever, which is made to rise and fall by the float, while the other end of the arm is fixed to an axis, and consequently, as the float moves up and down, the axis is turned round one way or the other. This axis is made conical, and passes through a conical socket, which is foldered to the side of the receiver, and upon that end of the axis which projects beyond the socket; and, therefore, at the outside of the receiver is fitted a second arm, which is also moved backwards and forwards by the axis, as the float rises and falls. By these means, the rising and falling of the surface of the water within the receiver communicates a correspondent motion to the outside, in order to actuate the reft of the gear, which regulates the opening and shutting of the steam and injection-cocks. A small cistern is foldered to the outside receiver, and, being kept full of water, surrounds the joint, or conical socket, through which the axis passes, the float passing both the axis and socket airtight. The cistern is contriv'd so as to keep the water full by means of a small leakage from the force-pipe, through a wooden peg, and the drops are conducted by a packthread down to the cistern. A small weight is applied to the arm on the outside of the receiver, to counterpoise the float within; also upon the same arm is a slider, which being fast nearer to, or farther from the axis, will rise or fall a greater or less space, as may be required; when the float within rises or falls, and the slider can be fastened by a screw at any part. A chain is attached to the slider, and gives motion by means of a shorter chain to a balance, or tumbler, which moves on an axis, and opens and shuts the cocks. The first-mentioned chain passes over two pulleys, supported by two arms, that are fastened to the side of the receiver, which give a chain a proper horizontal direction: in order to move the balance to the end of the chain, a weight is fastened sufficient to raise the balance to a perpendicular position, and also to overcome the friction of the float, and its axis with the pulleys and chain.

The balance moves upon an axis, which is supported in pieces projecting from the receiver; and it has three arms, one of which applies with a roller to the handle of the steam-cock, a second acts upon the lever of the injection-cock,
STEAM-ENGINE.

cock, and a third short arm has a piece of chain, to
fink the steam to the chain before-mentioned, at the part where the
fame extended horizontally between the two pullies. The
arms, which act upon the cock, are so placed, as to flut
the steam-cock the moment before the injection is opened,
and vice versa.

To put the engine in motion, press down the arm of the
axis, which raises the float within the receiver, and the coun-
ter-weight of the chain will bring the balance over to the
right side, and in its motion will open the steam-cock, and
flut the injection-cock: also open a small gauge-cock in
the top of the receiver, that the air may be dischaged by
the entrance of the stem into the receiver. This being
done, shunt the air-cock, and let go the arm of the balance:
the weight at the end of the chain will bring over the balance
to the left, and in its motion will shut the stem-cock and open
the injection-cock, to admit a small jet of cold water into
the receiver, which presently condenses the steam into water,
in a great measure leaves a vacuum in the receiver. In
this situation the preface of the atmosphere will cause the water
to mount through the injection-pipe into the receiver, where,
as its surface rises, it makes the float ascend, and depriving
the arm on the outside of the receiver, draws the chain and
raises the balance, till it has passed the perpendicular, when
it will fall over suddenly by its own gravity: in falling, the
roller of one of its arms takes hold of the handle of the
stem-cock, and opens it, whilst the other shuts the in-
jection-cock. This fall of the balance takes place when the
receiver is almost filled with water, and the balance cannot
return till the surface of the water therein subside, and suffers
the float to descend. This takes place as soon as the stem
causes to be condened by the cold receiver, and acquires
sufficient elastic force from its heat to fill the receiver and
drive out the water from the forcing-pipe. When the surface
of the water defends the float sinks, and suffers the counter-
weight to draw up the chain. By the short chain it draws
the balance beyond the perpendicular towards the left,
where it falls of its own accord; and in falling, the arm
takes hold of the handle and shuts the stem-cock, whilst the
other opens the injection-cock, as before.

In the "Machines approuvées par l'Academie de 1744," is a
description of an engine by M. Gentilans, which very
closely resembles M. De Moura's, but is more completely
described.

Mr. Blakely's Engine on Savery's Principle.—Long after
steam-engines furnished to Savery, he had become general, an
ingenious engineer, Mr. Blakely, made many attempts to
introduce Savery's engine in an improved form. He obtained
a patent in 1766, from the specification of which it appears,
that his improvement was to employ oil floating upon the
surface of the water in the receiver, to form a piston or diaphragm
between the hot steam and the cold water, to prevent the
steam being condensed as soon as it touches the surface of the
water; or air was to be admitted into the receiver for the
specific purpose. In this case, two receivers were to be
used, one in the same situation as Savery's, which was to
receive the air; and the hot steam, when admitted into it,
forced the air to descend by a pipe to the second receiver,
which was at the bottom of the well, and expel the water
therefrom, and elevate it in the force-pipe. By this means
he hoped to prevent the steam coming in contact with the
water, and avoid the condensation.

Mr. Blakely afterwards made some alteration in the form
of his engine, which is described as follows by Mr. Ferguson:
(See Plate I. fig. 3.) E is the boiler, set in a furnace to be
burnt with flame: F is the gauge-cock, to ascertain the depth of water in the boiler: D the steam
pipe, to which is foldered the cock and funnel C, for filling
the boiler before the engine is set to work: I is an air
vessel, and TT an injection-pipe, which passeth through across
the top of the receiver, and has small holes pierced in it for
the cold water to drop through and fall in a shower in the
air-vessel I, in order to form a condensation: the end of the
injection-pipe is carried into the steam-pipe D, to admit
a small quantity of water to run down the pipe D, and supply
the boiler: V is a receiver, communicating with the air
vessel I by a pipe; in the upper part of it is a callender S,
with small holes to disperse the injection-water, which falls
from the air-vessel I, equally through the receiver V: O is
a valve to admit air, which comes through the cock P into
the receiver: and H is an occasional cock, to let out the air
and steam when the engine is first set to work: Q is a pipe
from the receiver V, to the box which contains the valves B
and N at the bottom of the forcing-pipe A, which conveys the
water up to the reservoir: M is the suction-pipe, to draw
the water from the well up to the receiver: G is the fire
place belonging to the furnace, in which the boiler is set,
and beneath it is an ash-hole. It is needless to say any
thing of the scaffold or the well, they being always made
according to the size of the machine, and in proportion to
the place in which it is to be erected. All the vessels
and pipes of this engine are made of strong copper.

In order to set this engine to work, the receiver A A must
be filled with water, which will be retained in the
clack B; then more water must be poured into the
funnel C, which is on the steam-pipe D; from thence it falls
into the boiler E, and rises to the level of the cock F, which
must be open; but as soon as the water runs from it, the
funnel-cock C, as well as the gauge-cock F, must be shut,
and the air-gauge cock H must be opened. The fire
must then be put into the furnace G, and as soon as the water
is in ebullition in the boiler it creates steam, which finds
its way through the pipe D, and forces the air out of the
vessel I into the lower receiver V; the air is also forced out
at the cock H, the stem following it with great velocity.
In a second or two the cock H must be shut, and instantane
ously the injection-cock L must be opened, which lets cold
water run through the end of the pipe TT, into the steam
pipe D, to replace that which has been evaporated out of
the boiler E; and it also rushes out on all sides from the little
holes which are in the sides of the pipe TT, into the air
vessel I, and falls on the callender S: this cold water makes
ebullition in the boiler E and V, and forms a vacuum, which causes the atmosphere to press on the water
in which the lower end of the pipe N is immersed, and the
water ascends the said pipe with great rapidity, and passeth
through the clack N, and through the pipe Q, into the
receiver V, till it rises up to O, where is a floating-ball sat-
tened to a handle or lever, which in rising turns the key of
the cock P, and opens it; there is a valve at that end of the
cock which is within side of the receiver V, so that as soon
as the cock is opened, the valve O is forced up by the air,
which rushes through with great quickness and noise into
the vessel I; and when that vessel is full of air, the vacuum
is destroyed and no more noise is heard, which gives the
notice to shut immediately the injection-cock L: that being
done, the steam recovers its force, and makes its way
through the steam-pipe D into the air-vessel I; and as the
steam increases, being much lighter than air, it keeps upper
most, and forces the air on the water which is in the
receiver V, which water is forced through the pipe Q, and
lifting up the clack at B, goes with the pipe A, and expels
it into the reservoir M. When all the water is ex-
pelled out of the receiver V, the air follows, and expels
with

Vol. XXXIV.
with great velocity through the water which is in the pipe A: two or three seconds after the noise of this is heard, the injection-cock L must be opened to let in cold water, and cause the same effect as before. The noise of the air rushing in and out of the receiver gives proper notice when the manager of this hand-engine is to open and shut the injection-cock, which is the only thing required to work this machine, when once it has been put in motion, in the manner that has been described above.

This engine was not found to answer any better than Savery's, because the air will not make that complete separation between the steam and the cold water which the inventor expected; and there is a great loss of power to compels the air sufficiently to make it lift the column of water; and in order to get rid of this air it must be forced up the pipe, which takes as much power of steam as would be required to force up as much water as the air occupied the place of when in its condensed state. Mr. Blackey's intention in the injection of a small quantity of water into the boiler at every stroke, was the same as Mr. Payne's red-hot boiler, of which we have before spoken, but he was in practice obliged to employ a steam-cock in the pipe D, otherwise the steam which the boiler produces whilst the injection-cock is open would have been all condensed and lost.

Savery's engine can be usefully employed for lifting water 30 or 35 feet, which can be done principally by the suction, and with a very slight preasure for the remainder; but it is the most advantageous way to raise no more than 24 feet, and to perform the whole lift by the suction, and even to allow the water to sufficent amount to enter the receiver by its own gravity, without forcing it in the leaf by the steam. In this form of the engine, the steam need have no greater elastic force than the atmospheric air, or just as much as is sufficient to make it enter into the receiver, as the water runs out. The temperature of the steam, according to our table, will then be only a little above the boiling point, or above 216°, and consequently the loss by the condensation is not so serious; and as the steam is not pressed upon the water, it is not brought into such close contact with the cold water, as in the forcing engines. In this way, the injection must be forced in by a small force-pump.

Mr. Kier's Engine on Savery's Plan.—An engine upon this principle, with various judicious improvements, was erected some years ago by Mr. Peter Kier, at his manufactory of coach axletrees, near Swansea, as it proceeds a little further than the former, and as it allows of more material repair, it has almost constantly been worked since, to raise water and turn a water-wheel. The proprietor states it to answer his purpose very well, because it works without an attendant, and regulates its own motions; and, as might naturally be expected, the wear and tear are also inconsiderable.

Plate I. Steam-Engine, fig. 4, represents this engine, taken in a section through the centre. It represents an oval boiler, seven feet long, five feet wide, and five deep. Mr. Kier confesses it as being of dimensions sufficient to work a larger engine; a circumstance which must, in a certain degree, increase the consumption of fuel. It feeds itself with water conveyed through an elevated pipe, at the end of which is a valve. This valve does not open until the fall of the water within the boiler has suffered a float to subside, which, by its actual weight affixed to draw the valve open; but the float, by its tendency upwards, as the water in the boiler rises, serves effectually to close it. The water in the boiler, therefore, remains constantly at or near the same level. The steam is conveyed by a pipe, T A V, to a box B, through which, by the opening and shutting of a valve, it can be conveyed to the working chamber E. The axis, C, serves as a key to open and shut the valve; N O is a cistern of water, from which the engine draws its water through a vertical pipe, in which the valve Q is placed, to prevent the return of the water; G G is another cistern, into which the water is delivered through the pipe F, which is provided with a valve H, opening outwards; I M represents an over-shot water-wheel, 18 feet in diameter, moving on the axis K L, and communicating its motion to the latches, and other machines used in the manufactory. The water in both the cisterns becomes warmer than the hand, after working a short time; for which reason, the injection-water is forced up by a small pump from a well, supplied from the small steam on which these works are established. A leaden pipe passes from this forcing-pump to the upper or conical part of the chamber E, for the purpose of injecting cold water at the proper time. Neither of these could be represented with convenience in the present section.

The manner in which the steam and cold water are alternately admitted into the chamber E, remains to be explained. Upon the extremity, K, of the axis of the over-shot water-wheel there is fixed a solid wooden wheel, about four feet in diameter; it is also represented in fig. 5, as seen in the front; a, b, c, d, are four cleats, all or any number of which may be fixed on the wheel at a time. Each cleat has its corresponding block, e, f, g, h, on the opposite surface of the wheel. The use of these is to work the engine. Suppose the wheel I M K, with all the revolving apparatus, be turned round by hand, one of the cleats meets in its rotation with a lever, which opens the steam-valve by a bar of communication reaching to the handle of the axis C, fig. 2. The steam consequently falls into the chamber E, and the steam-valve shuts again, as soon as the cleat has passed. Speedily after this, the corresponding block on the other side of the wheel meets another lever, which is similarly attached to the handle of the forcing-pump, and, therefore, throws a jet of cold water into the chamber, and condenses the steam. The preasure of the atmosphere then forces the water from the cistern N O, through the valve Q, towards the chamber E. When the engine has been long out of work, two or three strokes may be necessary to raise the water to the top of the chamber E. As soon as this is the case, the re-entrance of the steam fills the whole body of water, above the valve H, to flow out of the chamber E, by its gravity. E, H, G G, are the water which, when driven upon the over-shot water-wheel, I M, through a sluice; and by that means keeps the work in motion, and replenishes the lower cistern. There is no reservoir for the injection-water, but the requisite quantity is driven up at each stroke.

Hence we see, that in effect this engine is the same as Savery's original engine, except that it is not applied for the immediate purpose of raising water, but gives motion to other apparatus; and it does not force the water by the steam at all. The water merely falls out of the chamber, and consequently never requires steam much stronger than the atmosphere. From the effect of this engine, under circumstances of such advantage, it may fairly be concluded, that the action of steam against water in forcing can never be beneficial, except at places where fuel can be had extremely cheap. It was found, at the first erection of this engine, that the consumption of steam, by contact with the water, was so great, that it could not be worked with advantage. This defect was remedied in the present engine, as in another which was at Norwich, by fixing a small air-valve in the steam-box, which is struck open by the machinery for an instant, immediately before the admission
STEAM-ENGINE.

It may be presumed, that, according to Mr. Blakely's idea, the air occupied a space above the water, and prevented their coming together. Mr. Kier, however, is disposed to think that the effect does not take place in this manner, but by some mixture and dilatation of the two fluids; because he imagines the mischief from the wet surface of the cylinder would remain the same, when the water descends. To get rid of this air, the steam in the boiler must be let off into a preceding space or the atmosphere, and to rush into the receiver with sufficient force to drive out the air through the same valve at which it entered, and which opens outwards for that purpose; but will shut, to prevent the air entering when the vacuum is made, except for an infant before the steam is admitted, when it is opened by the machinery. The motion of the orlofhot water-wheel is regulated by an apparatus called a governor, invented by Mr. Watt, and which will be described in our account of his engine. It is a pendulous axis, which revolves by communication with the engine, and carries round two pendulous balls; which pendulums move on a joint, fixed to the vertical axis. When the rotation is very quick, the balls fly out, and are applied to draw down a lever, which is connected with the sluice of the upper cistern; the sluice, therefore, is made to fall or rise, according as the velocity of the engine is greater or less. By this disposition, when the wheel moves very speedily from lightness of work, or any other cause, the quantity of water thrown down from the upper cistern is immediately diminished; and, on the contrary, the quantity of water is rendered greater, when the wheels of the movement shall move more as is wanted.

The engine here described has been at work many years, and from the simplicity of its construction has yet exhibited no proofs of wear.

Mr. Kier thinks it a profitable engine to himself, and that it would be serviceable for raising water where coals are cheap. It consumes fix bushels of good coals in twelve hours' work, when in its best state, or seven bushels when at the worst. Under these circumstances it gives ten strokes per minute, each throwing out seven cubic feet of water at an aperture of 20 feet above the water beneath. This quantity, namely, 70 cubic feet per minute, will weigh 4,375 lbs. raised 20 feet high, which being doubled, to reduce it to Defagelius' standard height of 10 feet, will amount to 9,750 lbs. raised 10 feet high; and this divided by 550, the number of pounds in a hoghead in a hoghead, will give a quotient of 16 hogheads raised 10 feet, representing the force of so many men, according to the estimate of that author, who reckons five men equivalent to one horse. The result is not quite half what is performed, with an equal quantity of coals, by the improved engines, with a piston of such size as to be equal to 20 or 25 horses. Philos. Journ. vol. 1.

Several other engines have been erected upon this plan; and where the water which is raised is to be immediately boiled, they are very capital machines, because all the loss of heat is thrown into the water and warms it before entering the boiler, so as to economize the whole: for instance, for the purpose of raising water into the boilers for a fullwork or a brewery, they are very applicable.

We have no accounts of the quantity of water which could be raised by Savery's original engine with a given quantity of fuel; but he tells us in the Miner's Friend, that to lift a three-inch bore of water 60 feet high, would only require a fire-place for the furnace of 20 inches deep, and 14 or 15 wide; the expense of fuel for which, he says, would be inconsiderable, when compared with the advantages to be derived from the use of the engine.

It has been proposed to construct a succession of engines upon Savery's plan in a mine, to raise water by fussion from one to another, and to have all of them worked by one common steam-boiler. For this purpose, the depth of the pit is divided into lifts of about 15 feet, and at each lift is a cistern, to receive the water raised by the different engines. Each engine consists of a vertical fussion-pipe, with the lower end immered in the water of the cistern of the engine below it, and a receiver at the upper end, which communicates with the fussion-pipe through a valve, to prevent the escape of the water from the receiver through the fussion-pipe. There is also a small spout or pipe leading from the side of each receiver into each cistern, which is to receive the water after it is raised into the receiver; and the ends of these spouts are covered with valves, to prevent the water running back into the receivers from the cisterns. All these receivers communicate with a common air-pipe, which leads up to the top close receiver, or air-veil, situated at the top of the pit, which veil is of at least double the capacity of all the receivers and the common pipe together. Immediately above the air-veil is the air-receiver, of equal capacity, and communicating with the air-veil by a pipe, which descends through the top of the cistern, and reaches nearly to the bottom of the air-veil, so that if there is any water in this veil, the end of the communicating pipe will be immered therein.

Suppose the cisterns at the different stages, and also the lower or air-veil, nearly filled with water, and the air-pipe and the small receivers filled with air, the action of the machine will be as follows: the steam is admitted from the boiler into the upper receiver, and expels the air therefrom through a proper cock or valve; when thoroughly filled with heated steam, the communication with the boiler is shut, and an injection of cold water thrown into the receiver; this condenses the steam, and forms a vacuum in the upper receiver: this being the case, the air contained in the air-pipe and receiver, by its elastic pressure upon the surface of the water contained in the great air-veil, causes the water to mount through the pipe of communication into the upper or steam-receiver. This causes the air in the pipes and receivers to occupy a greater space than it did before, and being thus rarefied, it no longer balances the pressure of the atmosphere upon the surface of the water contained in each cistern; it therefore forces the water up the respective fusion-pipes into the small receivers, and will fill each of them one half with water, and then the air contained in the remaining half of each receiver, and in the great air-veil above, comes to its equilibrium. The steam is now admitted a second time into the steam-receiver, and flashing upon the surface of the water therein, allows it to descend by its gravity into the air-veil beneath, from which it expels the air, and by the communication of the air-pipe it enters into the upper part of each of the small receivers, and entering the boiler, or to a boiler, for instance, for the purpose of raising water into the boilers for a fullwork or a brewery, they are very applicable.

We have no accounts of the quantity of water which could be raised by Savery's original engine with a given quantity of fuel; but he tells us in the Miner's Friend, that to lift a three-inch bore of water 60 feet high, would only require a fire-place for the furnace of 20 inches deep, and 14 or 15 wide; the expense of fuel for which, he says, would be inconsiderable, when compared with the advantages to be derived from the use of the engine.
STEAM-ENGINE.

of the steam to obtain a vacuum; for instance, it is not necessary for an engine of this kind to have steam in the boiler of much greater pressure than the atmosphere; suppose it is equal to raising water two feet, by our second table this will be at a temperature of 215°. Now, according to our first table, in order to obtain such a degree of rarefaction of preasure within the receiver as to lift a column of 30 feet of water, the temperature must be cooled down to 120°; therefore, at every stroke of the engine a change of temperature must be made equal to 95°, viz. between 120° and 215°. On this account, such an engine would require a great quantity of condensing water, and it is probable that it would be better to make the water, which the engine raises, pass through the receiver, on Savery's plan, or at least such a portion of it, as will keep the temperature of the water in the receiver sufficiently low to obtain the condensation which we have above mentioned.

In employing air in this manner to transmit the force of the steam into other vessels, there is always the loss from the elasticity or compressibility of the air, which, in the case above stated, will be equal to one-half; because, when a sufficient rarefaction is made within the steam-receiver to cause the atmosphere to press upon it equal to 13 lbs. upon the square inch, or to suck up water 30 feet, the air contained in the air-vessel and pipes will expand itself so as to balance one-half of that pressure; and, therefore, the degree of rarefaction within the small receivers will be only sufficient to raise the water 15 feet instead of 30. On the other hand, when the steam is admitted into the receiver, it must be in sufficient quantity to restore the air to its original density, before it will balance the pressure of the atmosphere, and allow the water to flow out of the receivers into their cisterns.

**Fig. 5.** represents a similar contrivance to the above, but it is for forcing. It was suggested by Mr. Kier, in 1783. A is a boiler, and B a steam-vessel; this last communicates with the vessels M, L, K, T, each of which, except the lower one, consists of two vessels; first, an external cistern, open at the top; and secondly, an interior receiver, immered in the water of the cistern, and closed on all sides, except where it communicates with B, by the branches of the receiver, the pipe F G H descending from B, and where the pipes P, O, N, I enter the upper part of each, and extend within or nearly to the bottom, and also where there is a valve at the bottom opening upwards. If steam be let pass from A to B, the air will be driven from B through the pipes F, and press upon the surface of the water in the lower receiver T, and drive the same up the pipes into the vessel or cistern K, but not into the receiver K, because the pressure of the air within that receiver keeps the valve in the bottom of the receiver shut. The next step of the operation consists in closing the cock C, and opening D, out of which a portion of steam will be driven, by the reaction of the water forcing itself through the valve in the bottom of the receiver T, from its natural tendency to rise to the same level as the surface of the water in the pit or well; and on the same account the water will enter into the receiver K, from the cistern in which it is immersed; the cock D is then to be closed, and C opened; in consequence of which, the contents of the receiver, T, will be forced up into the cistern K, by the steam, as before, and the receiver, K, will discharge its contents through the pipe, N, into the cistern L.

The steam being again shut off at C, and the cock D being opened, as before, the receivers, T, K, and L, will fill in the same manner, by the water from the exterior cistern entering through the valves in their bottoms, and a larger portion of steam will issue from D. A third repetition of the process will drive the contents of these three receivers a step higher; and a fourth repetition will cause the contents of the upper receiver, M, to flow out at P, after which, every alternation of the work with the cocks C, D, will throw out the same quantity from P.

The vessel B must necessarily contain a quantity of air capable of occupying the whole interior space contained in the closed receiver, with an allowance for the loss of bulk in condensation, under the pressure of a column of water equal to one of the lifts; and the quantity of steam to be discharged at each stroke, must occupy a space equal to that of all the water moved at each stroke; and much, in all cases, be considerably stronger than two atmospheres, in proportion to the heights of the lifts.

**Other Proposals for the Improvement of Savery's Engine.**—In the Memoirs of the Philosophical Society of Lanthorn, M. François has described a steam-engine on Savery's plan, which he proposes to be used for draining fens or marshes, and has added machinery to open and shut the cocks; it has otherwise nothing remarkable. See Repertory of Arts, first series, vol. iv.

In the American Philosophical Transactions there is a description of a steam-engine, on Savery's principle, by Mr. Nancarrow, which is applied to raise water for turning a water-wheel. In this engine, the receiver, into which the steam is admitted, is a tall cylindrical pipe, with only a slight enlargement at the top to form the receiver; and the water is only raised by the pressure of the atmosphere; and to prevent the water being changed and continuing cold, so as to condense the steam, it is not suffered to run off immediately from the receiver, as in Mr. Kier's engine, but nearly at the bottom of the tall cylindrical pipe it is joined to a box, as shewn by the dotted lines in the figure of his engine, and from this box a second vertical pipe, or force-pipe, ascends to the reservoir which contains the water; the valve to prevent the return of the water is placed at the lower end of this second pipe.

By this means, the portion of water which comes in contact with the steam rises and falls in the receiver, and alternately draws and forces other water through the box below, from the suction-pipe, and into the force-pipe and reservoir. But this water, when it becomes heated, acts like a floating piston on the surface of the cold water to prevent the contact of the steam. Mr. Nancarrow proposed to employ a separate condenser and air-pump to produce the vacuum, instead of making an injection into the receiver; but this would be attended with no advantage; and we have before stated the objections to the water growing heated any more than superficially.

At the same time we think that a very good and simple engine might be made, if this form of the apparatus, in which the water shall never be changed, was applied to forcing by the pressure of the steam only, on the marquis of Worceter's plan, and not to attempt condensation, which is impossible to effect perfectly, when the water has become very hot; but instead thereof, when the steam has exerted its force, to open a cock, and let off the steam into the open air. An engine of this kind, which only requires the additional receiver, is described in Leopold's Theatrum Machinarum Hydrostaticarum, vol. ii. 1724.

The last improvement which we have noticed in Savery's engine, is by Mr. James Boaz, of Glasgow, who took out a patent in 1805, for several different forms of the engine. In all these the receiver is made cylindrical, and a piston is applied to float upon the surface of the water, upon Papin's plan; and in the same manner as Nancarrow's engine, he
STEAM-ENGINE.

be proposes to employ such an arrangement of the force-pipes, and of a second small receiver, that the water which comes in contact with the steam shall not be changed, but shall always remain the same; a method which precludes the use of the vacuum by condensation. The specification of this patent is published in the Repertory of Arts, vol. viii.

Newcomen’s, or the Atmospheric Steam-Engine.—This engine is named after its inventor, Mr. Thomas Newcomen, an ironmonger of Dartmouth, in Devonshire. He appears to have been a person of ingenuity, and of some reading; and was acquainted with the famous philosopher Dr. Hooke. Newcomen was in the habit of visiting the mines of tin and copper in Cornwall, where captain Savery was well known, from his attempts to introduce his engine for the draining of mines, which, at that period, were nearly all of them at a stand, for want of some more powerful and cheap machines than hand-pumps or horse-machines.

The captain was not successful in his attempts, principally because he employed the direct action of the steam upon the water, which either confined him to the height of 25 feet, or compelled him to employ steam of a great elastic force; in which case it became an indispensible condition, that the boiler and vessels should be very strong, as well as that a large quantity of fuel should be consumed, to produce steam sufficiently dense. It is probable that these inconveniences may have early directed the thoughts of other ingenious men to the application of a piston; but the difficulties of the undertaking seem to have retarded this pursuit for a considerable time.

The first steam-engine with a piston, made by Papin in 1707, which we have described, was not at all calculated to remove the difficulties; and it is to Newcomen, and his associate Cawley, that we are indebted for the application of a piston with machinery, by which the indirect action of steam a little stronger than the atmosphere, or rather the direct action of the atmosphere upon a piston, is made to act with safety and effect against the most severe preffures. It appears that they had brought their atmospheric engine, about the year 1713, to a degree of perfection little inferior to that which are to be seen at present.

Principle of the Atmospheric Engine.—To have an idea of its principles and mode of action, suppose a very large syringe or cylinder to be placed upright, and a piston or plug inserted at the upper end, the usual aperture being supposed to be at the lower extremity. If this last aperture be opened, the piston will descend by its own weight, neglecting the effect of friction at its circumference. But let it be imagined that the piston is supported by a counter-weight applied at the opposite extremity, a lever, or by any other means: in this case the piston will not descend unless more weight is added to it.

Among the various ways of applying such a weight, there is one which consists in exhausting the air from the internal part of the cylinder, beneath the piston; and if this is done, it is evident that the whole preffure of the atmosphere, amounting to about 14.4 pounds on every square inch, will become active upon the upper surface of the piston. This method of gaining a great force was invented by the famous Otto Guericke; see his Experimenta Magdeburgica, 1672.

If the vacuum was to be produced by means of an air-pump on Guericke’s plan, it must be allowed that the labour of effecting it would be at least equal to that of any work which could be performed by the subsequent descent of the piston; we must therefore seek some other means of producing such a vacuum. We have seen that in Savery’s engine the operation of steam is two-fold, namely, by the direct preffure from its elasticity, and by the indirect influence of its condensation, which affords a vacuum. This last is the only principle employed in Newcomen’s engine.

In order to produce the vacuum at pleasure in the interior capacity of the syringe or cylinder, of which we have been speaking, it becomes requisite that several apertures should be formed at the bottom of the cylinder; one to communicate steam from a boiler, and provided with a cock to cut off or open the communication at pleasure; another to admit at pleasure a jet of cold water, to condense the steam during the interval in which the communication from the boiler is cut off; a third, provided with a drain-pipe, called the eduction-pipe, to carry off the condensed steam and injection-water; and lastly, a small lateral aperture, with a valve, to allow the escape of the air, or permanently elastic fluid, which will not condense by the application of cold water, or run off through the eduction-pipe: this last is called the snuffing-clack.

By these provisions the operation of the cylinder is made to take place in the following manner. The piston-rod is attached by a chain to the end of a long lever, at the opposite end of which are suspended the rods of the pumps which are to draw the water; and the weight of these rods exceeds the weight of the piston so much, as to draw the piston up to the top of the cylinder. In this state, the steam-cock is opened, and steam issues from the boiler; but being less than half the weight of common air, it rises to the top of the cylinder, and expels the air through the snuffing-valve and eduction-pipe, of which the lower extremity is covered with a flap-valve, in a trough of water. When the noise of its escape through these valves is heard, the steam-cock is shut, and the injection-pipe being opened, throws up a stream of cold water in a jet within the cylinder, and strikes against the bottom of the piston: the steam becomes immediately condensed, and the preffure of the atmosphere forces the piston down into the vacuum. Upon its progress downwards, the injection-pipe is closed; and when it has arrived nearly at the bottom of the cylinder, the steam-cock is again opened. The elastic steam fills the small space between the cylinder and the bottom, and its preffure on the under surface of the piston affords it to rise, and also affords the eduction-water which remains in the bottom of the cylinder to pass off through its pipe: the steam also drives the air, or other elastic fluid which will not condense, through the snuffing-valve. In this state, therefore, the steam is somewhat stronger than the atmosphere, and rather more than counterpoises its action on the upper surface of the piston; in consequence, the piston itself rises by the action of the counter-weight, or pump-rods, at the opposite end of the lever, and regains its original position at the top of the cylinder.

A second repetition of the process, namely, of shutting off the steam, and injecting cold water, causes the piston again to descend, and in this manner the alternations may be continued without limit.

It is to be understood, that the opening and shutting of the steam and injection-cocks are performed by apparatus fixed to the working lever, in such a manner as to strike the levers of those cocks at the precise instant of time when their effects are required to be produced. The attendant has no other office to perform than that of keeping up the fire. To apply this power to the purpose of raising water for draining a mine, suppoce a common sucking-pump placed in the pit to lift the water fifty yards high. If the pump is 7½ inches bore, the column of water which must be raised when the rod or bucket of the pump is drawn up, will weigh 3060 lbs.; a chain being attached to the upper end of the rod of the pump, and suspended from the extremity of the
STEAM-ENGINE.

long lever or working beam; and at the opposite extremity of the same beam another must be attached, to suspend the piston of the steam cylinder, which we have just described.

To give this piston a sufficient power of descent to make it draw up the water in the pump at the opposite end of the beam with celerity, the piston must be 22 inches in diameter; the area or surface of the piston will then be 350 square inches, $32 \times 22 = 464 \times 7854 = 350$. In this case, if each square inch is pressed with a weight of eight pounds, it will balance the weight of the water in the pumps within 30 pounds; for 350 $\times 8 = 2800$, instead of 3500; but the pressure on each square inch will be considerably more than eight pounds; for, provided the vacuum was perfect within the cylinder, the pressure of the atmosphere would be 142 pounds; but the condensation of the steam in the cylinder is so far incomplete, that it leaves steam or vapour within the cylinder of some density. If the steam is cooled by the injection down to 140°, it will be seen by our first table, fourth column, that it will leave the cylinder mixed with a vapour of an elastic force equal to 23 oz. per square inch; which force acting beneath the piston, will deflect from the pressure of the atmosphere, and reduce the next pressure on the piston, to 11 lbs. 13 oz. per square inch, as shown by the last column. The excess of pressure beyond what is necessary to balance the weight of water is 3 lbs. per square inch, amounting, on the whole surface of the piston, to (3 x 380 =) 1140 lbs. nearly, a weight which is allowed to overcome the counter-weight which is to draw the piston up again, and the friction of the piston and pump-buckets, and make the engine move with a sufficient velocity, which will be more or less according to the state of the engine. But taking this velocity at 16 strokes per minute of six feet length each = 96 feet motion per minute, the pump of 7½ inches diameter will raise 192 gallons per minute, or 185 hogheads 15 gallons per hour. An engine of these dimensions is but a small one, yet it serves to show the superiority of Newcomen's over Savery's engine, in principle. Savery's was an engine which really raised water by the force of steam; but Newcomen's raises water entirely by the pressure of the atmosphere, steam being employed merely as the most expeditious method of condensing the air into which the atmospheric pressure may impel the first mover of his machine. The elasticity of the steam is not the first mover. In the example of the engine we have just given to drain the same mine on Savery's plan, he must have employed steam of a pressure of 55 pounds per inch, and of a temperature of 325 degrees, to raise a column of water to a height of 125 feet; the condensation of this steam would be so great on coming in contact with water of only 50 degrees, that he would have found it scarcely practicable to have thrown up any considerable quantity.

We see also the great superiority of this new machine. There is no need of steam of great and dangerous elasticity, as it operates by means of very moderate heats, and consequently with much smaller quantities of fuel; and there are no other bounds to the power of this machine, than the strength of the materials of which it is composed. How deep forever a mine may be, a cylinder may be employed of such dimensions, that the pressure of the air on its piston may exceed in any degree the weight of the column of water to be raised; and lastly, this form of the machine renders it applicable to almost every mechanical purpose, because a skilful mechanic can readily find a method of converting the reciprocating motion of the working beam into a motion of any kind which may suit its purpose. Savery's engine could not admit of such an immediate application, and was restricted to raising of water.

Invention of Newcomen's Engine.—Referring the invention of this engine, it was less a matter of original discovery, than of a combination of the inventions of others, viz. of Savery's invention of the means of producing a vacuum by the condensation of steam, with Otto Guericke's exhausted cylinder.

Savery made claim to the invention, and in consequence of the claim he made to the mode of condensation, as being a part of his patent, he was admitted by Newcomen and Cawley to an association with them in the patent which was granted in 1705, but it does not appear that they made any perfect engine until 1711.

Defenestrians, in his account of the invention, makes no mention of captain Savery being associated; but says "that Thomas Newcomen, ironmonger, and John Cawley, glazier, of Dartmouth, in the county of Southampton (Baptists), made several experiments in private about the year 1710, and in the latter end of the year 1711 made proposals to drain the water of a colliery at Leigh, in Warwickshire, where the propietors employed 500 horses at an expense of 4000 a year; but their invention not meeting with the reception they expected, in March following, through the acquaintance of Mr. Potter of Bromsgrove, in Worcestershire, they bargained to draw water for Mr. Back of Wolverhampton; where, after a great many laborious attempts, they did make the engine work: but not being either philosophers to understand the reason, or mathematicians enough to calculate the powers and proportion of the parts, they very stalkly, by accident, found what they sought for. "They were at a loss about the pumps, but being near Birmingham, and having the assistance of so many admirable and ingenious workmen, they soon came to the method of making the pump-valves, clacks, and buckets, whereas they had but an imperfect notion of them before. One thing is very remarkable; as at first were working, they were surprized to see the engine go several strokes, and very quick together, when, after a search, they found a hole in the piston, which let the cold water in to cool the steam in the cylinder, whereas before they had always done it as the outside. They used before to work with a buoy in the cylinder, inclosed in a pipe, which buoy rose, when the steam was strong and opened the injection, and made a stroke; but they were not capable of giving six, eight, or ten strokes in a minute, till a boy, Humphrey Petter, who attended the engine, added (what he called soggess) a catch, that the beam always opened, and then it would go 15 or 16 strokes a minute. But this being perplexed with catches and frings, Mr. Henry Beighton, in an engine he had built at Newcastle-upon-Tyne, in 1718, took them all away, but the beam itself, and supplied them in a much better manner." Since that time no very material alterations have been made in this species of engine, except the addition of the crank to make it turn mills.

The French authors have claimed this engine also as the invention of their countryman Papin, but without any reason: Papin had gained a knowledge of the expansive force of steam in his digester, and he invented the mode of working the pistons and cylinders by a vacuum and the pressure of the atmosphere; but he was not the first inventor of either of these, Otto Guericke and the marquis of Worcechester having discovered the same things long before him; and further, he had no pretensions to claim Savery's discovery of the condensation of steam, upon which the engine of Newcomen depends.

Papin's Air Cylinder Engine.—Papin's invention of the cylinders
The consequence will be, that by the continual suction of the air-pumps a vacuum will be found under one piston, and the pressure of the atmosphere will act to press it down in its cylinder; and by the rope which is attached to it and wound round the axle of the wheel, its descent will cause the axle and wheel to turn round and draw up the cord which pulls over the wheel at one side, so as to raise up one bucket in the mine and lower down the other; but, during the descent of this piston, the other piston is freely at liberty to be drawn up in its cylinder, because the cock admits the atmospheric air into the same. When the piston under which the vacuum has been made is pressed down to the bottom of its cylinder, the other piston will be drawn up to the top of its cylinder, by its rope winding upon the axle. In this state the cock is turned the other way, and will then draw off the air from the cylinder in which the piston is at the top, and admit fresh air into the cylinder in which the piston is at the bottom. This will cause the axle and wheel to turn round in an opposite direction to what it did before, and draw up the opposite bucket from the mine.

In this way a continual reciprocation of the motion of the axle is kept up, and the power of the water-wheel is transmitted simply by the conveyance-pipe to any required distance, where, by using a larger or smaller cylinder, it may be made to act with any required force. The inventor proposed this method to be used to convey the power of the water-wheels in the Seine to work pumps at Vertaults, instead of using the cumbersome machinery employed at Massy for conveying the motion; and it is rather surprising that so simple and advantageous a method should have remained so long neglected and unknown, that even now, when its effects are publicly exhibited, the means are not known. The only improvement upon the method of Papin, which it is necessary to put in practice, is to have a receiver or air-chamber near the cylinders, to be kept exhausted by the pumps; and this being of sufficient capacity the air will rush into it, and be taken away from beneath the piston the instant the cock is opened; whereas, without it, it would be drawn off more slowly by the pumps. If the conveyance-pipe is made of large dimensions, it will effect the same end most completely.

**Description of the Atmospheric Engine.**—Our readers being now acquainted with the principle of Newcomen’s engine, we shall proceed to describe it in the state to which it was brought by Mr. Beighton, and which for more than half a century was the standard engine for raising water from mines. See the perspective view in Plate II., fig. 1., which represents the engine complete, the front wall of the house being supposed to be removed to shew the interior.

A, the fire-place under the boiler for raising the steam, and the ash-hole below it.

B, the boiler, made of iron plates; it is filled with water about three feet above the bottom.

C, the steam-pipe, through which the steam passes from the boiler into the receiver.

D, the receiver, a close iron vessel or box, in which is the regulator or steam-cock, which opens and closes the hole of communication with the cylinder at each stroke.

E is the communication-pipe, between the receiver and the cylinder; it rises five or six inches up in the interior of the cylinder above the bottom, to prevent the injected water from descending into the receiver.

F, the cylinder of cast-iron, about ten feet long, bored smooth in the inside; it has a broad flange in the middle, on the outside, by which it is supported when hung between the cylinder-beams, which extend across the house, and are let into the side-walk.
STEAM-ENGINE.

G, the piston, made to fit the cylinder exactly, but with liberty to slide up and down; it has a flange rising four or five inches upon its upper surface, between which and the side of the cylinder a quantity of junk or oakum is stuffed, and kept down by weights, to prevent the entrance of air or water, and the escape of steam.

H, the chain and piston-shank, by which it is connected to the working beam by an arc of a circle.

I, I, the working beam, or lever, working on its centre, in the manner of a scale-beam; it is made of two or more large logs of timber, bent together at each end, and kept at the distance of eight or nine inches from each other in the middle by the gudgeon or centre, as represented in the plate.

The arch-heads I, I, at the ends of the beam, are for giving a perpendicular direction to the chains of the piston and pump-rods, which are fastened at the opposite ends.

K, the pump-rod, which works in the great fucking-pump L, and draws the water from the bottom of the mine to the surface.

M, a cistern, into which the water drawn out of the pit is conducted by a trough, so as to keep it always full, and the superfluous water is carried off by another trough.

N, the jack-head pump, which is a smaller fucking-pump, wrought by a small lever or working beam, by means of a chain connected to the great beam or lever near the arch g, at the inner end; and the rod of the pump N is fastened by a chain at the outer end. This pump commonly stands near the entrance of the house, and raises a column of water up to the cistern O, into which it is conducted by a trough.

O, the jack-head cistern, for supplying the injection; it is always kept full by the pump N, and is fixed so high above the cylinder bottom, as to give the jet of injection a sufficient velocity into the cylinder when the cock is opened. This cistern has a waiste-pipe on the opposite side for conveying away the superfluous water.

P, the injection-pipe, of two or three inches diameter, which descends from the cistern, O, to the injection-cock r, after passing which it turns up in a curve at the lower end, and enters the cylinder bottom. It has a thin plate of iron screwed upon the end d, which is within the cylinder, with three or four ajutage holes in it, to cause the jet of cold water from the jack-head cistern to fly up in as many streams against the under surface of the piston, and condense the steam contained in the cylinder each stroke, when the injection-cock is open.

Q, a valve upon the upper end of the injection-pipe, which is shut, to prevent waife of water by leakage when the engine stands still; but before the engine is set to work, this valve must be lifted up, and kept open by a string.

R, a small pipe, which branches off from the injection-pipe, and has a cock to supply the piston with a little water to keep it air-tight.

S, the working plug, suspended by a chain to the small arch g, of the working beam. It is usually a heavy piece of timber, with a slit vertically down its middle, and holes bored horizontally through it to receive pins, for the purpose of opening and shutting the injection and steam-cocks, as it ascends and descends by the motion of the working beam.

b, the handle of the steam-cock or regulator. It is fixed to the regulator by a spindle, which comes up through the top of the receiver. The regulator itself is a feotorial plate of bras, shaped like a fan, which is moved horizontally by the handle b, and opens or shuts the communication at the lower end of the pipe E, within the receiver. It is represented separately in the plate by fig. 2.

i, the spanner, which is a long rod or bar of iron, for communicating motion to the handle of the regulator, to which it is fixed by means of a flit in the latter, and some pins put through to fasten it.

k, the vibrating lever, called the tumbling-bob, or the Y, having the weight k at one end, and the two forked legs at the other end, like the letter A turned. It is fixed to an horizontal axis, moveable about its centre pins, or pivots, m, m, and is put in motion by means of the two shanks o, o, fixed to the same axis, which are alternately raised and depressed by means of two pins in the working plug, and the bob or weight at the top of the Y is thrown backwards and forwards; one pin on the outside, depring the shank o, throws the loaded end, k, of the Y from the cylinder into the position represented in the plate, and causes the leg, b, of the fork of the Y to strike against the end of the spanner, which forcing back the handle of the regulator or steam-cock opens the communication, and permits the steam to fly into the cylinder. The piston immediately rises by the weight of the pump-rod, on the admission of the steam: the motion of the working beam, I, also raises the working plug s and another pin, which goes through the flit, raises the shank, p, of the axis, which throws the end, k, of the Y towards the cylinder, and the leg of the fork, striking the end of the spanner, forces it forwards, and shuts the regulator or steam-cock.

q, r is the lever for opening and shutting the injection-cock, called the F. It has a rack or toothed feotor fixed upon its axis, which takes the teeth of a pinion, fixed on the top of the plug or key of the injection-cock.

When the working plug has ascended nearly to its greatest height, and shut the regulator, as above described, a pin catches the end, q, of the F, and raises it up, which opens the injection-cock, and admits a jet of cold water to fly into the cylinder, and condensing the steam, makes a vacuum within. Then the preufure of the atmosphere, forcing down the piston into the cylinder, causes the plug-frame to descend, and another pin fixed in it catches the end of the lever, q, in its descent, and by pressing it down shuts the injection-cock; at the same time the regulator is opened to admit steam, and so on alternately; that when the regulator is shut, the injection-cock shall be open, and when the former is open, the latter shall be shut.

R, the eutufion-pipe, to convey away the water which is injected into the cylinder at each stroke; its upper end is even with the cylinder bottom, and its lower end has a lid or cover, moveable on a hinge, which serves as a valve to let out the injected water, and shuts clofe each stroke of the engine, to prevent the water being forced up again when the vacuum is made.

S, the hot-well, which is a small cistern made of planks, to receive all the waife water from the cylinder, and keep it in reserve for feeding the boiler, to supply the waife occasioned by the continual evaporation of the steam.

T, the feeding-pipe, to supply the boiler with water from the hot-well. It has a cock to let in a large or small quantity of water, as occasion requires, to make up for what is evaporated; it goes nearly down to the boiler bottom, so that the lower end is always immersed in water.

U, two gauge-cocks, in the upper ends of two pipes which descend into the boiler; one is deeper than the other; their use is to try when a proper quantity of water is in the boiler, for upon opening the cocks, if one gives steam and the other water, it is right, because the intended level of the water in the boiler is between the ends of the two. If they both give water there is too much.

W is the man-hole; it is a plate which is screwed over a hole
STEAM-ENGINE.

a hole on the side of the boiler, to allow a passage into it for the convenience of cleaning or repairing.

X, the steam-clack or puppet-valve, which is a brass valve, on the top of the pipe opening into the boiler, to let off the steam when it is too strong. It is loaded with lead at the rate of one pound to an inch square; and when the steam is nearly strong enough to keep it open, it will do for the working of the engine.

Y, the safety-valve, by which, at every ascent of the piston, the steam discharged from the cylinder which was admitted with the injection, and would otherwise obstruct the due operation of the engine.

Z, the cylinder beams, which are strong girders going through the house, for supporting or rather keeping down the cylinder.

G, the cylinder cup of lead surrounding the top of the cylinder, to prevent the water upon the piston from floating over when it rises too high.

H, the waste-pipe, which conducts the superfluous water from the top of the cylinder to the hot-well.

I, iron bars, called the catch-pins, fixed horizontally through each arch-head to strike the floor, and prevent the beam descending too low, in case the chains at either end should break, or if the engine makes too long a stroke.

J, two strong wooden springs, to weaken the blow given by the catch-pins, when the stroke is too long.

K, two friction-wheels or fectors, on which the gudgeons, or centres of the great beam, are supported; they are the third and fourth part of a circle, and move a little each way as the beam vibrates.

Their use is to diminish the friction of the axis, which being necessarily very large for so heavy a lever, would otherwise be very great.

Operation of the Atmospheric Engine.—When this engine is to be set to work, the boiler must be filled about two or three feet deep with water, and a large fire made under it; and when the steam is heated to be of sufficient strength to exert a pressure of about one pound beneath each quarter inch of the safety-valve, it will lift up the valve and escape. The water in the boiler being superheated to be in a strong state of ebullition, and the steam issuing by the safety-valve, we will consider the machine in a state of rest, having both the steam-cock and injection-cock shut. The refilling position or attitude of the machine is such as appears in the drawing, the pump-rods, K, preponderating by their weight, and the great piston being drawn to the top of the cylinder.

The man who attends the engine depresses the handle p, so as to throw the thumbling-bob into the position of the figure; and the leg of the fork thrusting back the spanner is, opens the regulators on steam-cock, when the steam from the boiler immediately rushes in, and flying all over the cylinder, will mix with the air: much will be condensed by the cold surface of the cylinder and piston, and the water produced from it will trickle down the sides, and run off at the aduction-pipe, R, as soon as any quantity is accumulated. This condensation and waste of steam will continue, till the whole cylinder and piston are made as hot as boiling water.

When this happens, the steam will begin to open the safety-valve s, and issue through the pipe; at first slowly and very cloudy, being mixed with much air, the cloudy appearance of steam being always owing to its mixture with common air. The blast at s will grow stronger by degrees, and more transparent, having already carried off the greatest part of the common air which filled the cylinder. We supposed, at first, that the water was boiling briskly, so that the steam was issuing by the safety-valve, which is in the top of the boiler. The opening of the steam-cock puts an end to this at once, because the cold cylinder draws off the steam from the boiler with astonishing rapidity, until it becomes heated so as not to condense.

When the manager of the engine perceives that not only the blast at the safet-valve is strong and steady, but that the boiler is fully supplied with steam of a proper strength, which appears by the renewal of the discharge at the safety-valve, the engine is ready for starting. He now lifts up the handle o or q, till the thumbling-bob, Y, falls over the perpendicular towards the cylinder, and its leg striking the cross-pin of the spanner, i, draws it forwards, and shuts the steam-regulator; at the same instant he lifts up the handle, q, of the F, which opens the injection-cock. The preasure of the column of water in the injection-pipe, P, immediately forces some water through the spout d, by the jets.

The cold water coming in contact with some of the pure vapour, which now fills the cylinder, condenses it, and thus makes a partial void into which the more distant steam immediately expands; and by this very expansion its capacity for heat is increased; or, in other words, as it grows cold, it absoals the heat more powerfully from the steam situated immediately beyond it.

In this expansion and refrigeration the steam is itself partly condensed or converted into water, and leaves a void, into which the circumjacent steam immediately expands, and produces the same effect on the steam beyond it: and thus it happens, that the abstraction of a small quantity of heat from an inconsiderable mass of steam produces a condensation throughout a cylinder which is very extensive.

What remains in the cylinder no longer balances the atmospheric preasure on the surface of the water in the injection-cistern, and, therefore, the water spouts rapidly through the holes d, by the joint action of the column P, and the unbalanced preasure of the atmosphere; at the same time the safety-valve s, and the eduction-valve R, are shut by the external preasure of the atmosphere, and prevent the entrance of air or water into the cylinder. The velocity of the injection-water must therefore rapidly increase, and the jets dash against the bottom of the piston, and be scattered through the whole capacity of the cylinder. In a very short space of time therefrom, the condensation of the steam becomes universal, and the elasticity of what remains is very small. The whole preasure of the atmosphere, therefore, being exerted on the upper surface of the piston, while there is hardly any on its under side, if the load on the outer end of the working-beam is inferior to this preasure, it must yield to it. The piston G must descend, and the pump-piston K must ascend, bringing along with it the water of the mine; but the motion does not begin at the instant the injection is made.

The piston was kept at top by the preponderancy of the outer end of the working-beam and the load of water in the pumps, and it must remain there, till the difference between the elasticity of the steam below it, and the preasure of the atmosphere, exceed this preponderancy. There must, therefore, be a small space of time between the beginning of the condensation and the beginning of the motion: this is very small, not exceeding the third or fourth part of a second; but it may be very distinctly observed by an attentive spectator, who may perceive, that the instant the injection-cock is opened, if the cylinder has the slightest yielding in its fulness, it will heave upwards a little by the preasure of the air on the bottom. Its own weight is not at all
STEAM-ENGINE.

equal to this pressure; and instead of its being necessary to support it by a strong floor, it must be kept down by large beams, loaded at the end with heavy weights. This heating of the cylinders causes the instantaneous commencement of the condensation; and it is not till after this has passed, that the piston is seen to start, and begins to descend.

The motion must continue till the great piston reaches the bottom of the cylinder, because it is not like the motion which would take place in a cylinder of air rarified to the fame degree. In this latter case, the impelling force would be continually diminished, because the capacity of the cylinder diminishing by the descent of the piston, the air in it would continually become more dense and elastic, until the piston would float at a certain height, where the elasticity of the included air, together with the load at K, would balance the atmospheric pressure on the piston. But when the contents of the cylinder are pure vapour, and the continued stream of injected cold water keeps down its temperature to the fame pitch as at the beginning, the elasticity of the remaining steam can never increase by the descent of the piston, nor exceed what corresponds to the temperature, according to our table. The impelling or accelerating force, therefore, remains the same; and the descent of the piston will be accelerated almost uniformly, unless there is an increase of resistance, arising from the nature of the work performed by the other end of the beam. And it may be frequently observed in a good steam-engine, where every part is air-tight, that if the cylinder has been completely purged of common air before the steam-cock is shut, and if none has entered since, the piston will descend to the very bottom of the cylinder. It sometimes happens, by the great pump drawing air, or some part of the communication-chains giving way, that the piston descends with such violence as to beat out the bottom of the cylinder with the blow, and it is to prevent this accident that the catch-pins are applied at the end of the beam.

When the manager feeds the piston as low as he thinks proper, he shuts the injection-cock, by depressing the lever g; and at the same time he opens the regulator, by forcing down the handle s, which overfrets the tumbling-bob, and its leg catching the crook-pin of the spanner, t, opens the regulator.

The steam has been accumulating above the water in the boiler during the whole time of the piston's descent. The moment, therefore, that the steam-cock is opened, the steam, having an elasticity of rather more than one pound per square inch greater than that of the air, rushes into the cylinder, where it immediately blows open the snuffing-valves, and aslips the water which had come in by the former injection, and which arose from the condensed steam, to descend by its own weight through the eduction-pipe S, and open the valve to run out into the hot-well R.

This water is nearly boiling-hot; or at least its surface; for while lying in the bottom of the cylinder, it will condense steam till it acquires this temperature, and therefore cannot run down till it will condense no more. There is a cause of some waste of steam at its first admission, in order to heat the inside of the cylinder, and the injected water, to the boiling temperature; but the space being small, and the whole being already very warm, it is very soon done; and when things are properly constructed, little more is wasted than was necessary for the eduction-pipe is made of large dimensions, and receives some of the injection-water even during the descent of the piston, and this portion will be removed out of the way of the steam.

The first effect of the entering steam is of great service; it drives out of the cylinder the vapour which it finds there. This is seldom pure steam, or watery vapour, because all water contains a quantity of air in a state of chemical union; but the union is only feeble, and a boiling heat is sufficient for disengaging the air. If the latter part of the piston descends, and the steam is subjected to increased pressure, the air is freed, or is reduced to the state of a gas, and is driven off. The steam may also be disengaged by simply removing the external pressure of the atmosphere. This is clearly seen when we expose a glafs of water in an exhausted receiver. Therefore the small space below the piston contains watery vapour, mixed with all the air which had been disengaged from the water in the boiler by ebullition, and all that was separated from the injection-water by the diminution of external pressure, in addition to any which may enter by leakage.

Let us now consider the state of the piston, when letting out on its return; as it is evident that it will start, or begin to rise by the counter-weight, the moment the steam-cock is opened; for at that instant the excess of atmospheric pressure, by which it was kept down in opposition to the preponderancy of the outer end of the beam, is diminished. At the first instant of the return of the pump-rods, they draw up the piston with great violence, all the weight of the water in the pumps acting in addition to the counter-weight; but the falling of the lower valves in the pumps, after an inch or two of motion, arrests the further descent of the water, and bears the weight of the column of water; and after this the piston will rise gradually by the action of the counter-weight.

The action of the counter-weight is very different in the two motions of the engine; for while the engine is making a working stroke, it is lifting not only the column of water in the pump, but the absolute weight of the bucket-rods also; and while the pump-rods are descending, there is a diminution of the counter-weight, by the whole weight of the water in the pump, by the immersion of the rod in water. The wooden rods which are generally used being soaked in water, and joined by iron straps, are heavier, and but a little heavier, than water, and they are generally about one-third of the bulk of the water in the pumps.

By this counter-weight the piston is drawn upwards; and it would even rise, although the steam which is admitted was not quite so elastic as common air.

Suppose the mercury in the barometer to stand at 30 inches, and that the preponderancy at the outer end of the beam was equal to 4th of the pressure of the air on the piston, the piston would not rise if the elasticity of the steam was equal to 100; that is, to 26½ inches nearly; but if the steam was just equal to this quantity, the piston would rise as fast as the steam of that density could be supplied to the cylinder through the steam-pipe; and on this supposition, the velocity of the ascent would depend on the velocity of that supply. But this is not the case in practice, because the steam must be stronger than the air, in order to blow out and discharge the air; it will therefore enter the cylinder without any effort on the piston to draw or suck it in. At the same time, the counter-weight must not be so great as to draw up the piston with that force which will cause a suction within the cylinder greater than the steam-pipe can supply, or it would diminish the preasure of the steam within the cylinder lower than the atmosphere, and prevent it from fertilizing or blowing out the air.

In filling the cylinder with steam, it will require a much more copious supply of steam than merely to fill up the space left by the ascent of the piston; for as the descent of the piston was only in consequence of the vacuum occasioned by the interior of the cylinder being sufficiently cooled so as to condense the steam, this cooled surface must be again presented to the steam during the rise of the piston.
STEAM-ENGINE.

piston, and must condense steam a second time. The piston cannot rise another inch, till that part of the cylinder which the piston has already quitted has been warmed up to the boiling point, and much steam must be expanded in this warming; for the inner surface of the cylinder must only be raised to the heat of boiling water while the piston rises, but must also be made perfectly dry; and the film of water left on it by the ascending piston must be completely evaporated, otherwise it will continue to condense steam.

On this account, although the counter-weight is not necessary to suck in the steam, the moving force during the ascent of the piston must be considered as resulting chiefly, if not solely, from the preponderating weight of the great pump-rods; and this force is expended partly in returning the steam-piston to the top of the cylinder, where it may be again pressed down by the air, and make another working stroke by raising the pump-rods; and partly in returning the pump-buckets into their places at the bottom of their respective working barrels, in order that they may also make another working stroke. This latter requires force independent of the friction and inertia of the moving parts; for each bucket must be pushed down through the water in the barrel, which must lift up and rise through the valves in the bucket with a velocity proportioned to the velocity of the bucket, in the same degree as the area of the pump-barrel is proportioned to the opening of the valves through which the water must pass.

From this general consideration of the ascent of the piston, we may see that the motion differs greatly from the descent; it can hardly be supposed to accelerate, even if the steam was supplied to the cylinder in ever such quantity; for the resistance to the descent of the pump-bucket is the same with the weight of the column of water, which would cause water to flow through the valves of the buckets with the velocity with which it really rises through them, and this resistance must therefore increase as the square of that velocity increases; that is, as the square of the velocity with which the bucket descends. Independent of the force of friction, and the weight of the valves, the velocity of descent through the water must soon become a maximum, and the motion will become uniform. Accordingly, any one who observes with attention the working of a steam-engine, will see that the rise of the piston and descent of the pump-rods are extremely uniform, whereas the working stroke is very feebly accelerated.

These two motions complete the period of the operation, and the whole may be repeated by shutting the regulator, and opening the injection cock whenever the piston has attained the proper height. For the first two or three strokes, the opening and shutting of the cocks are performed by the attendant; but when he has thus ascertained that all parts are in order, he puts pins into the holes of the plug-frame, and the motion of the engine will then actuate its own machinery, and perform its reciprocations with greater regularity than can be done by hand.

Particulars of different Parts of the Atmospheric Engine.—We shall now pay some attention to the construction of the parts of this engine, and notice some further particulars.

The furnace or fire-place should not have the grate-bars too close as to prevent the free admixture of air, nor so open as to let the coals fall through. About two inches are sufficient for the distance between the bars. The height from the bars to the bottom of the boiler in the centre should not be more than two feet, and the concavity or rife of the bottom in the centre about one foot.

The size of the furnace depends upon the size of the boiler; but in every case the air-hole ought to be capacious, to admit the air. If the flame is conducted in a flue or chimney round the outside of the boiler, or in a pipe round the inside of it, it ought to be gradually diminished from its entrance at the furnace to its egress at the chimney; and the portion of the chimney at that place should not exceed the portion of the flue or pipe, and should also be somewhat less at the chimney-top.

The boiler or vessel, in which the steam is made by the force of fire, may be formed of iron plates, or copper, or of cast-iron, the bottom being of such materials as can withstand the effects of the fire, and have sufficient strength to retain the elastic force of the steam. It may be considered as consisting of two parts; an upper part, which is exposed to the steam, and an under part, which is exposed to the fire. The form of the latter should be such as to receive the full force of the fire in the most advantageous manner, so that a certain quantity of fuel may have the greatest possible effect in heating and evaporating the water; which is best done by making the sides cylindrical, and the bottom a little concave, and then conducting the flame by an iron flue or pipe round the inside of the boiler, beneath the surface of the water, before it reaches the chimney. For by this means, after the fire in the furnace has heated the water by its effect on the bottom, the steam heats it again by the pipe being wholly included in the water, and having every part of its surface in contact with it; which is preferable to carrying it in a flue or chimney round the outside of the boiler, as a third or a half of the surface of the flame only can be in contact with the boiler, the other being spent upon the brick-work. This cylindrical lower part may be left in its diameter than the upper part, and may contain from three to five feet perpendicular height of water in it.

The upper part of the boiler is best made hemispherical for retaining the elasticity of the steam; yet any other form may do, provided it be of sufficient strength for the purpose.

The quick going of the engine depends much upon the capacity of the boiler-top; for if it be too small, it requires the steam to be heated to a greater degree to increase its elastic force sufficiently to work the engine, and then the condensation on entering the cylinder will be greater. If the top is so capacious as to contain eight or ten times the quantity of steam used at each stroke, it will require no more fire to preserve its elasticity than is sufficient to keep the water in a proper state of boiling; this, therefore, is a sufficient fire for the boiler-top.

It is usual to place a damper, or iron slider, in the chimney, or in the flue leading into the chimney; and this has a chain or lever, by which the attendant can regulate the aperture of the chimney, and consequently the draught of the fire, so as to keep the steam to a great regularity: for it is evident, that when the engine works slowly, it will require less steam and fuel than when working rapidly; and without the damper, the engine would be constantly exposed to an excess or deficiency in the supply of steam. The boiler is, in some engines, placed immediately beneath the cylinder, the same as represented in Plate III.; and then the regulator is placed immediately within the boiler, and acts against the under surface of its top, in the same manner as in the first engine of Captain Savery, who invented the regulator.

It was a subsequent improvement of Newcomen's engine to remove the boiler from immediately beneath the cylinder to a small hole on the outside of the engine-house, and smaller in the beam-centre, so as to be carried to a greater height; it is more enabled to withstand the violent shocks to which it is constantly subjected from the working of the engine.
STEAM-ENGINE.

The greater advantage is, that two boilers can be employed; or when the original boiler requires to be repaired or renewed, it can be replaced by erecting another at one side, and carrying another steam-pipe to the steam-box: in this way the working of the engine can be continued without any stoppage; a circumstance of the greatest importance where the water must be constantly kept drained.

In either case, whether the regulator is placed in the boiler itself, or in the steam-box beneath the cylinder, it is constructed in the manner represented in Plate II. Fig. 2. It is a flat plate of brass, in shape resembling a fan, the upper surface of which applies itself exactly to the whole circumference of the orifice of the steam-pipe, and completely excludes the steam from the cylinder, being moveable round an upright axis, which is accurately fitted into a conical socket coming through the lid of the steam-box. It can be turned aside by a lever, or handle, on the upper end of this axis, so as to uncover or open the passage. The profile shows that, in the section of this plate, there is a protuberance in the middle. This rests on a strong flat spring, fixed below it, across the mouth of the steam-pipe, which spring presses it strongly towards the steam-pipe, causing it to apply very close, and the protuberance slides along the spring, while the regulator turns to the right or left. Both the handle of the regulator, and the end of the rod or spanner, are pierced with several holes, and a pin is put through them, which unites them by a joint. The motion of the handle of the regulator may be increased or diminished, by choosing for the joint a hole near to the axis or remote from it, and the exact position at which the regulator is to stop on both sides is determined by pins stuck in a horizontal bar, on which the end of the handle rests.

The tumbling-bob of the Y has a long leather check-flap fastened to it by the middle, and the two ends of the flap are fastened to the beams above it in such a manner, that the lump may be alternately caught, and held up to the right and left of the perpendicular. By adjusting the length of the two parts of the flap, the Y may be stopped in any defined position. The two legs of the fork spread out from each other, and also from the line of the fluke, thus, and they are of such length as to reach the horizontal pin, which crosses the fork or stirrup of the spanner below.

Now, suppose the pin of the spanner hanging perpendicularly beneath the axis, and the flake of the Y also held perpendicular; carry it a little outward from the cylinder, and then let it go, it will fall farther out of its weight, without affecting the stirrup of the spanner, till the inner leg strikes on the horizontal pin of the stirrup, and then it pulls the pin of the stirrup and the spanner towards the cylinder, and stops the regulator. It thus sets the regulator in motion with a smart jerk, which is an effectual way of overcoming the cohesion and friction of the regulator against the mouth of the steam-pipe. This push is adjusted to the proper length by the check-flap, which stops the Y when it has gone far enough. If we now take hold of the flake of the Y, and move it up to the perpendicular, the width between its claws is such as to permit this motion, and something more, without affecting the stirrup. But when pushed still nearer to the cylinder, it tumbles suddenly towards it by its own weight, and then the other leg of the fork strikes the pin of the stirrup of the spanner in the opposite direction, till the bob is checked by the flap.

Thus, by the motion of the Y, the regulator is open and shut suddenly. This opening and shutting of the steam-passage has an effect in the precise moment that is proper, by placing the pins in the plug-beam, which set upon the handles o and p, at a proper height. For this reason, it is pierced through with a great number of holes, that the places of these pins may be varied at pleasure; this, and a proper curvature of the handles o and p, make the adjustment as nice as we please.

In the same manner the motions of the injection-cock are also adjusted to act at the precise moment that is proper for them. The different pins are so placed in the plug-frame, that the steam-cock may be completely shut before the injection-cock is opened. The inherent motion of the machine, or the momentum of its parts, will give a small addition to the ascent of the piston, without expending steam all the while, and by leaving the steam rather less elastic than before, the subsequent descent of the piston is promoted.

The injection-cock is frequently provided with a tumbling-bob, to make it open suddenly. This is an arm extending from the centre of the F, or lever g, upon which the toothed sector is fixed, and having at its extremity a sufficient weight to open the cock in an instant. When this weight is lifted up to its utmost, the cock is shut, and in this position the weight is detained by a small latch, which is lifted up by a pin in the plug-frame, at the moment when the piston arrives at the top of the cylinder, and thus releasing the weight, it falls all at once, and opens the cock in an instant; but when the piston descends nearly to the bottom, another pin in the plug-frame takes the handle of the sector, and gradually closing the cock, raises the weight till the latch detains it, which happens when the piston is quite at the bottom of its motion.

The injection-cock ought to be opened suddenly; but there is much propriety in closing it gradually: for after the first dace of the cold water against the bottom of the piston, the condensation is nearly complete, and very little more water is necessary, although a continual ascension of water is absolutely required for completing the condensation as the capacity of the cylinder diminishes, and the water which is already injected becomes warmed. It is the continuance of this small injection which prevents the vapour in the cylinder becoming more dense as the piston descends.

The effect of the injection in condensing the steam in the cylinder depends upon the height of the reservoir and diameter of the orifice: if the engine makes a six-feet stroke, then the head and cistern should be at least twelve feet perpendicular above the top of the cylinder. The size of the orifice must depend upon the capacity of the cylinder, as steam will fly by a small orifice, but if the cylinder be very large, it is common to have three or four small holes rather than one large one, in order that the jet may be dispersed more effectually through the whole capacity of the cylinder. The injection-pipe, or pipe of conduct, should be sufficiently large to supply the injection freely with water. The injection-cistern is a common source from which all the parts of the machine receive their respective supplies of cold water. In the first place, the small branch s, which proceeds from the pipe F, immediately below the cistern, and is conducted to the top of the cylinder, has a cock at the end, which must be so adjusted, that no more water will run from it than what will keep a constant supply of a few inches of water above the piston to keep it tight. Every time the piston comes to the top of the cylinder it will bring the water along with it, and the surplus of its evaporation and leakage runs off by a waste-pipe w. This water necessarily becomes alight boiling-hot, and it was thought proper to employ its surplus for supplying the water of the boiler. This was accordingly practised for some time; but Mr. Beighton improved this economical thought by supplying the boiler from the eduction-pipe S, the water of which coming
STEAM-ENGINE.

coming from the cylinder, must be still hotter than that above the piston.

This contrivance requires attention to several circumstances, which will be easily understood by considering the perspective view. The eduction-pipe comes out of the bottom of the cylinder in an inclined direction, and descends into the hot-well R, where it turns up, and is covered with a valve; in the perspective view may be observed an upright pipe T, which goes through the head of the boiler, and reaches to within a few inches of its bottom. This pipe is called the feeder, and rises about three or four feet above the surface of the water in the boiler; it is open at both ends, and has a horizontal branch from its upper end, communicating with the hot-well R. This communicating branch has a cock, by which its passage may be diminished at pleasure. Now, supposing the steam in the boiler to be very strong, it will cause the boiling water to rise in the feeding-pipe T, and pattering along this branch, to rise also in the hot-well, and run over. The height of the surface of water in the hot-well, above the surface of the water in the boiler, is such, that the steam is never strong enough to produce this effect; but, on the contrary, the water in the hot-well will run off by the branch, and go down into the boiler by the feeding-pipe, as fast as the opening of the cock will admit. These things being understood, let us suppose a quantity of injected water lying at the bottom of the cylinder, it will run into the eduction-pipe S, and open the valve in the bottom, will flow into the hot-well. By properly adjusting the cock on the branch of T, the boiler may be supplied with water as fast as the waffes in steam-engine requires.

The small quantity that is necessary to supply the boiler might be immediately taken from the cold cistern, without sensibly diminishing the production of steam; for the quantity of heat necessary for raising the feline heat of cold water to that of the boiling temperature is small, when compared with the quantity of heat that must be combined with it, in order to convert it into steam. The heat expended in boiling off a cubic foot of water, is as much as would bring six cubic feet to a boiling heat from the temperature of 55°; and little difference can be observed in the performance of such engines as are fed with hot water, and those which have their boilers supplied from a brook. The hot water has, however, the advantage of being free from air; and when an engine must derive all its supplies from pit-water, the water from the eduction-pipe is far preferable to that from the top of the cylinder, because it has been in a measure boiled and distilled.

The interior surface of the cylinder requires to be bored with great exactness; and it must have a sufficient thickness of metal to resist the pressure of the atmosphere, without bending or altering its figure. The piston is made of cast-iron, as nearly as possible to fit the inside of the cylinder, and has all round it, within two inches of the edge, a circular ledge or rim projecting upwards from it, which is both to strengthen the piston, and also to leave a space round between it and the side of the cylinder, to receive the packing or wadding which keeps the piston tight. Mr. Smeaton, who made the best engines on Newcomen's plan, casted the lower surface of the piston to be always planked with elm or beech, about 3¼ inches thick. The planking consisted of two broad planks, crossing each other at right angles, and halved into each other at the interfection, so as to come to an equal thickness; the remaining parts or sectors between the arms of this cross were filled up with pieces of the same plank, well tongued and fitted together, and bolted fast to the cast-iron of the piston with one or two iron rings, let in flat under the lower surface to make it strong; the whole was surrounded with an iron hoop, a quarter of an inch less than the internal diameter of the cylinder. In this case, the cast-iron piston was made less than the wood which formed the bottom of the groove, to receive the wadding, whilst the edge of the cast-iron formed the upright side thereof. The wooden bottom was fitted to the iron with a double thickness of flannel and tar, to exclude the air between the iron and the wood. By this means the piston was less liable to conduct heat; and the wood, being placed with the grain radiating in all directions from the centre, was not liable to expand by the wet. The shank of the piston is made with two prongs, to unite it firmly to the piston; and if the engine is large, it has four prongs, to balance it equally; and the shank must also have two or four chains upon the arch-head. But the chains, when more than one is used, must be united in pairs to the ends of a short horizontal link; and from the middle of this the shank must be suspended, by which means the strain will be equally divided between the two chains. When there are four chains, they must be divided into two pairs, with horizontal links, as above; and the middle parts of these two links must be united to the ends of a longer horizontal link, from the middle of which the shank of the piston is hung; and in this way all the four chains will bear equally.

The upper ends of the chains are jointed to the ends of strong iron bars, supported on the ends of the arch-heads; and at the other ends bolted to the top of the beam, by which means they brace the arch-head.

The original method of making the great working beam was to employ a large tree, and to place the gudgeon or fulcrum under the middle of it, with proper bands to fasten it. The framed beam, represented in the view, was made by Mr. Smeaton: the two middle pieces are formed of whole balks, 12 inches square, put together with the gudgeon as it is now, which is five inches thick, and notched into the beams, to make it keep its place; the ends of the beams are then sprung together, and bolted fast. This being done, another pair of timbers is applied upon the outside of the two former, and others on the outside of these, for the largest engines, making ten balks in the whole. When all these are firmly united, several mortises are cut through between the joints, as shown by the small square marks in the figure; and into these, hard oak wedges are driven, so that they will be half in each beam, and prevent them from slipping or sliding upon each other in the least; and, in this case, the beams act as ties by the longitudinal strength rather than their flexibility. The great beams which suspend the cylinder, and extend across the house, are compounded of several pieces, in the same manner; and the cylinder has a projecting flange from the middle of it, to bolt it down to the beams.

The pump-rods or pins, K, are made of wood, with iron straps let in and bolted to them at each end, to join them together: they are made of fir, which is very good wood, and it will bear a great strain endways, if the iron straps are well fitted, and can be obtained in very long pieces. When a mine is of a considerable depth, the pumps cannot be made to lift the whole at once; but the pit must be divided into two, three, or four lifts, and as many different pumps employed; each lifting the water into a cistern, for the supply of that which is above it. Fifty yards are as much as is proper for each lift, but in some very deep mines they are obliged to make them more. It is very difficult in these cases, to make all the pipes sufficiently strong to bear the pressure of the water, particularly the shock which takes place
STEAM-ENGINE.

place when the whole column of water falls upon the valves in shutting: the blow which they then make is like the stroke of a forge-hammer, and soon beats every thing to pieces. The only effectual remedy is the addition of an air-velvet at the side of the pump; but in general the miner makes a hole in the suction-pipe of the pump, just below the plunger, and fixes in a cork, with a small valve opening outwards: through this they admit a certain quantity of air every time the pump draws, and this air, mixing with the water in the barrel, condenes, when the valves shut suddenly, and by its elasticity eases the violence of the shock. When the mine is pumped almost dry, the engine will draw a little air at every stroke, at the bottom of the pipes; and this answers the same purpose. See a description of a new pump for mining in our article PUMP.

Rules for determining the Proportions of Atmospheric Engines.

—Mr. Newcomen brought forward his engine at a time when almost all the valuable mines in England were coming to a stand for want of more powerful or cheaper machines than were then known; and in consequence, in a few years his invention was put in practice at almost all the mines then existing; and new ones were opened in situations where it would have been impossible to have done it before. The first perfect engine which they erected at Grift, in Warwickshire, had only a 22-inch cylinder, and it was many years before any were made so large as 36: those which we now call small engines, were so much more powerful than any former means of draining water, that they were amply sufficient, until the mines, by growing deeper, required more power. The most obvious means of increasing the force was to change the cylinder for a larger one, and this was most frequently done one or more times; and then, when the beam and other parts would bear no greater strain, a new and larger engine was erected. In this manner they proceeded for many years, until, by gradual increase, the cylinders for common use had reached the enormous powers of 50, 60, and 72 inches diameter.

When it became impracticable to extend them much larger, engineers began to consider the means of improving their performance without increasing their dimensions: also, the consumption of fuel in these large engines was so serious an expense, as to balance the profits of many mines.

At first the fuel was not considered as an object, because the steam-engine, on the whole, was found so much cheaper than any other means of draining water. The best engineers were those who made engines which would fulfill the task assigned to them, and, in comparison to their dimensions and expense of erection, would draw the most water, and be the most certain in the continuance of their operation. We have no accounts of the quantity of fuel consumed by any of those early engines, in proportion to the water which they raised to any given height; but the rules by which they apportioned their cylinders to the work to be performed have been preserved.

Defaguliers tells us, that Mr. Newcomen's way of finding the power of his engine, was to square the diameter of the cylinder in inches, and cut off the left figure, and then call it long hundred weights; and writing aoyer on the right hand, he called the number on that side odd pounds: this he reckoned tolerably exact at a mean, or rather when the barometer was at 30 inches, and the air heavy. The effect of cutting off the left figure from the square of the diameter, is to divide the number of superficial circular inches on the piston's surface into portions of 16 circular inches each; and the pressure on each of these portions is estimated at a long hundred weights; 120 lbs. therefore, the pressure will be

\[
\frac{120}{10} = 12 \text{ lbs. per circular inch, or } 12 \times 3.1416 = 37.68 \text{ lbs. per square inch for a circular area of } 16 \text{ in.}^2.
\]

This, however, must be considered as the full pressure of the atmosphere, if the vacuum was perfect. But to compensate for imperfection, Newcomen allowed between one-third and one-fourth part, and also for what is lost in the friction of the several parts, and for accidents. Now, instead of the long hundred of 120 lbs., he would have the

\[
\frac{120}{10} = 12 \text{ lbs. per circular inch, or } 144 \text{ lbs. per square inch, which is still nearer the medium pressure of the atmosphere.}
\]

Defaguliers says this rule will agree pretty well with the work at Grift engine, there being lifted at every stroke between two-thirds and three-fourths of the weight of the atmospheric column preying on the piston; i.e. between 10 and 11 lbs. on each square inch. To give the estimation in round numbers, the diameter of the cylinder of Grift engine will be 22 inches; this squared is 484, cut off the left figure, and we have 48 cwt. 40 lbs. for the preasure of the atmosphere. The column of water in the pumps weighs about 274 cwt., to which adding the weight of 73 yards of iron rods, equal about 9 cwt., the weight lifted at the end of the beam would be 564 cwt., from which we must subtract about 4 cwt. for the piston, and the other weight at that end of the beam, reducing the load to 32 lb. cwt.; so that the weight of the atmosphere being 45 cwt. 40 lbs. raises a weight of 32 cwt. with a velocity of six feet in two seconds, conferring only the descending stroke of the piston. This requires an effective pressure on the piston of nearly 11 lbs. per square inch, including friction and counter-weight; but to balance the weight of the water in the pump, demands a pressure of only 8 lbs. per square inch of the piston.

In calculating the powers of the steam-engine, it has been a common mistake with engineers to take into the account no other circumstances than the diameter of the cylinder, and the perpendicular height and diameter of the pumps; from which they calculate only what burden is laid upon each square inch of the cylinder or piston area, supposing the piston to be at rest, but without paying any regard to the velocity of the engine's motions under such burden, or the number of strokes per minute. Without taking these particulars into the account, it is impossible to calculate the quantity of water raised to a given height, which is the only means of obtaining the exact power or acting force of an engine: it would be like attempting to measure the contents of a solid body by only two dimensions. Steam-engines have different times been calculated to carry a load varying from 5 lbs. to upwards of 10 lbs. to the square inch; but when working with the light pressure of 5 lbs. to the inch, they are expected to go with double the velocity; that is, the piston to move through double the space in the same time that it would with a pressure of 10 lbs. In this case the same quantity of water would be raised to a given height in the same space of time; in the steam-engine, as well as in other machines, there is a maximum, which cannot be exceeded without applying some new principle; and though by bad workmanship an engine may fall short of what it should do, the best workmanship can only produce a certain effect.

In estimating the power or effect of engines in this manner by the pounds per inch in the area of the piston, it must be considered as the clear product of the engine in the column of water it will raise, abstracted of all deductions for friction, counter-weight, &c. For, by attending to the different lifts of pumps in the engine-shaft of a coal or a copper mine, we find that we must, beside the altitudes and diameters, take into the account the friction of the buckets, and of the water on the sides of the pumps; the
STEAM-ENGINE.

opening of strong double-leathered valves, together with the stones and gravel that enter at the foot of the pump; the inertia of the pump-roads, the chains, the massive lever placed between the cylinder and the pumps, all to be overcome by the preffure on the piston, in addition to the 7 or 8 lbs. per square inch. These additions to the power required for the mere raising of the water are so considerable, as to be at least equal to half what is required for the work performed: this will raise the real acting preffure of the atmosphere to 104 or 115 lbs. per square inch. When this is the case, the vapour which remains in the cylinder must be equal in preffure to 45 or 53 lbs. per square inch; and this, by our first table of expansion, will indicate a temperature of from 15° to 14° of Fahrenheit.

In general, the water in the hot-well indicates a lower temperature than this; but although we have but little information concerning the rate of the vacuum in the atmospheric engines, when working in their usual state, it must be considerably more perfect than has been suggested by the idea of a preffure of 8 lbs. per inch; for an engine carrying a load of 75 lbs. on the square inch of the piston, together with the friction and inertia, even in large engines, cannot be less than 114 lbs. on the inch. Mr. Hornblower informs us that he tried the vacuum of several engines in the county of Cornwall; and in one, which was reckoned the least, he had 24 inches, instead of 30 inches, at which it would have had if the vacuum was perfect. If we take the extreme of these observations, it will be 11.6 lbs. on each square inch.

Mr. Henry Beighton seems to have been the first who reduced the steam-engine to any degree of certainty in its calculations, and laid down the rules for calculating its powers. Beighton was a mathematician as well as an engineer, and conducted the Ladies Diary from 1714 to 1744. For several years he lived at Griff, and had constant opportunities of trying experiments on engines.

We have before noticed his invention of the working-gear, or mechanism, by which the regulator and steam-cock are alternately opened and shut. In 1717, Mr. Beighton published the following table of the necessary proportions of the cylinders of engines to the pumps, when drawing water at different depths, from 15 to 100 yards, in different quantities, from 48 to 480 hogheads per hour.

This table is formed on the foundation of the ale-gallon, (containing 282 cubic inches,) which, when filled with pure running water, weighs 10 lbs. 3 oz. and 70 cubic inches; and a superficial inch, on a vacuum, takes in about 14 lbs. 13 oz. of the atmosphere, when the mercury stands in a medium in the barometer.

But allowing for several frictions, and to give a considerable velocity to the engine, experience has taught us to allow but little more than 8 lbs. to an inch in the cylinder's base, that it may make about 16 strokes in a minute, at about six feet each.

An Example for the Use of this Table.-Suppose it was required to draw 150 hogheads per hour, at 90 yards deep; in the seventh column, I seek the nearest number, viz. 149 hogheads, and against it, in the first column, I find a pump of seven-inch bore; then under 90, the depth on the right hand in the same line, I have 27 inches, the diameter of the cylinder fit for that purpose, and so for any other. Henry Beighton.

This estimation of 8 lbs. preffure for each square inch continued for many years to be the rule with engineers who constructed their engines according to this proportion; and if the engines were of a better or worse construction, they would move with a greater or less velocity, because all the excess of preffure which could be obtained above the 8 lbs. was appropriated to overcome the friction and inertia of the machine; and also to raise the counter-weight: if, therefore, this additional quantity was greater or less, the engine would move quicker, and raise a greater quantity of water.
STEAM-ENGINE.

water in the same time. Mr. Brighton expected his engine to move 16 strokes  per minute, of six feet each, or 96 feet of motion per minute; but succeeding engineers found these seldom to come up to this, and then began to diminish the burden to 7 lbs. per square inch, and even 6 lbs., in order to obtain a greater velocity of motion.

The celebrated engineer Mr. John Smeaton carried the engine of Newcomen to perhaps as great a degree of perfection as its principle admitted. Having constant occasion to employ large steam-engines in the great works which he executed, he turned his attention to consider the means of improving their effect, and diminishing the consumption of fuel. In calculating the proportions for an engine for the New River Company, in 1757, he considered that the stoppage of the water at every stroke, as well as putting the lever-beam, piston, heavy rods, and chains, from a state of rest into motion, twice at every stroke, was a great loss of power; he therefore determined to work the engine slower, and with larger pumps, and put upon the piston all the load it would bear. To reduce the velocity of the column of water still more, he would place the fulcrum of the beam out of the centre, and make the stroke of the piston nine feet, while the pump, which lifted 6 feet, should work with only six feet stroke. This arrangement obliged him to employ a long narrow cylinder, of only 18 inches diameter, and from this he also expected to obtain other advantages; viz. that every part of the steam, being nearer the surface of the cylinder, would be more readily condensed; and, in consequence, that a less quantity of injection-water would serve the cylinder, which would itself be more heated. Under all these appearances of advantage, he ventured to burden the piston with a preasure of 70.4 lbs. per inch. Thus, area of piston (18 inches diameter) 254; weight of the column of water 96 feet in the pumps, 18 inches diameter, 35,960 lbs., of which take 3 lbs. for the difference of the length of Stroke, and gives 2640 lbs. for the weight to be lifted by the piston; and dividing 2640 by 254, the area of the piston, gives 10.4 lbs. preure per inch. "Having once seen a common engine struggle under this burden, I thought myself (says this ingenious engineer) quite leuer under those advantages; but now great was my surprize and mortification, to find that, instead of requiring less injection-water than common, although the injection-pump was calculated to as much injection-water as usual, in proportion to the area of the cylinder, with a sufficient overplus to answer all imaginable wants, it was unable to support the engine with injection; and that two men were obliged to assist to raise the injection-water quicker by hand, to keep the engine in motion: at the same time that the cylinder was so cold, I could keep my hand upon any part of it, and bear it for a length of time in the hot-well. By good fortune, the engine performed the work it was appointed to do, as to the raising of water; but the coals by no means answered my calculation. The injection-pump being enlarged, the engine was in a state of doing business, and I tried many smaller experiments, but without any good effect, till I altered the fulcrum of the beam so much, as reduced the load upon the piston from 104 lbs. to 82 lbs. per inch. Under this load, though it shortened the stroke at the pump-end, the engine went so much quicker, as not only to raise more water, but consume less coals, took less injection-water, the cylinder became hot, and the steam-engine was at last the same in a cylinder of Fahrenheit; and the engine in every respect not only did its work better, but went more pleasantly. This at once convinced me that a considerable degree of condensation of the steam took place in entering the cylinder, and that I had lost more this way by the coldness of the cylinder, than I had gained by the increase of load. In short, this single alteration seemed to have unfettered the engine; but in what degree this condensation took place under different circumstances of heat, and where to strike the means as upon the whole to do best, was still unknown to me. But resolving if possible, to make myself master of the subject, I immediately began to build a small fire-engine at home, that I could easily convert into different shapes for experiments, and which engine was very near ready to set to work in the winter of 1769."

With this experimental engine, which is representet in Plate III. Steam-Engine, Mr. Smeaton made a multitude of experiments, which he noted down with great care in tables, and from their results deduced rules for the proportions of the parts of his engines: he afterwards erected many engines of the largest dimensions, which fully verified his experiments; the first of these was at Long Benton colliery, in 1774, which had a 52-inch cylinder, and afterwards a 72-inch, for the empress of Ruffia, at Cronfalta.

Mr. Smeaton's Experimental Engine.—Plate III. contains an elevation of this engine, shewing all its parts at one view; and, after the minute description which we have given of Mr. Newcomen's engine in Plate II., it is not necessary to enlarge on the particulars of the present. A, B, are the walls of the building; C groundflats, extending from the wall B, to the wall of the boiler or furnace; D are strong upright timbers, to support the cross-beams d, on which the centre of the beam is fullscreened; P are the cylinder-beams, framed into the upright D, and the walls A, B; and the cylinder G is hung between them by thick cross-planks g, g.

M is the great beam, librating on its centre, and formed to arcs of circles at the ends, to which are fastened the chains b for the piston, and the chain of the main-pump over H. It has also attached to it the plug-frame Q, and at the other end an iron rod k, which works the injection or jack-head pump, I, by means of a counter lever a a, which brings the rod, i, of the pump to a convenient place, near the main-pump O O'. The proper distance for the motion of the beam is limited by two iron fixds or pins b, b, which reach out from each side of the arch-heads, and stop on pieces of wood, supported by the beams S, called the forming-beams. The beam a, which supports the upper floor of the house, are let into the walls A, B, at the ends, and rest in the middle on the cross-beam d, and are firmly bolted down, as shewn in the drawing.

N is the injection-pipe, n the injection-cock, and X the piston water-cock, branching off from the injection-pipe N, L is the injection-cittern, placed in the highest part of the house; k k is the pipe from the injection-pump I, by which it is supplied; and T is the waste-pipe, at which the excess of water runs off. The pipe T leads down to the small cittern s, which will always be kept full, and the overflow will run down the waste-pipe t, and escape out of doors.

f is the fire-door, and the ash-pit is beneath it: the fire circulates round the boiler, and then passes into the chimney: p is a small door at the bottom of the chimney, to clear the foot, and there is also a damper to regulate the draft: n is the boiler, and its figure below is shewn by the dotted lines: w is a pipe rising from it, which has the safety-valve at the top of it, contained in a box or trough, which carries the steam through the wall at w: s is the steam-gauge, a small height of tube, which contains mercury, and shews the preasure of the steam. The cylinder G, besides the bored part in which the piston works, has a bottom W, screwed on by a flanch at the lower part, and from this bottom part descends the steam-beam s. The short pipe, x, joins to the lower end of the injection-pipe N N; and opposite
STEAM-ENGINE.

opposite to this is a similar short pipe, for the snifting-valve. Also from the bottom of the cylinder there descends the funk, or education-pipe s, which enters the hot-well R, and the end is covered with a valve. S is the waft-pipe, from which the excess of hot water in the hot-well is carried off into the well E E.

As the hot-well is placed so low that the boiler cannot be supplied from it, a small feed-pipe, p, proceeds from the lower part of the cylinder, and enters the boiler, having a cock, p, to regulate the quantity which shall pass through, and a valve to prevent the water being drawn up from the boiler into the cylinder. In the top of the boiler is the regulator-plate, 7, to the under surface of which the regulator is fitted: the handle or lever of the regulator is also seen, and the spanner or rod 5, by which it is alternately moved backwards or forwards by the arms 3 and 4 of the \(\Delta\). When its weight or bob, 3, falls over on either side of the perpendicular, it is checked by the trap 9; 1 and 2 are the arms or handles by which the \(\Delta\) is moved when the pins in the plug-beam, Q, act upon them, and \(\delta\) is a weight to balance the weight of the handles.

10 is the E, or lever of the injection-cock; it is connected with the handle of the cock, 13, by a fork, which cannot be seen; and the end, 11, is loaded with a sufficient weight to cause its descent, and open the cock, except when it is elevated, by pressing down the end 10; and when it is held up by the hook 12, the cock will then be shut; but when the plug-frame rises to its highest, it draws the wire 14, and lifts the catch 12, so as to let fall the weight 11, and opens the cock in an instant.

The action of this engine is apparent after the explanation which we have given of the former engine, and it is only necessary to explain a small machine which is called the citera \(\Phi\), called the citera or citera \(\Phi\), it was very commonly used in the engines for draining foundations, or other temporary works. It had a pulley or wheel, to receive the chain which communicated motion from the piston to the pump-rod, instead of a beam; and the whole machine being supported in one frame of wood, it had no connection with the building in which it was placed, or it could work all together in the open air. The frame was shaped like the letter A, and the vertex supported the pivots of the wheel, which the cylinder and pump were bolted down to the ground fulks, on which the A was erected. The engine in its action was the same as others; the boiler required no setting in brick-work, but was in the shape of a large tea-kettle, and the fire-place was in the centre of it, surrounded on all sides by the water. On one side was an opening for the fire-door, and a large tube or pipe led through the water to a hollow sphere of cast-iron, in which the fire was made, upon a grate; and from the grate another large tube or ash-pit descended perpendicularly through the bottom of the boiler, and was open below to supply air to the fire; also opposite the fire-door was a small large tube or chimney, leading from the sphere through the side of the boiler, and it then turned up in the manner of the spout of a tea-kettle, to carry off the smoke into a tall chimney of brick or of iron-plate.

From Mr. Smeaton's manuscript papers (now in possession of Sir Joseph Banks) we gain much practical as well as philosophical information on the atmospheric engines; and as these engines are still used very extensively at coal-mines, we think the publication of the particulars will be of service.

Mr. Smeaton's experiments with his experimental engine were very numerous, and so diversified, as to afford all the information which can be derived upon Newcomen's engine. It would exceed our limits to transcribe many of these experiments; but we think it will be serviceable to give the table of proportions, which he settled from the results of all his experiments, and after which table, between the years 1774 and 1785, he erected no less than eight first rate engines, with cylinders of five and six feet diameters, and many others of smaller dimensions. A full description, with drawings, of one of these engines, is given in the publication of Mr. Smeaton's Reports, 3 vols. 4to. London, 1811.
Mr. Smeaton's Table for the Proportions of the Parts of Newcomen's Engines, deduced from actual Experiments.

</table>
STEAM-ENGINE.

The different columns of this table explain themselves, except the great product per minute. This is the effect of the engine expressed in a convenient manner, to separate it from all considerations of the diameter or lift of the pumps, or of the number of strokes which the engine makes in a minute; being the multiple of all these, and is thus obtained. Multiply the square of the diameter of the cylinder in inches, by the preffure on each square inch of the piflon, not expressed in pounds weight, but in the height of a column of water in feet; and this again is multiplied by the velocity of the motion of the piston per minute. For example, a 26-inch cylinder: square of diameter, \(676\times 18\) feet, the preffure per square inch in feet of water, \(= 12.6 \times 76.21\) feet, the journey per minute, \(= 927333\), the great product per minute, as per table. The table is calculated upon the supposition that the preffure upon each square inch of the piflon is 8 lbs. avoirdupois, or 18 feet column of water.

The last column, or effect per minute of one bushel per hour, is a comparative view of the effect of different-sized engines, showing the advantages of large engines in respect to small, in the quantity of work they will effect in proportion to the coal they consume.

To find the number of bushels of coals which any of the engines will consume per hour, calculate the internal surface of the cylinder in square inches, and add to it three times the square of the diameter, to allow for the piflon bottom, cylinder bottom, and the surface of the pipes which are within the cylinder. Next calculate the solid content of the cylinder in cubic inches, and find the proportion between the superficial and the solid measure of the cylinder: according to the number of this proportion, find a number in the following table for a divisor.

<table>
<thead>
<tr>
<th>Proportion of the Surface of the Cylinder to its Capacity in square and cubic Inches.</th>

</table>

Lastly, cut off three places of figures from the great product per minute, and dividing by the divisor, the quotient will be the effect of one bushel per minute.

For example, a 72-inch cylinder: its circumference will be 326.3, which, multiplied by 135 inches, the length, gives 30550 square inches; and adding thereto 15558, which is three times the square of the diameter, we have 46102 superficial inches; and the content of the cylinder is 549852 cubic inches, which is 110 times the number of the superficial inches. By seeking in the last table for 11.9 or 12, we find the number 572 for the divisor of the great product, after cutting off its three last figures, viz. 7558 \(\div 572\) = 13 bushels per hour.

By this way of finding the proportion between the surface and the content of the cylinder, an allowance is made for the loss of steam which takes place from condensation, when it enters into the cylinder at every stroke, after it has been cooled by the injection thrown into it.

The quantity is very considerable, and forms the greatest objection to this form of the steam-engine. An attentive observation to the action of an engine will shew that there is a waste, but not the quantity in which it takes place. The moment the regulator is opened, when the piston is at the bottom of the stroke, the steam may be perceived to issue from the stuffing-valve with a strong puff, because the steam is more elastic than air by one or two pounds per square inch; but as the piston rises, this steam diminishes, and soon ceases, and no more steam will issue during the whole rise of the piston.

To ascertain the quantity of this loss by condensation, it becomes first necessary to know to what degree water is expanded, when converted into steam, at the preffure of the might be, and compare this with the degree of expansion which it requires to convert the water, which the boiler consumes in a given time, into such a quantity of steam as will fill the cylinder the requisite number of times in the same period.

Mr. Beighton made an experiment at Griff engine, in Warwickshire, on the degree of rarefaction of water when converted into steam, but without determining the temperature. The preffure of the steam was just one pound upon the square inch, as he determined by the reed-yard of the fly-serve; and by our second table, we find this to denote a temperature of about 210°. The cylinder of the engine contained 113 gallons of steam at every stroke, which, at 16 strokes per minute, is equal to 1808 ale-gallons, or 1808 \(\times 8\) = 14464 pints of steam per minute. He found that the necessary supply of fresh water for the boiler, under these circumstances, was about five pints per minute, to keep the surface of the water at a constant level; therefore, the relative bulk of the steam of one pound per inch preffure, and the water from which it was produced, were as 5 to 14464, or as 1 to 2893 nearly. By an unaccountable rule, Delaugiers, who relates the above experiment, deduces from the same data, that the expansion is 13488, a number which has been frequently quoted by other writers. Mr. Beighton's experiment cannot be admitted as conclusive, because the cylinder being cooled by the condensing water at every stroke, the steam would be condensed, and lose much of its bulk in entering into the cold cylinder. But without making any allowance for that loss, Mr. Beighton's experiment makes a greater degree of expansion than has been found by others; and we should not have mentioned this experiment at all, had it not been so frequently quoted after Delaugiers with his enormous error, even by Belidor, Prony, and other foreign writers.

Mr. Smeaton made some experiments by weighing a Florence flask of four inches diameter, first when it was perfectly dry and empty, and afterwards when it was full of water; then pouring out all the water, except a small quantity, he put the globe on the fire, and made it boil strongly, till the last drop of water disappeared, and at that instant he stopped up the mouth to retain the steam which was within it. The flask being now weighed, gave the difference of weight between the flask filled with water and with steam of an elastic force equal to that of atmospheric air; and deducting the weight of the empty flask from each of these experiments,
ST. EAM-ENGINE.

experiments, it gave the proportion of the bulk of the steam to that of the water: this, by a mean of fixx different experiments, he determined to be as viii vii. But supposing that some air was contained in the flasks along with the steam, he inverted the mouth of it in water when it was filled with the hot steam, and found it to draw up the water in the same manner as after seeing by captain savery; but it was not quite filled with water, for a small bubble of air remained in the flask, and this he estimated to be such a portion of the whole content, as induced him to reduce his estimate of the expansion from 2450 times to 1800 times; and this number, the same number that Mr. Watt had determined, he used in his calculations.

His investigation of the quantity of steam destroyed by a given surface of the cold cylinder was as follows. The cylinder of the experimental engine was 9.9 inches diameter and 50 inches long making the requisite additions to its bottom and piston, the internal surface was 2340 square inches, and the solid content was 3940 cubic inches. The quantity of water necessary to supply the boiler at each stroke was found to be 8.7 cubic inches; which 3940 divided by 8.7, was 463 times, which the 8.5 cubic inches of water must have expanded to fill the cylinder at each stroke. But supposing the water to have expanded 1800 times, the 8.5 inches x 1800 = 15300 cubic inches of steam produced, which is 3.88 times the quantity employed to fill the cylinder. The difference of these numbers, viz. 15300 - 3940 = 11360 inches of steam condensed and lost. This, divided by the number of superficial inches on the surface of the cylinder, gives 4.9 cubic inches condensed by every square inch of surface.

It will be readily seen, that the proportion between the quantity of steam which must be produced, and the quantity which will be employed, will be less in large cylinders than in small ones; hence the above is the extreme case; and in a similar trial of a 52-inch cylinder, he found the waste to be only 2.7 cubic inches for each inch of surface. Hence we see the reason for Mr. Smeaton's rule of making the proportion of the surface of the cylinder to its capacity the ground-work for the calculation of the quantity of coal.

In common engines, which are loaded to seven or eight pounds upon inch, and which are of a middle size, the quantity of steam which is condensed in refilling to the cylinder the heat which it had lost, is equal to the full content of the cylinder, besides what it really required to fill it; so that twice the contents of the cylinder are employed to make it raise a column of water equal to about seven or eight pounds for each square inch of piston; or to take it more finely, a cubic foot of steam makes a sufficient vacuum to raise a cubic foot of water about eighteen feet high, besides overcoming the friction of the engine, and the resistance of the water to motion.

In all Mr. Smeaton's experiments he observed the quantity of water which was evaporated in proportion to the coal, and found by a mean of a great number of experiments, that a bushel of coal evaporated 12700 cubic inches of water, or 7.35 cubic feet; and estimating the expansion at 1800 times, the bushel of coal will produce 13230 cubic feet of steam, of little more in elasticity than the atmosphere, and about 214 degrees Fahrenheit's thermometer.

The Work actually performed by Atmospheric Engines in proportion to the Coal.—We shall first give the results of the performance of some old engines, according to Mr. Smeaton's account, before he began his improvements. The engine at Long Benton colliery, which was considered as one of the best in the neighbourhood of Newcastle, was tried by Mr. Smeaton in 1772; it was of the following dimensions. Cylinder 52 inches diameter, stroke 7 feet. The pump was 12 inches diameter, and drew the water 61 fathoms high; and also an injection-pump 8 inches diameter, and 5 feet 7½ inches stroke, which raised water 58 feet. This engine consumed 8 bolls (of 2 cwt. 1 qr. 21½ lbs. each) of coals, such as are generally used for engines, in two hours and two minutes, when working at the rate of from 7 ½ to 8 strokes per minute, or 7 ½ per minute at the medium.

The computations from these data are first to ascertain the real weight of water in the pumps; the main pump being 12 inches diameter, and the injection-pump 8, the proportion of the areas of the two will be as the squares of their diameters, and their load in proportion to their height of column; therefore, as 144.445.88 feet high; 25.7 feet; that is, the whole load of the injection-pump will be equal 25.7 feet of the main column of 12 inches diameter; but this is, provided that the length of stroke was the same in both.

To reduce them to one, say as a 7 feet stroke, or 84 inches, : 07.5 in. :: 25.7 ft. : 20.7 feet of the column of the main pump, say 21 feet.

Hence, the whole load consists of the main column of 12 inches diameter, and 61 fathoms or 366 feet, and the injection-pump equal to 21 feet thereof, 366 + 21 feet = 387 feet.

To obtain what Mr. Smeaton calls the great product, by which the powers of different engines can be compared, multiply the square of the pump's diameter 144 inches X 387 feet lift = 55728, which multiplied by a 7 feet stroke = 36006, and again by 7.75 strokes per minute = 303244, the whole product or effect of the engine, regardless to coal, or without any allowance for the weight of the pump-rod, and the counterpoise of the engine.

The quantity of coal was 2 cwt. 1 qr. 214 lbs. = 2734 lbs. x 8 bolls = 2188 lbs. which divided by 88 lbs., the weight of a London bushel, gives 24.86 bushels consumed in the whole time of the experiment, viz. two hours and two minutes, or 122 minutes.

To find the coals for one hour's work, say as 122 minutes : 60 min. :: 24.86 bushels : 1.2 bushels per hour.

Lastly, the whole product 303244, divided by 12.2, gives 247401 for the product or effect of one bushel of coal per hour.

This engine was rebuilt according to Mr. Smeaton's plan, with the same cylinder of 52 inches and 7 feet stroke, but the pumps were enlarged to 12.3 inches diameter, and lifted in two columns each 24 fathoms 4 feet high. The injection-pump was 7 inches diameter, 5 feet 6 inches stroke, and lifted 70 feet 7 inches high.

In 1774 Mr. Smeaton tried the experiment, and found that when this new engine was working at the rate of twelve strokes per minute, a cwt. 1 qr. 16 lbs. of the common engine coals supplied it 22 minutes.

From this he made a similar computation to those for the former engine. Square of 12.3 inches the diameter of the main pumps 148.84; square of 7 inches the diameter of injection-pump 49; its lift 70.5 feet. Then say as 148.84 : 49 : 70.5 : 23.21 feet of the main column, if the lengths of the strokes were equal; but as they are not, say as the long stroke 84 in. : 66 in. :: 23.21 ft. : 18.2; therefore the load of the injection-pump is equal to the load of 18.2 feet of height of the main column.

The total load then is equal to a barrel 12.2 inches diameter, twice 24 fathoms 4 feet, or 296 feet + 16 feet, viz. 314 feet of lift.

To obtain the great product, multiply the square of the pump's diameter 148.84 by 314 feet; the height lifted = 5 46735.76.
STEAM-ENGINE.

46735.76, which multiplied by 7 feet stroke = 32150.121
and again by 12 strokes per minute = 382780.24 for the whole product or effect of the engine, without regard to coals, or without allowance for the weight of the pump-rod, nearly 3 tons, and the counter-weight of the engine.

For the quantity of coals 2 cwt. 1 qr. 16 lbs., or 268 lbs., divide it by 88 lbs., the weight of a London bushel, and it makes 3.05 bushels consumed in 22 minutes, the time of the experiment; therefore say, as 22 min. : 60 min. :: 3.05 : 8.32 bushels per hour.

Lastly, the whole product 392804.84, divided by 8.32, gives 471851 for the product, or effect of one bushel of coals per hour. Therefore the effect of this new engine, compared with the former engine, is as 471851 to 247401.

To this computation, which is chiefly comparative between the two engines, we may add the following, to show the pressure upon each square inch of the piston. The area of the 52-inch cylinder is 52 x 52 = 2704 x .7854 = 2123 square inches.

The weight of the column of water in the pumps, 12.2 inches diameter, will be about 50.08 lbs. weight for each foot in height. For 12.2 x 12.2 = 148.34 x 7.854 = 116.8, the square inches of the area of the cylinder, we have the weight of the column of air into which the water will rise, with the square inches of the area of the piston. If we multiply 116.8 by one, the square inches in a square foot, and it will give 434 lbs., which is the weight of a column of water one inch bale and one foot high. Multiply 116.8 x .434 = 50.7 lbs., the weight of the column of water in the pumps a foot high; and this multiplied by 314 feet, the whole lift equals 15010 lbs., the total weight of water.

Divide this number by 2123, the number of square inches in the surface of the piston, and it will give 7.14 lbs. for the pressure upon each square inch, 7.14 very nearly, and a very small number.

Another method of readily finding the pressure per square inch in the piston is thus. As the square of the diameter of the cylinder (52 x 52 = 2704) is to the square of the diameter of the pump (12.2 x 12.2 = 148.34), so is the height which the pump lifts, 314 feet, to 17.24, the height of a column of water, which, if it refted on the piston, would balance the water in the pump. Then multiply 17.24 feet by 434 lbs., the weight of an inch square of water one foot high, and the result is 7.48 lbs. for the pressure per square inch, the same as before.

Since Mr. Smeaton introduced his improved engines, it has been customary to compare their effects by the number of pounds of water which they can raise to one foot high by the consumption of a bushel of coals, without regarding the time in which it is expended. To reduce these two engines to that standard, we must say the first engine consumed 24.86 bushels in 122 minutes; therefore, as 24.86 bu. :: 122 min. :: 1 bu. :: 49 min.; that is, one bushel will lift 49 minutes.

At every stroke, the pump draws up a cylinder of water, 12 inches diameter and 7 feet long, 387 feet high. This cylinder of water will weigh 343 lbs.; for 12 x 12 = 144, x .7854 = 113 inches, the area of the pump. This, multiplied by .434 lbs., the weight of a column one inch square, and one foot high; will be 49 lbs.; and again, multiplied by 7 feet for the length, will equal 343 lbs.

The quantity of coals consumed in the first experiment was 24.86 bushels; the experiment lasted 122 minutes, during which time the engine, working at 7 1/2 strokes per minute, made 945 strokes; then say, as 24.86 bu. :: 945 strokes :: 1 bu. :: 38; therefore the engine makes 38 strokes for every bushel of coals which it consumes.

At every stroke the engine raises 343 lbs. of water 387 feet. Multiply 343 by 38, the number of strokes, and it gives 13034 lbs., hit 387 feet by each bushel of coals. Lastly, 13034 x 387 = 5044,158 lbs. of water raised one foot high with a bushel of coals.

The new engine consumed 3.05 bushels in 22 minutes, during which time it worked 12 strokes per minute; it is therefore 264 strokes; then say, as 3.05 bu. :: 264 strokes :: 1 bu. :: 86.5, the number of strokes which the engine will make for each bushel it consumes.

At every stroke the engine raises a cylinder of water, 12.2 inches diameter, 7 feet long, and weighing 354.8 lbs. 314 feet high. Multiply this 354.8 lbs. by the 86.5 strokes which the engine makes for each bushel of coals, and we have 30690, the number of pounds of water lifted 314 feet by each bushel of coals. And lastly, 30690 lbs. x 314 feet

= 9,636,660 lbs. of water lifted one foot high with each bushel of coals.

Mr. Smeaton's Directions for making Engines. — Mr. Smeaton made his engines with a wooden bottom to the piston, as we have before noticed. This was because wood communicates heat much less rapidly than metals. The piston is kept much cooler than any other part to which the steam has direct access, not only from the water which is poured upon it to keep it tight, and prevent the leakage of the steam, but also from the conduction of the cold injection-water; and as the steam in entering the cylinder through the steam-pipe first meets the cold surface of the piston, it is thereby condensed in a greater degree than by an equal portion of the internal surface of the cylinder. By covering the bottom of the piston with wood, it will receive or conduct less heat from the steam; and for the same reason, the cold water, when it is thrown upon against the piston, will be less heated by the contact of it, the wood acting as a neutral body on the fluid, which alternately acts as a conductor.

The injection-cap, or jet, according to Mr. Smeaton, should be a square hole through a brass plate, and rounded from the under side, that it may throw up a full bore. The middle of the jet should not be directed to strike the centre of the piston bottom, but it should rise perpendicularly, so as to strike the piston bottom at right angles. That part of the injection-pipe which is within the cylinder should be made of wood, or if of metal, wrapped round with tarred marine, or small rope, to separate the metal of the pipe from the condensation of the steam, or hot water, which not only faves the conduction of some fume, but by preventing the pipe becoming hot, that portion of injection-water which is contained in the pipe is kept cool, and the steam which afterwards flows through the pipe will enter in its coolest state. The injection-cylinder should be placed as high as the building will admit, so as to give a smartness to the jet.

A pipe should be applied beyond the stuffing-valve, with a cock in it, which being partially closed, the stuffing can be regulated, if it should be found too great, so as to emit more steam than is requisite. Mr. Smeaton also placed a small air-cock on the upper part of the eduction-pipe, or some other part having free communication with the cylinder, for the largest engine. This was to be only the size of a small common beer-cock; and when the cock was properly regulated, this cock was to be opened as much as it could be, to allow the piston to come fully down into the cylinder. We suppose this air-cock must have been found practically beneficial, or such an experimental engineer as Mr. Smeaton would have discontinued to recommend it; but we do not know on what principles the admission of air could be serviceable, unless it was to diminish the defending power of the piston when it arrived near the bottom of the cylinder, and thus diminish that acceleration of the piston, of which we
STEAM-ENGINE.

we have before spoken in the description of the action of the engine.

Lastly, in adjusting the engine to its work, to determine the proper degree of counter-weight, it was to be put together, and the pumps filled with water, but the buckets without the leathers, and the piston without any packing. In this state, a weight, equal to about 1lb. per square inch, being laid upon the piston, the engine was ballasted at either end of the beam, as it might require, until it was found in exact balance. Then, when the piston was relieved from its weight, it would have a counter-weight tending to draw it up with a force equal to 1lb. per square inch. This was for engines of the largest dimensions; but as the proportion of loss by friction of the piston and buckets is greater in small cylinders and pumps, smaller engines must have 1½lb., and the smallest engines 1½lb. per inch. When it is not convenient to fill the pumps with water up to the top, allowance must be made for the difference of the pump-rod not being immersed.

Mr. Smeaton expected his engines, which were calculated to be loaded with a neat burden of 8lbs. per square inch, would, with the counter-weight as above, make their returning stroke rather quicker than the working stroke, and this he preferred. The proper proportion of the counter-weight has been a matter of much mathematical investigation by writers on the engine, particularly M. Boffist; but it depends upon so many contingent circumstances, that it would be impossible to apply any theorem to practice, even if the theory were established; and the adjustment is easily ascertained by experiment.

The design of the engineer in giving or allowing a preponderancy to the outer end of the beam, is simply that the buckets may descend, and that the piston may rise and allow the steam to fill the cylinder, without any further combination of apparatus being employed for that purpose. Now let us observe its operation, and the manner of adjusting its quantity in an engine's first setting to work. Suppose the water already up to the top of the pump; the steam being admitted into the cylinder till it has driven out the air, the operator shuts the steam-cock, without supplying any injection; and the engine will make its first stroke, though very quietly, by the external condensation from the surface of the cylinder: he then allows steam again to enter the cylinder, and according to the piston's tendency to rise, he suits his judgment to the degree of counter-weight necessary: if it rises too low, he puts iron or other ballast upon the pump-end of the beam; and if it rises too quick, he places these weights on the piston-end. We have then two important circumstances to attend to in this regulation. First, that the pump-bucket shall descend as quick as it can, but without such force as shall occasion a violent shock to stop the motion at the end of the strokes; and secondly, that the piston shall not be drawn up faster than the steam-regulator (with the degree of opening that is given to it) can supply steam; for that would impede the discharging functions of the engine, or getting rid of the air and condensing water; and unless these are performed punctually, the engine soon ceases to work. Now neither the air nor the water can be discharged instantaneously from the cylinder, but require a certain time, in proportion to the quantity of each, and the degree of strength in the steam; and therefore the piston must not rise so quick as to prevent the steam acting on the air and condensing water, which it will do if the engine has too great a counter-weight, and the steam is low; for if the piston ascends faster than the boiler supplies steam, there can be no discharge, and after a stroke or two the engine will stop.

But this is on the supposition that the engine is working with its full intended velocity. When an engine is erected on a mine or pit which is sinking, the quantity of water to be lifted by the pump being small, the engine must work slowly, and the counter-weight must be in proportion; the beam will nevertheless require an extra counterpoise at the pump-end, because of the lightness of the pump-rod; but as the mine or pit becomes of greater depth, and successive lengths of rods are applied for the different lifts of pumps, the weight must be diminished, and at length transferred to the piston-end of the beam, in such quantity as to keep the engine under command; for as the velocity of the returning stroke depends upon the quantum of counter-weight, this must be regulated according to the quantity of water which this engine has to draw, or rather to the number of strokes the engine is to make in a minute. As this velocity is to be increased when the quantity of water increases, a greater counter-weight must be added; but it is not until the engine works at its intended load, that the counter-weight must be brought to the degree we have mentioned.

While an engine is working, as we have supposed, with a small portion of its full load, the injection must be very sparingly applied, fo as to condense imperfectly within the cylinder, or the piston will descend with such velocity, and strike upon the spring-beams with such violence, as to beat every thing to pieces.

When a mine is going down, and the engine-shaft receives all the water from the different parts of the mine, the quickness of the engine's stroke must depend upon the uniform influx of the water, and the engine must be so accurately regulated to the pint of the load, as to stop it up at every stroke. Now if this stopping up is violent, the air will be drawn into the pumps at the conclusion of every stroke, and cause the engine to work irregularly; and, on the other hand, if the strokes of the engine are not quick enough, the water will gain on the miners and prevent their working. The velocity, as we have before stated, must be regulated by the quantity of injection which will determine the motion of the stroke, and the counter-weight will regulate the time of the returning stroke: but a much better regulation of the velocity of the engine can be attained by the cataracts, which we have before described.

Even when the engine comes to work with its full load and counter-weight, and when a proper injection is allowed to condense fully, the engine-man can retard or accelerate the returning strokes of the engine, in some degree, by the regulation of the fire; for if the engine should return too quick, he lets down the damper in the flue of the chimney; or if it is too slow, he raises the damper. By these means he can vary the action of the steam, on the lower side of the piston, from one to two pounds on the inch, greater than the prensure of the atmosphere, which in a sixty-inch cylinder will amount to 2800 pounds, and is sufficient for the engine return very quick or very slow, but does not alter the period of the working of the stroke.

Other Improvements on Newcomen's Engine.—Mr. Smeaton's improvements on the engine, as we have shewn, consisted only in proportioning its parts, but without altering anything in its principle.

In 1759, Mr. James Brindley, the engineer who designed and executed the duke of Bridgewater's canal, obtained a patent for improvements in the structure of the fire-engine. The boiler he proposed to be made of wood and stone, with a cast-iron flue or fire-place within of it, and surrounded
STEAM-ENGINE.

rounded on all sides, so as to give its heat to the water. The chimney was an iron pipe or tube, also immered in the water of the boiler. This plan he expected would save a considerable portion of the fuel. The feeding-pipe for the boiler was to be made with a clack, to be opened and shut by a float upon the surface of the water in the boiler, so as to supply it with water always to the same level, without any care on the part of the engine-man. The great chains for the arches of the beam were to be of wood, and his pumps were also to be made of wooden flates hooped together. These are all the improvements mentioned in the specification of his patent; but in the new edition of the Biographia Britannica, we are informed that, in 1756, Mr. Brindley undertook to erect a steam-engine near Newcastle-under-Lyme upon a new plan. The boiler of it was made with brick and stone, instead of iron plates, and the water was heated by internal iron flues of a peculiar construction, by which contrivances the consumption of fuel necessary for working a steam-engine was reduced one-half. He introduced also into his engine wooden cylinders, made in the manner of cooper's ware, instead of iron ones, the former being cheaper and more easily managed in the shafts; and he likewise substituted wood for iron in the chains which worked at the end of the beam. He had formed designs of introducing other improvements into the construction of this useful engine, but was discouraged by obstacles that were thrown in his way.

The most important improvement in the atmospheric engine was the application of it, by means of a crank and fly-wheel, to the purpose of turning mills. This was not much invention to any one who had considered the action of a foot-lathe; but it does not appear to have been put in practice till a late period, or brought into any extensive use till after Mr. Watt invented his engine. Mr. Jonathan Hills had a patent in 1756, for working rowing-wheels at the side or head of a boat by the force of Newcomen's engine, and we believe he proposed to employ a crank, to produce the rotary motion of the wheels.

In 1759, Mr. Keane Fitzgerald propounded, in the Philosophical Transactions, a contrivance to work the ventilator by the fire-engine, for the benefit of those who work in mines, where it is employed to draw off the water. By this contrivance the lever of the fire-engine, which works up and down, and performs at a medium about twelve strokes in a minute, is made to turn a wheel constantly one way, and the number of strokes is also increased to fifty or sixty in a minute. The machine is described by three figures annexed to the memoir, and is considered as ingenious. It is stated that it may easily be made to turn a mill to grind corn, or a wheel to raise coals.

It is related in the Encyclopaedia Britannica, that Mr. Fitzgerald took out a patent for communicating a rotative motion from the steam-engine, but we believe this is a mistake. In the Edinburgh Review it is stated, that an atmospheric engine was employed at Hartley colliery, in Northumberland, as early as 1768, to draw coals out of a pit. It had a toothed sector on the end of the working beam, working into a trundle, which, by means of two pinions with ratchet-wheels, produced a rotative motion in both the ascending and descending arch of the sector; and by shifting the ratchets, the motion could be reversed at pleasure. This engine had no fly-wheel, and went sluggishly and irregularly. Who the inventor was is not mentioned.

A patent was taken out in 1769 by a gentleman of the name of Stewart, for an engine which produced a rotative motion by a chain going round a pulley, and also round two barrels furnished with ratchet-wheels, with a weight suspended to the free end of the chain, which served to continue the motion during the return of the engine. About the year 1778, Mr. Matthew Wathbrough, of Bristol, also obtained a patent for communicating a rotative motion from the steam-engine, by a method which was virtually the same as that at Hartley; only he added a fly-wheel, which we believe was then, for the first time, employed in the steam-engine. Two or three of these engines were erected, one at his own works, for turning lathes, &c. and also one at Southampton, at Mr. Taylor's works, besides two or three for grinding corn; but, owing to the defective mode of communicating the motion, they were subject to such irregularities as rendered them of little use.

The crank, which is now the universal method of communicating the motion of the engine to machinery, was, we believe, first applied to an engine at Birmingham. This method of converting the reciprocating motion into a continuous rotary motion, was by employing a great beam to work a crank or train of wheelwork. As the real action of the engine was confined to its working stroke, it was soon found advantageous to equalize, as nearly as could be, the power of the working and returning strokes. For this purpose, the rod which extended from the beam to the crank, and connected the engine and the mill together, and which is called the connecting rod, was made equal in weight to half the power of the engine, being made of cast-iron of large dimensions; and when the weight was not in the rod, it was placed on the beam at that end.

Suppose that by this means the engine is made to exert an equal force to turn round the crank in the ascent and descent of the connecting rod, still it remains to find some force which shall continue the motion in the interval of its change from ascending to descending, and vice versa. To accomplish this, it is necessary to connect with the crank or wheel-work a very large and heavy fly, which shall accumulate in itself the whole force of the engine during its time of action; and therefore continue the motion, and urge forward the working machinery, while the steam-engine is going through its inactive period of changing the crank or train of wheelwork. This will be the case, provided that the resistance exerted by the machine during the whole period of the working and returning stroke of the steam-engine, together with the friction of both, does not exceed the whole preface exerted by the steam-engine during its periods of action upon the crank; and provided the momentum of the fly, arising from its weight and velocity, be sufficiently great; so that the resistance of the work, during the changing of the stroke of the steam-engine, will not make any very sensible diminution of the velocity of the fly. This is evidently possible and easy, for the fly may be made of any magnitude; and being exactly balanced round its axis, it will soon acquire any velocity conincident with the motion of the steam-engine.

During the working stroke of the engine, it is uniformly accelerated; and by its acquired momentum, it produces the movement of the mill until the engine changes, and makes its returning stroke; but in doing this, its momentum is shared with the inert matter of the steam-engine, and consequently its velocity diminished, but not entirely taken off. The weight of the connecting rod, therefore, by preying on the crank affrelish during the returning stroke, increases the remaining velocity in the fly, by a quantity equal to the whole that it lost during the inactivity of the engine. This must be acknowledged to be a very important addition to the engine; and though sufficiently obvious, it is ingenious, and requires considerable skill and address to make it effective.

Mr. John Steed, in 1781, had a patent for applying the crank to a steam-engine; and in the same year, the abbé Arnal
STEAM-ENGINE.

Mr. Curr's Table of Proportions for the Parts of Atmospheric Steam-Engines.

</table>

In all these engines, he supposes the length of the stroke to be nine feet, and that they work 8 1/2 feet stroke in common work.

In 1793, Mr. Francis Thompson had a patent for making the atmospheric engine work a double stroke, for the convenience of turning machinery by a crank; this he effected by employing two cylinders, one inverted over the other, and the piston of both connected by one rod, which passed through the bottom, or rather the top, of the inverted cylinder, and was connected with the beam: by this means the cylinder acted alternately to make an up or down stroke. This never came into use, for the engine was as complicated as Mr. Watt's, without any of his advantages.

Mr. Watt's Steam-Engine.—The principle of this valuable invention will be best explained by a statement of the manner in which it originated, and the steps by which it attained its present degree of perfection.

Mr. James Watt was, in 1763, a maker of mathematical instruments at Glasgow, and being a man of truly philosophical mind, and well conversant with all branches of science, he was in habits of associating with the most celebrated scientific men at that time in Scotland, particularly with Dr. Black, Dr. Roebuck, and Dr. Robison, then a young philosopher. About this time he undertook to repair a working model of a steam-engine belonging to the university of Glasgow, and during this employment, observed the great loss of steam from the condensation of the cold surface of the cylinder, which we have before explained in Mr. Smeaton's investigations, though the latter were not made till after Mr. Watt's. He observed that a great quantity of heat is contained in a very minute quantity of water, in the form of elastic steam; for when a quantity of water is heated several degrees above the boiling point in a close digester, if a hole be opened, the steam rushes out with great violence, and in three or four seconds, the heat of the remaining water is reduced to the boiling heat. If the steam be condensed, the whole of it will afford only a few drops of water; yet this small quantity, in the state of steam, carried off with it all the excess of heat from the water of the digester. Mr. Watt reasoned, that if so great a quantity of heat is contained in a certain quantity of steam, the economical use of the steam was a matter of the first importance in the improvement of the engine, more than the construction of the furnace, which had been the chief object of former efforts to improve the engine, the improvement of the application of the steam having been much neglected after it was first settled by Beighton.

The cylinder of the little model was heated when the steam was in it, so that it could not be touched by the hand; but before a vacuum could be made, it required to be cooled by the injection, and then was to be heated again by the re-entrance of the steam; this, he feared, could not happen, unless the heat was abstracted from the steam, which must occasion the condensation and wastage of a considerable portion. His first enquiry was, what portion of the steam was thus wasted; but so few experiments had been made, even upon the most essential part of the subject, that the real bulk of water, when converted into steam of a given heat, remained unknown, until he determined it by new experiments in the year 1764. The opinions which had been entertained concerning its bulk before that time were much beyond the truth, and could by no means be deduced from the very inaccurate experiments which were said to have been made. Thus
STEAM-ENGINE.

Thus furnished with data, he was enabled to ascertain that the loss of steam, in alternately heating and cooling the cylinder, was not less than three or four times as much as would fill the cylinder and work the engine. The boiling of water in an exhausted receiver at low heats, which had been discovered, we believe, by M. Coulomb, was about this time communicated to Mr. Watt; but it was neither known what these heats were, nor what proportion they observed under various prehures, before he made his experiments on this subject. These experiments produced another defect of the common steam-engine, viz. that the injection-water thrown into the cylinder to condense the steam becoming hot, and being in a vessel exhausted of air, it produces a steam or vapour, which in part refills the prehure of the atmosphere upon the piston, and leffens the power of the engine: this might be remedied by throwing in as much water as would cool the whole vessel below the point at which water boils in vacuo; but then it would increase the first-mentioned inconvenience, which is the destruction of steam that unavoidably happens upon attempting to fill a cold cylinder with that fluid. Others, who had constructed steam-engines, found, that as they made their exhaustion more perfect by making the cylinder colder, they increased the consumption of steam in a greater proportion than they gained power. Though it appears they were ignorant of the cause, they were so sensible of the effect, that they contented themselves with causing the engine to raise a load equal to seven pounds upon the square inch of the area of the piston; whereas the prehure of the atmosphere would have raised much more, if the cylinder had been perfectly exhausted.

Mr. Watt's first attempt at the improvement of the engine was by employing a wooden cylinder, which would transmit the heat more slowly: this had some effect, but did not answer in other respects, and he was obliged to abandon it, as well as Mr. Brindley, who had before tried the same thing. He then caled his metal cylinders in a wooden cale with light wood-ashes: by this, and using no more injection than was absolutely necessary for the condensation, he reduced the waste almost one-half. But by using so small a quantity of cold water, the inside of the cylinder was hardly brought below the boiling temperature, and there consequently remained in it a steam of very considerable elasticity, which robbed the engine of a proportionable part of the atmospherical prehure.

It was not until the next year (1765) that Mr. Watt made his great invention of performing the condensation in a separate vessel from the cylinder. He conceived, that if a vessel, which he afterwards called the condenser, was made to communicate with the cylinder by a pipe, and filled with steam at the same time, an injection being thrown into the latter vessel would condense the steam therein, and cause a vacuum. Under these circumstances, the elasticity of the steam in the cylinder would cause it to rush into the vessel to restore the equilibrium; but this steam being condensed immediately it entered the vessel by the continuance of the injection, the vacuum would fill remain, and draw off the remaining steam from the cylinder until some was left. Here then was the vacuum in the cylinder produced, without any necessity for diminishing the temperature below the boiling point. Having thus obtained the vacuum to cause the defect of the piston, the subsequent re-äsent could be obtained by cutting off the communication between the cylinder and the condenser, and admitting into the former a fresh supply of steam from the boiler; but it was not necessary to admit any fresh steam from the boiler to the condenser, as the vacuum produced therein still continued, and it would be ready to receive and condense the steam from the cylinder, as soon as the piston arrived at the top of it, ready to make another stroke.

The first difficulty which opposed itself to this beautiful chain of reasoning was, how to continue the action, and prevent the separate condensing vessel from filling with the injection-water, and also how to get rid of the air. To shift by blowing steam into the vessel, in the manner of the former engine, would have caused him as great a waste of steam from condensation, as he would have by all his discovery. He then thought of condensing without injection, simply by the application of cold water to the outside of the condenser, on Savery's first plan; and to get rid of the small quantity of water produced by the condensation of the steam, he intended to carry a pipe down from the condenser to a depth of 34 feet, from the end of which the water would run off by its gravity. But the air which is carried over by the steam would also accumulate by descents, and could not be so easily evacuated; a small pump then would be to draw it off, and keep the condenser empty.

Mr. Watt at the same time conceived, that it would be very advantageous to employ the prehure or expansive force of the steam to actuate the piston in its deficient, instead of the prehure of the atmosphere, as it would be more manageable than the other in its intensity. Thus was the whole discovery made in a day; and it only remained to invent the details of the mechanism to carry it into effect, and to establish by experiment the requisite proportions of the parts.

Mr. Watt's first experiment on these new ideas was to try the effect of the separate condenser; but before he had made the apparatus for the experiment, he resolved to extract the condensed water from his condenser by means of the same pump which should draw off the air, as this method would be applicable in all situations.

The first apparatus was a cylindrical vessel, fitted with a piston, which could be drawn up in it to exhaust the air therefrom. This vessel was made to communicate, by means of a long pipe half an inch in diameter, with the cylinder of the engine, which was two inches in diameter, and ten inches long. The pipe had a stop-cock, to cut off the communication at pleasure; and the cylindrical vessel, which was made of thin tin-plate, was immersed in cold water. The piston of the cylindrical vessel being pressed to the bottom to displace the contained air, was then drawn up to leave a vacuous space, and the cylinder of the engine, having its piston at the top, was filled with steam. The cock in the communicating pipe being then opened, the piston descended with a velocity, which showed that the vacuum in the cylinder was almost perfect; and he found, that when he used water in the boiler purged of air by long boiling, nothing that was very sensibly inferior to the prehure of the atmosphere on the piston could hinder it from coming quite down to the bottom of the cylinder. This alone was gaining a great deal; for in most engines, the remaining elasticity of the steam arising from the heated injection-water was not less than one-eighth of the atmospherical prehure, and therefore took away one-eighth of the power of the engine.

Mr. Watt was so much occupied in other business, that it took him much time to complete his machine, and bring the whole to bear, so that he did not apply for his first patent until 1768, which bears date 5th Jan. 1769, and is for his method of leffening the consumption of steam and fuel in fire-engines. The specification contains the following principles.
STEAM-ENGINE.

"First. That the vessel in which the powers of steam are to be employed to work the engine, which is called the cylinder in common fire-engines, and which I call the steam-vessel, must, during the whole time that the engine is at work, be kept as hot as the steam that enters it; first, by enclosing it in a case of wood, or any other material that transmits heat rapidly; secondly, by furnishing it with steam, or other heated bodies; and thirdly, by suffering neither water, nor any other substance colder than steam, to enter or touch it during that time.

"Secondly. In engines that are to be worked wholly or partially by condensation of steam, the steam is to be condensed in vessels distinct from the steam-vessels or cylinders, although occasionally communicating with them. These vessels I call condensers; and while the engines are working, these condensers ought at least to be kept as cold as the air in the neighbourhood of the engines, by applications of water, or other cold bodies.

"Thirdly. Whatever air, or other elastic vapour, is not condensed by the cold of the condenser, and may impede the working of the engine, is to be drawn out of the steam-vessels or condensers by means of pumps, wrought by the engines themselves, or otherwise.

"Fourthly. I intend, in many cases, to employ the expansive force of steam to press on the pistons, or whatever may be used instead of them, in the same manner as the pressure of the atmosphere is now employed in common fire-engines. In cases where cold water cannot be had in plenty, the engines may be wrought by the force of steam only, by discharging the steam into the open air after it has done its office.

N. B. This should not be understood to extend to any engine where the water to be raised enters the steam-vessel itself, or any vessels having an open communication with it.

"Fifthly. Where motions round an axis are required, I make the steam-vessels in form of hollow rings, or circular channels, with proper inlets and outlets for the steam, mounted on horizontal axles, like the wheels of water-mills. Within them are placed a number of valves, which suffer bodies to go round the channels in one direction only. In these steam-vessels are placed weights, so fitted to them as entirely to fill up a part or portion of their channels, yet rendered capable of moving freely in them by the means hereinafter mentioned or specified. When the steam is admitted into these engines, between the weights and the valves, it acts equally on both, so as to raise the weights to one side of the wheel, and by the reaction on the valves, successively to give a circular motion to the wheel; the valves opening in the direction in which the weights are preffed, but not in the contrary one, as the steam-vessel which moves round it is supplied with steam from the boiler, and that which has performed its office may either be dischaged by means of condensers, or into the open air.

"Sixthly. I intend, in some cases, to apply a degree of cold, not capable of reducing the steam to water, but of conveying it considerably, so that the engines shall be worked by the alternate expansion and contraction of the steam.

"Lastly. Instead of using water to render the piston or other parts of the engines air and steam-tight, I employ oils, wax, refrangible bodies, fat of animals, quicksilver, and other metals, in their fluid state."

Soon after his patent, Mr. Watt became associated with Dr. Roebuck, who established the Carron iron-works. They proposed establishing an extensive manufactory for such engines under the patent; and Mr. Watt began his first real engine of 18 inches cylinder, at Kinnell, near Borrowstounness. This was a sort of experimental engine, and was successively altered and improved till it was brought to considerable perfection. In the details of its construction, the greatest difficulty of all was in the packing of the piston, so as to be steam-tight; because Mr. Watt's principle did not admit of water being kept on the piston to prevent the leakage, as in the old engines. He found great difficulties in procuring a cylinder sufficiently accurate, until a new method was introduced at Durham foundry, by Mr. John Wilkinson. In the old method of boring, the instrument which performs the part of cutting the metal was guided in its progress only by the incorrect form given to the cylinder by the mould; and though it infurred that every part of the cylinder should be circular, it gave no certainty that the cylinder would be straight. This was quite sufficient for the old engines, but Mr. Watt's engines required greater precision. Wilkinson's machine, which is described in our article Cylinder, infures all the accuracy the subject is capable of; and if the cylinder should be cast ever so crooked, the machine will bore it straight and true.

Dr. Roebuck becoming embarrased, from the failure of his vast undertaking in the Borrowstounness coal and salt works, was unable to prosecute the manufactory of steam-engines, and, in 1774, disposed of his interest in Mr. Watt's patent to Mr. Matthew Boulton, whose establishment at Soho, near Birmingham, was then the most complete in England, and conducted with the most spirit. A portion of the works was allotted to Mr. Watt, who erected a foundry, and the necessary works to carry his invention into effect, on a grand scale.

In consequence of the great loss of time, and the enormous expense necessary for bringing the engine to perfection, Mr. Watt was not able to produce any large engines, as specimen of his invention, until 1774; and found, from the difficulty of introducing them, that the term of his patent was likely to pass away before he should be reimbursed: he, therefore, applied to parliament for a prolongation of his term, which was granted for 21 years, by an act passed in 1775. With this encouragement, and with the advantage of Mr. Boulton's alliance in systematizing the manufacture of the parts, Mr. Watt soon produced many capital engines, which were ered at Staffordshire, Shropshire, and Warwickshire, and a small one at Stratford near London. He found it was necessary to admit a small jet of injection-water, of sufficient dimensions to extract both the condensed steam and injection-water, as well as the air; for the condensation, by the application of external cold, was not sufficiently rapid, and the engine was so much improved as to afford amply for the power requisite to work the air-pump.

The condensing of the steam, by injection into the admission-pipe, was an idea as early as the other kinds of condensers, and was tried in the very first engine built at Kinnell; but the other imperfections of that machine, owing to its leaky and bad workmanship, made it unsuitable, and this being attributed to the air which came in with the injection-water, Mr. Watt diffused the injection into the condenser, until the size and expence of the tubulated condenser for large engines, made him resolve to sacrifice a part of the power of the engine to convenience, and to employ larger air-pumps. In an engine at Bedworth, three air-pumps were used, two below, which were side by side, and worked by chains from each side of the beam, and a third above these two, and between these, a third one received the hot water lifted up by the other two; and by leaving the surface exposed to the pressure of the atmosphere, extracted the water with
STEAM-ENGINE.

with greater ease. In 1778 he only employed two air-pumps for the largest engines, one being double the area of the other, and there was used only one, as at present, which is the air-pump of Smeaton.

A sketch of one of these first engines is given in Plate IV.

Steam-Engine, fig. 4. The cylinder, and great beam, with its arch-heads and the pumps, stood in the same position as the former engines; but the cylinder, A, was smaller in proportion to the load than those before used, as it was generally loaded to 1½ pounds on the square inch. The cylinder was very accurately bored within side, to make it straight and cylindrical, and externally it was surrounded by a second cylinder, or jacket B B, leaving a small space, G, all round between the bored or internal cylinder, and the outer jacket B.

This space, G, communicated by a large pipe, F, with the boiler, and always remained full of steam, so as to keep the cylinder, A, at the same heat with the steam, and thereby prevent any condensation within it, which would have been a much greater loss than an equal condensation on the external surface of the jacket B. The jacket, B, was furnished with a lid, C, which had a hole in the centre for the piston-rods, a, to pass through. The rod was made truly cylindrical, so that the hole could be kept steam-tight by a collar of oakum screwed round it at E. The inner cylinder, A, had a close bottom, and the jacket, B, joined to the same, the cylinder being fitted with the piston H H, as usual; but the top of the internal cylinder, A, did not reach quite up to the lid of the jacket B, or outer cylinder; by which means the steam had always free access to the top of the piston, H, from the space, G, between the cylinders, and consequently from the boilers through F. At the bottom part of the inner cylinder there were two regulating valves, O and K, one of which, O, either admitted the steam to pass from the interval, G, between the jacket and the cylinder, through a passage, I, into the space of the interior cylinder below the piston, or shut out the steam from that space at pleasure: the other valve, K, opened or shut the end of the eduction-pipe M, which conducted to the condenser L. The condenser, L, was a close vessel, made of thin metal, and furnished with an air-pump N. The air-pump had valves, and a bucket, d, for exhausting the air, and drawing off the water which was produced by the condensation of the steam, along with which the air is extracted from the water in boiling, and rises with the steam. The air-pump was constructed nearly the same as a common pump, except that it had a lid or cover on the top of the barrel, to keep the pressure of the atmosphere from bearing constantly upon the bucket. The rod, a, of the bucket passed through a stuffing-box in the lid, and was suspended by a chain from the great working beam of the engine. The condenser, L, together with the air-pump N, were placed in a large cistern of cold water X, situated generally under the floor of the engine-house, between the cylinder and the wall on which the beam rested, and supplied constantly with fresh cold water from a small pump worked by the engine, or the cistern was placed outside of the wall, between the wall and the pit of the pump.

The action of this engine is as follows: suppose steam from the boiler to enter at F, and fill the space, G, between the jacket and the cylinder, and also the upper part of the cylinder above the piston. The condenser, L, is exhausted of its air, by opening both valves, O and K, in the bottom of the cylinder, and allowing the steam from the space, G, to blow through it, and through the valves of the air-pump: both valves are then shut, and the external cold condenses it so as to leave a vacuum in the condenser, whilst the cylinder, A, is all the while full of steam, from the space G, both above and below the piston H: the steam-valve, O, being shut, cuts off all communication with the under side of the piston from the steam in G, or in the boiler, and at the same time the eduction-valve, K, from the condenser is opened, when the steam rushes from the space of the cylinder A, below the piston, through the eduction-pipe M, into the vacuum of the condenser, with great violence, till it comes in contact with the cold sides of the condenser L, which is made of thin metal, and immered in cold water. Under these circumstances the steam is immediately deprived of its heat, and reduced into water; more steam immediately rushes in from the cylinder, until it is exhausted, and makes a vacuum beneath the piston H. The steam which is above the piston ceasing to be counteracted by the steam which was below it, presses between the top of the piston and the bottom of the lid, C, with its whole elastic force, and causes the piston to descend to the bottom of the cylinder, carrying along with it the beam, and raising the pump-buckets at the other end. The exhausting-valve, K, is then shut, and the steam-valve, O, opened, which allows the steam to enter below the piston, leaves it at liberty to rise; in which case, the superior weight of the pump-rods raises the piston on the top of the cylinder, ready to commence another stroke.

The advantages that arise from this construction are these: the cylinder, being surrounded with the steam from the boiler, is always kept uniformly as hot as the steam itself, and is therefore, incapable of destroying any part of the steam which should fill it, as the common engines do. Secondly. The condenser being kept always as cold as water can be procured, and colder than the point at which it boils in vacuo, the steam is perfectly condensed, and does not oppose the descent of the piston; it is, therefore, forced down by the full power of the steam from the boiler, which is somewhat greater than that of the atmosphere. Thirdly. The elaticity of the steam being employed to press down the piston, instead of the pressure of the atmosphere, the air does not enter the cylinder, or cool its interior surface; and the engine is not confined, as is the former engine, to work with its whole force, but it is only to administer steam of a proper elasticity, and we can vary the force of the engine very considerably, without losing any more fuel than that for which we obtain the effect.

When an engine of the old form is to be erected, the engineer must make an accurate estimate of the work to be performed, and must proportion his engine accordingly. He must be careful that it be fully able to execute its task; but its power must not exceed its load in any extravagant degree. This would produce a motion which is too rapid, and which, being alternately in opposite directions, would occasion jolts, which no building or machinery could withstand. Many engines have been shattered by the pump’s drawing air, or a pump-rod breaking; by which accidents, the steam-piston descends with such force and rapidity, that every thing must give way. But in most operations of mining, the task of the engine increases, and it must be so constructed, at first, as to be able to bear this addition. It is very difficult to manage a common engine when it is much inferior to its task: the only mode of as, as we have described, by the supply of a scanty injection; but the easiest way is to work the engine almost full loaded, and that only during a few hours each day, allowing the pit-water to accumulate during its repose. This increases the first cost of the erection, and wastes fuel; the miners are also much incommoded with water during the inaction of the engine. Mr. Watt’s engine can, at all times, be exactly fitted, during the working stroke, to the load of work that then happens to be upon it: it is only necessary to administer steam of a proper elasticity. At the first erection of the
STEAM-ENGINE.

engine, it may be calculated equal to twice its task, supposing that the steam admitted above the piston is to be three or four pounds per square inch more elastic than the atmosphere; but when the engine is first set to work, it may be made to act with a small portion of its force, by using weaker steam; for when once the ebullition in the boiler is fairly commenced, and the whole air is expelled from all parts of the apparatus, it is evident that, by damping the fire, the steam of half this elasticity may be continually supplied, and the water will continue boiling, although its temperature does not exceed \(15^\circ\) of Fahrenheit's thermometer. This appears, by inspecting our first table of vaporous elasticity.

The method now proposed has one inconvenience; for, while the steam is weaker than the atmosphere, there is an external force tending to squeeze the fides and bottom of the boiler, which could not be refilled in a large boiler, if the difference was considerable, and common air would rush in through every crevice of the joints of the engine. The regulation of the velocity of the engine may be produced by diminishing the passage for the steam into and out of the cylinder; for this purpose, the exhaustion-valve, \(K\), by which the steam passes away from the cylinder, may be so contrived, that its mechanism will lift it more or less high from the conical face in which it is lodged, and consequently the passage can be enlarged or contracted at pleasure, by the distance to which the valve is drawn up. The degree of opening given to the exhaust-valve would determine the rate at which the steam would flow off from the lower part of the cylinder to the condenser, and consequently the velocity of the descent of the piston; also the degree of opening of the other, or steam-valve, \(O\), would determine the rate of the ascent of the piston, by regulating the rate at which the steam could pass from the boiler into the lower part of the cylinder.

But to save the trouble of making the adjustment for the degree of opening of the working-valves, it is better to place a separate valve in some part of the steam-pipe, \(F\), which brings the steam from the boiler to the jacket of the cylinder; then if this valve, which is called the throttle-valve, and is solely for the purpose of regulation, be partially closed, so that it will not admit steam into the jacket as fast as the descent of the piston makes room for it in the cylinder, it is evident that the flow of steam will be less; and being there condensed, the jet will follow till none remains; then the steam, flowing through the throttle-valve, and passage \(d\), into the top of the cylinder, presses down the piston into the vacuum cylinder, until it arrives at the bottom; the exhausting-valve, \(K\), is then shut, and at the same time the steam-valve, \(O\), is opened by the plug-frame: this suff ers the steam from the boiler to rush into and occupy that small portion of the bottom of the cylinder beneath the piston, which being filled with steam of an equal density to that above it, there will be an equal preasure on both sides of the piston and the opening of the valve, \(O\), having made a free communication between the top and bottom of the cylinder, the piston is at full liberty to rise by the action of its counter-weight, until it arrives at the top of the cylinder, and then the steam-valve, \(O\), is shut, and the exhausting-valve, \(K\), opened, to make another stroke, as before.

The sketch in fig. 2, was taken from an engine of Mr. Boulton and Watt erected at Hull, in 1779; and this, with some slight variations in the manner of its action, which we shall afterwards describe, is the present standard engine for pumping water: the variety of the regulating-valve, \(F\), is made to open and shut at every stroke, and for regulation, another valve is applied in the steam-pipe just before it arrives at \(F\).

In the two engines which we have described, the piston descends in consequence of the preasure of the steam being
STEAM-ENGINE.

made to act upon it whilst there is a vacuum beneath; and the ascent is made, when the piston is placed in equilibrio, by an open communication being made between the upper and lower parts of the cylinder; and this will always be an exact equilibrium, not imperfect, as in the old engine, where the varying pressure of the steam and of the atmosphere always renders the circumstances in which the piston rises uncertain.

It is evident that the ascent of the piston may be as well performed in vacuo, provided the vacuum is made at the same time both above and below the piston. This form of the engine is represented in fig. 4, in which, as the same letters of reference are used, it is needless to repeat the description of the cylinder and piston. F is the valve which admits the steam to the top of the cylinder, to press upon the piston: this valve is shut when the engine makes its return or up-stroke. K is the exhaust-valve, placed close beneath the steam-valve W, instead of being at the bottom of the pipe W, which descends to the condenser, and gives off a branch, I, to the bottom of the cylinder; by this pipe the steam is always drawn off from the bottom of the cylinder, to keep a constant vacuum therein. Suppose the exhausting-valve, K, open, the steam in the top of the cylinder will also pass off to the condenser through the pipe W, and leave a vacuum in the whole cylinder: in this case the piston rises freely by the counter-weight to the top of the cylinder; and being arrived there, the exhausting-valve, K, is shut, and the steam-valve, F, opened. The steam from the boiler entering into the top of the cylinder, and preffing between the lid and the top of the piston, presses down the latter to the bottom of the cylinder, where being arrived, the steam-valve, F, is shut, to prevent the farther admission of steam from the boiler; and at the same instance, the exhausting-valve, K, being opened, the steam from the top of the cylinder passes off to the condenser, and this makes a vacuum above the piston, the same as was before made beneath it: in consequence, the piston is left at full liberty to rise by the action of the counter-weight, until it arrives at the top: the exhausting-valve, K, is then shut, and the steam-valve, F, opened, to make a fresh descent. The advantage of this contrivance is, that the whole time, during which the ascent of the piston is allowed for making the condensation; but this is found of little importance in practice, because the vacuum takes place almost instantaneously, when the exhausting-valve is opened, to allow the steam to pass off to the condenser.

Mr. Watt's Expansion-Engine.—This was a most important improvement, of which Mr. Watt had the first idea in 1769, but did not fully put it in practice until 1778. It consists in shutting off the farther entrance of steam from the boiler, when the piston has been pressed down in the cylinder for a certain proportion of its total descent, and then leaving the remainder of the descent to be accomplished by the expansive force of that steam which is already introduced into the cylinder. This gives the means of regulating the acting force of the engine, because the pins of the plug-frame can be placed in such a manner, as that the steam-valve shall be shut when the piston has descended one-half, one-third, one-fourth, or any other proportion; and so far the cylinder will be occupied with steam of the same elasticity as that in the boiler, which is usually about the same as the atmosphere. In order to press the piston farther down, the steam must expand; and though its elasticity will diminish, it will be enough to complete the stroke. It is plain that this can be done in any degree at pleasure, as the adjustment of the pins in the plug-frame can be varied in an instant; and according as the engine requires more or less power, to allow the steam to act with its full force upon the piston for a greater or less portion of its total descent. If this method of working an engine had no other advantage than the regulation of the power, it would not effect the end better than the throttle-valve; but by the expansive principle a great saving of steam is made. We have before observed, in describing the action of Newcomen's engine, that the motion of the piston is accelerated in its descent by the continued action of the pressure of the atmosphere whilst the load is constant, or even greatest at the first, considering the vis inertiae. Mr. Watt's engine is the same, but in a less degree, when it has a throttle-valve, because the steam cannot then come to the piston, except in a limited quantity; but when the top of the cylinder is open to the boiler, or the throttle-valve fully open, the effect is the same as if the atmospheric air had free entrance into the top of the cylinder. Now by stopping the further entrance of the steam at a certain portion of the descent, the piston can be made to descend with an uniform velocity, by the expenditure of only a portion of that quantity of steam which would be required, if steam of its full density was employed to press it down to the bottom with an accelerated velocity.

But when the steam is shut off at a portion of the descent, the pressure on the piston is continually diminishing as the descent becomes more and more rare; and, consequently, the accelerating force which works the engine diminishes. The motion of the descent, therefore, will no longer be uniformly accelerated; it will approach much faster to uniformity; or it may even be retarded; because, although the pressure on the piston at the beginning of the stroke may exceed the resistance of the load, yet when the piston is near the bottom, diminution of the pressure may occasion the resistance to exceed the pressure; in this case the motion can only be continued by the momentum of the moving parts. Whatever may be the law by which the pressure on the piston varies, it is possible to contrive the connecting machinery in such a way, that the chains or rods at the outer end of the beam shall continually exert the same pressure to lift the pump-rods, or that the machinery shall vary its resistance according to any law which is found most convenient. This may be done on the same principle that the watch-maker, by the form of the fusee, transmits an equal pressure to the wheel-work, from a very unequal action of the main-spring. In like manner, by making the communication from the piston-rod to the pump-rod by means of chains, which wind upon head-arches, formed to portions of a proper spiral instead of a circle, the force of the piston upon the beam and pump-rods can be regulated at pleasure, so as to produce an uniform effect.

This was the subject of Mr. Watt's patent, March 19, 1782, for certain improvements upon steam-engines, and certain new pieces of mechanism to be added to them. The specification of this patent, which is lodged in the Rolls chapel, states the invention to consist in shutting off the steam at a portion of the descent, as we have described, and applying combining levers, or other contrivances, so that the unequal or decreasing action of the steam upon the piston shall produce an uniform effect in raising the water in the pump-barrels.

The action of the expansion of the steam on the piston is thus explained. Suppose the whole descent of the piston diametrically divided, viz. into ten parts, and each subdivided, the varying pressure of the expanding steam on the surface of the piston at each division will be according to the following table.
table, which we have made out from the information given in Mr. Watt’s specification, and which is on the supposition that the cylinder is eight feet long, or an eight-feet stroke, and that the steam is shut off at one-fourth of the descent, or at two feet from the top; but the same law will hold generally as to these particulars. The pressure of the steam in the boiler is supposed to be equal to that of the atmosphere, or 14 lbs. per square inch, and the load of water in the pumps equal to 10 lbs. per square inch of the piston’s surface.

| .25                                  |                                                   0.375                                                                                 |

Thus, let the diameter of the piston be 24 inches, and the pressure of the atmosphere on a square inch be 14 pounds, the pressure on the piston is 6333 pounds. Let the whole stroke be 6 feet, and let the steam be stopped when the piston has descended 18 inches, or 1.5 foot. The hyperbolic logarithm of 6 is 1.3862943; therefore, the accumulated pressure $\CrF\ell\IC$ is $6333 \times 1.3862943 = 15114$ pounds.

As few professional engineers are possessed of a table of hyperbolic logarithms, while tables of common logarithms are or should be in the hands of every person who is much engaged in mechanical calculations, let the following method be practised: Take the common logarithm of $\IC$ and multiply it by 2.3026, the product is the hyperbolic logarithm of $\IC$. The accumulated pressure, while the piston moves from $\Cr$ to $\EF$, is 6333 x 1, or simply 6333 pounds; therefore, the steam, while it expands into the whole cylinder, adds a pressure of 8781 pounds. Suppose
STEAM-ENGINE.

Suppose that the steam had been freely admitted during the whole deficit of the piston, the accumulated pressure would have been 533.10, or 15,332 pounds. Here Mr. Watt observed a remarkable result. The steam expended, in this case, would have been four times greater than when it was stopped at one-fourth, and yet the accumulated pressure is not twice as great, being nearly five-thirds. One-fourth of the steam performs nearly three-fifths of the work; and an equal quantity performs more than twice as much work, when thus admitted, during one-fourth of the motion.

This information is curious and important, and the advantage of this method of working a steam-engine increases in proportion as the steam is sooner stopped; but the increase is not great, after the steam is rared four times, as the curve then approaches near to the axis, and small additions are made to the area. The expense of such great cylinders is considerable, and may sometimes compensate this advantage.

Let the Steam be stopped at its Performance is multiplied

\end{array} \]

The advantages of the expansive method of working an engine are more fully obtained, when steam of an elastic pressure considerably greater than the atmosphere is employed. The second table of expansion shows, that the increase of the force of steam, heated much above the boiling point, is very great by a small increase of heat. For instance, at 212°, the steam is equal to the atmosphere; by only increasing the heat 40°, viz., to about 252°, we obtain a double pressure, or two atmospheres; and the farther increase of 30°, viz., to about 282°, makes an additional force, which renders it equal to three atmospheres. Again, 24° higher, or about 306°, makes the steam equal to four atmospheres; and if it were practicable to go much farther, probably the same law would hold. Now it follows as a consequence, that if such small accretions of heat produce so rapid an increase of the expansive force, small abstractions of heat from highly expansive steam will also reduce its expansibility in an equal degree, so that steam highly heated is more readily diminished in bulk by the application of cold than weaker steam; that is, it can be more readily reduced in its pressure to any certain proportion of the pressure it had before. But if we would take away all its pressure, and leave a vacuum, we must apply a sufficiency of cold water to take away all its heat, which is greater than weaker steam, though not in direct proportion to its elastic force.

Mr. Watt's first specification (1769) describes the method of working by cooling or reducing the force of the steam, without wholly condensing it; but it has always been found most advantageous to condense effectually, even though the power necessary to draw out the injection-water from the condenser is considerable; the engine, in consequence of the greater perfection of the vacuum, is well able to afford this deduction. The most advantageous application of highly heated steam is on Mr. Watt's principle of admitting it in its full power, for a small portion of the deficit of the piston; and then shutting off the supply, the remainder of the action is effected by the expansive force of that portion of steam already admitted. But to obtain the full advantage of the varying forces, it is necessary to have some contrivance, by which the effect of the engine, on the work which it is performing, shall be uniform, or nearly so. Mr. Watt's specification of 1782 contains a great number of different methods: first, by chains acting upon spirals, on the principle of the fuses; secondly, by levers acting unequally upon each other; thirdly, by a large weight attached to the working-beam, at a considerable height above the centre of motion. When the piston begins its descent, this weight will oppose itself to the motion of the piston, until the descent of the latter has inclined the beam so much, that the centre of gravity of the weight is perpendicularly over the centre of motion of the beam; the weight has then no effect on the engine; but after it has pulled this position, it must evidently tend to aid the effort of the piston to draw up the load of water in the pumps. And it is possible to adjust the weight in its position, quantity, and height above the centre of the beam, that it will very nearly equalize the diminishing force of the piston; but this must be when the beam is always stopped at the same proportion of the total descent.

Fourthly: Another method, which is very ingenious, is to have two large cylinders or pumps, open at top and bottom, and each furnished with a piston without valves. The pistons of the two are fulminated from the opposite ends of the beam, so that the deficit of one will produce the ascent of the other. The cylinders are filled with water, which is conducted by a large trough from the top of one cylinder to the top of the other, so that the water is alternately transferred from one to the other. Suppose each piston at the middle of its respective cylinder, the water will be equally divided between them upon their pistons, and will hang in equilibrio on the beam; but suppose one end of the beam depressed, the piston fulminated from the opposite end will rise and raise up part of the water, which rests upon it, into the trough, by which it will run into the opposite cylinder, and as the corresponding deficit of that piston has made room for it, the water becomes unequally divided. When one piston is at the top of its cylinder, the other will be at the bottom, and have the whole of the water resting upon it. Suppose this piston to be that which is at the outer end of the beam, the steam-piston will be at the top of the cylinder; then if steam be admitted, it will press down the steam-piston, and draw up the water in the cylinder at the outer end of the beam. The weight of this water opposes the motion of the steam-piston, because the whole of the water in the water-cylinder must be lifted; but by the time the steam-piston has descended one-third or one-fourth, and the steam is shut off, the pressure on the steam-piston begins to diminish. The weight of the water on the water-piston has diminished also, because part of the water in it has run off by the trough, and entered into the opposite cylinder, where its weight upon the water-piston tends to aid the steam-piston in descending; and this aid continues to increase as the steam-piston descends farther, by the water being regularly transferred from the ascending to the descending water-piston; until the whole of it rests upon that piston which is at the bottom of its stroke. It is evident that the same action must take place in returning, and therefore this contrivance is only applicable to a double acting engine, and such engines are not commonly used for pumping water.

The application of any of these ingenious contrivances to the vaid engines employed in pumping would be attended with great difficulties; and if attempted to be used to equalize the action of the expansive principle, when applied
STEAM-ENGINE.

plied to its fullest extent, would, we think, be impracticable: we mean, when steam of great elastic force is employed, and when the floppage of the supply is made to take place at a very small portion of the deficient. In this case, the strain upon the centres of the shafts or levers, sufficiently oblique to equalize the action, would be beyond all bounds. Lord Stanhope has applied the principle of Mr. Watt's levers, in the most judicious manner, to the printing-prefs. (See Part II.) It is in so small a machine, worked only by the strength of one man, the firmest cast-iron frame of the press has been frequently broken.

We suppose it is for such reasons, that Messrs. Boulton and Watt have not, that we know of, applied these contrivances to any of their engines, but have contented themselves with employing a steam a little more than the preface of the atmosphere, and stopping the supply at one-fourth or one-third of the deficient, according to the circumstances under which the engine works. In this case, the decreasing preface in a large engine is not much greater than to counteract the acceleration, and aided by the moment of the heavy working beam, pump-rods, and rising column of water, produces nearly uniform motion.

Mr. Hornblower, about 1781, had a patent for a method of applying the expansive principle of Mr. Watt in two successive cylinders in such a manner, as to approach more nearly to an equality of force, by which steam of great preface can be employed to act by its expansion. This kind of engine, of which a description is to be found in Mr. Watt's specification of 1782, has since been brought to a great degree of perfection by Mr. Woolf, as we shall notice.

Description of Messrs. Watt and Boulton's complete Single Engine.—Plate III. fig. 1. is taken from the engine at Chelsea water-works, for pumping water for the supply of London: it was erected in 1804, and is estimated at fifty horses' power. We have hitherto considered Mr. Watt's engine as being fitted up with the great wooden beam, and arch-heads, chains, and pumps, the same as the old engine. This was the form of the engine for some years; but since 1804, when Mr. Watt invented the parallel motion for his double acting engine for turning mills, that ingenious contrivance has been applied to the pumping engines, instead of the arch-head and chains, as being more correct in its action. Also, for about fifteen years past, they have employed cast-iron working beams instead of wood. A B C is the beam, which is made of cast-iron instead of wood, and is composed of two large plates, of the shape represented in the figure, put together at twelve inches distance from each other, leaving a space between them, the centre or axis B passing through the middle of both plates. The axis lies on the floor D, which is sustained by the wall E, built beneath the centre. Q is the cylinder, contained within a steam-jacket, composed of segments screwed together. F is the steam-pipe coming from the boiler G. a b is the piston-rod, connected with the end, C, of the beam by links a, b; and whilst the upper ends of these links move in the arc of a circle, with the end of the beam, the lower ends, b, are made to accommodate themselves to the vertical motion of the piston-rod a, by means of the rods, c, extending to the smaller links, d, which form a parallelogram. The motion of the parallelogram is governed by the bridle-rods, which move about a fixed centre m. The action of this contrivance is fully explained under the article Parallel Motion; and it is enough for our present purpose to understand, that the lower ends, b, of the links, b, c, will ascend and descend in a perpendicular right line. A similar motion, but of half the quantity, is given to the rod, R, which works the air-pump, N, of the engine at the lower end, and the middle part of the rod has the plunger, R, attached to it, which has pins, or chocks, screwed on it to actuate the handles, x y, and z, of the mechanism for the valves, which mechanism is very different from that employed in the old engines, and even from that of the first engines of Mr. Watt. But to describe all the varieties which have been adopted, would occupy a volume, and afford information of but little value.

The pump-rod, p, is connected at the end, A, of the beam by another parallel motion, and the upper part, S, of the rod is made of cast-iron, and very massive, to have a sufficient weight in itself to draw up the piston, and make the return-stroke. The real pump-rod, p, is joined to the heavy counter-weight S, and is polished, like the piston-rod a, that it may slide through a collar of leathers in the head of the pump Y, because the pump is of that kind called lifting-force-pumps; its bucket raises the water in ascending, but it forces it through the air-reel T, and pipe X, which leads to a reservoir two miles distant in Hyde Park, and elevated 150 feet above the level of the water in the well where the pump draws from. This well has a communication with the river.

The cylinder, Q, is kept down by the weight of a pillar of masonry, on which it is placed, and large iron bolts, u, descend from the lower flank to the groundfells, upon which the masonry is built. Immediately before the pier is the condensing cistern, M, which contains the air-pump N, the condenser L, partly concealed, and hot-well g, and is kept supplied with cold water by the cold-water pump I, worked by the beam at the outer end, and the waffe runs off again into the well, so as to keep the water in the cistern always cold.

The valves, which must be opened and shut to produce the action of the engine, are four in number; viz. the upper steam-valve at F, the lower steam-valve O, and the exhaust-valve K, and a small valve l, beneath the water in the cistern M, to admit the injection into the condenser; but these parts are better explained in fig. 2, which is a section of the cylinder, air-pump, and condenser on a double scale.

A is the section of the cylinder, in which the piston, X, moves; F is the steam-pipe coming from the boiler; L, the condenser; N, the air or discharging-pump; m, a passage or pipe from the pump to the condenser, in which passage an occasional communication by a hanging-valve at m, which flushes towards the condenser; I is the injection-valve, to be lifted by the engine at every stroke, for the purpose of condensing the steam in the condenser L; w is the snorting or blowing-valve, placed outside the condensing cistern (of which MM is a section, on purpose to shew the contents); the snorting-valve, w, communicates with the condenser by a pipe passing through the side of the cistern M, and is inserted at the side of the condenser; K is the exhaust-valve, to be lifted by the engine, and open a communication between the cylinder A and the condenser L; O is the steam-valve, to be lifted by the engine, and open a communication between the lower part of the cylinder, and upper part thereof, through the steam-pipe r; and F is the upper steam-valve of the same kind, opening a passage from the boiler to the top of the cylinder; and thence by the pipe r, and valves O, K, to all parts of the engine.

We must now attend to the mechanism by which the engine is made to feed itself, and perform its reciprocations. The valves are lifted by means of a lever applied to each, within the iron box in which it is contained, entering into an opening in the stem of the valve; and a second lever is fixed on the axis of the lever, on the outside of the box, to be connected with
with the levers and handles, $x$, $y$, $z$, which open and shut the valves. There are three separate axles, or spindles, placed parallel and above one another, and each has a handle or spanner, $s$, $y$, $z$, by which it is moved, either by the hand, to start the engine, or by the clock on the plug-beam $R$, when the engine is in action. The two upper spindles, $x$ and $y$, have short levers projecting from them towards the cylinder; and from each of these levers a rod is suspended, with a sufficient weight, $w$, at the lower end to turn round the spindle, each upon its axis, in the direction which will cause the handles, $x$ and $y$, to fly upwards. Also the lower spindle has a lever projecting from it, away from the cylinder, with a heavy weight, $n$, fixed at the end; but this being applied, on the opposite side, to the weights of the two upper handles, $x$, $y$, the weight, $n$, causes the handle, $n$, to descend. Both the axles of the lower handles, $x$, $y$, have small levers, or catches, $t$ and $s$, which act in the hooks of a double latch, or detent, $t$s, which is moveable upon a centre-pin situated between the two axles. The hooks of this detent are to detain the catches of the spindles, and prevent them $x$, $y$, from moving by the action of their respective weights, until the detent is moved upon its centre, so as to relieve the catches of the levers from its hooks, $s$, $t$. But it is evident, from fig. $A$, that when only one catch, $t$, is hooked by the lower hook, $s$, of the detent, and consequently the weight of the spindle is held up, if the other catch, $s$, is moved by depressing its handle, $x$, so as to pull down the weight in the act of entering the hook, $s$, of the detent, it will press the end, $t$, of the detent forwards upon its centre, and this at the same time pressing back the hook, $s$, at the opposite end of the detent, releases the catch, $s$, of the lower handle, $x$, therewith, and the weight, $n$, on that spindle immediately falls.

The spindle of the upper handle, $x$, is devoted to opening and shutting the upper steam-valve $F$, having a lever which communicates by a rod, $x$, with the lever, $x$, of that valve; so that, by pressing down the handle, $x$, the valve is opened. The weight, $w$, which is applied to the upper spindle, tends to lift up the handle $x$, and open the valve $F$; and when the upper handle, $x$, is depressed, the valve will be shut; or when the handle is suffered to fly up by the action of its weight, it will open the valve.

The second spindle, $y$, has a lever communicating with the lever of the exhausting-valve $K$, by a rod $y$. The weight, $w$, applied to this like the former, tends to lift up the handle, $y$, and draw open the valve; but when the handle, $y$, is depressed, the valve is shut, and in this position the catch, $t$, is held down by the hook, $s$, of the detent before explained, and retains the valve shut.

Lastly, the lower spindle, $z$, is for the lower steam-valve $O$, which is opened by the rod $z$, when the handle, $z$, is suffered to fall down, and shut when the fame is up, being held by the catch, $s$, and hook, $w$. In all these the weight tends to open the valve; but when the valve is to be kept shut, the detent holds the weight up. Now, by removing the detent, the weight falls and opens the valve in an instant.

The upper spindle has no detent to detain it; but what is wanted by it is $s$ to be jointed to the other spindle, axis which has its weight and rod, $s$, suspended from it. The upper end of the rod, $s$, is made with a loop, or long slit, in which works $s$ pin at the end of a lever, $s$, projecting from the upper axis towards the cylinder. The consequence of this is, that while the middle axis is detained by its catch, and detent $s$, to keep the exhausting-valve, $K$, shut; the lever, $s$, of the upper spindle will be borne up by its pin resting in the bottom of the loop of the rod, $s$.

So as to keep the weight from opening the upper steam-valve $F$, as long as the exhausting-valve is kept shut; but when the catch, $t$, of the middle axis is discharged, and its weight has opened the exhausting-valve, the looped rod, $s$, will no longer support the lever, $s$, of the upper axis, but allows its weight to descend and open the upper steam-valve; but at the same time the upper steam-valve, $F$, is not confined to be always open when the exhausting-valve, $K$, is open; for the upper steam-valve may be shut by depressing the upper handle, $x$, without affecting the exhausting-valve at all, because the slit, or loop, in the top of the rod, $y$, allows that motion. This property must be attended to, because the action of the engine, by expansion, depends upon it. We have not before noticed the injection-valve, from which a long wire ascends, and is attached to a strap, $y$, which winds upon the middle axis; therefore, when the middle handle, $y$, flies up by its weight, it winds the strap, and opens the injection-valve at the same instant that the exhausting-valve is opened.

The injection-valve, $s$, is placed to close the orifice at the end of a short curved pipe, which enters into the condenser and turns up; and the pipe has a cock in it, between the valve and the condenser, to cut off the communication, or to regulate the supply of injection when the valve is opened. This cock must be always shut when the engine is not at work, to prevent the condenser filling with water.

**Operation of the Engine.**—We will now consider the action of the engine. Suppose the fire lighted beneath the boiler $G$; all the valves are kept shut by pressing down the two upper handles, $x$ and $y$, and lifting up the lower one, their respective catches detaining them in those positions, until the steam is sufficiently heated, and the engine is ready to work. In the quietest position of the engine, when it is at rest, the counter-weight always draws the piston fully at the top of its cylinder, as in the figure; the air-pump bucket will also be at the top of its barrel.

In order to prepare for setting the engine to work, all the three valves must be opened at once. This is done by relieving the spindles from their several catches, when the weights immediately open the valves. The steam enters through the valve $F$, into the top of the cylinder, and by the pipe, $s$, through the lower steam-valve, $O$, into the bottom of the cylinder; also through the exhausting-valve $K$, into the condenser $L$, driving before it some air, which passes out at the snuffing-valve, $w$. At first, the coldness of the parts cools the steam which enters; and it is not until all the iron, with which the steam comes in contact, is heated to the temperature of boiling water, that the steam ceases to flow from the boiler in a steam, and is condensed as it arrives at the cylinder and condenser; but after this, the steam acquires the same force in the cylinder and pipes that it has in the boiler: it then occupies every cavity and crevice of the engine, and in a little while displaces all the air in the cylinder, condenser, and pipes, which passes out, and is discharged at the snuffing-valve, $w$. This valve is always covered with water in a small cistern attached to the side of the large one, to ensure its tightness. Through this valve the air is discharged by the steam, not at every stroke, as in Newcomen's engine, but only at first setting the engine to work, and this operation is called the blowing through. It is well known when the cylinder and other vessels are properly heated, and the air discharged, by a very smart cracking noise at that valve, like a violent decrepitation of fault in the fire; this noise being occasioned by the water in the small cistern producing a sudden and rapid condensation of the issuing steam when the air is all gone.
STEAM-ENGINE.

It is being known by this sign that all parts of the engine are cleared of air, all the three valves are to be shut, by pressing and holding down the two upper handles $x, y$, and lifting up the lower handle $z$, in which situation its catch, 2, will retain it. This cuts off the farther supply of steam from the boiler, and also intercepts the passage of the steam from the cylinder to the condenser; and as the cold surface of the condenser still continues to condense a considerable portion of steam, there will soon be none left, and a vacuum will be formed in the condenser, while the cylinder both above and below the piston is full of steam. The vacuum in the condenser will soon become perfect from the external cold alone, though more slowly than when an injection is made.

In this state the engine is prepared for starting at a moment's notice, by the engine-man letting the two upper handles, $x$ and $y$, rise up, by their respective weights: this opens the upper steam-valve, and the exhausting and injection-valves; the former admits the steam into the top of the cylinder, to press upon the piston; while the latter allows the steam, already in the lower part of the cylinder, to flow into the vacuous condenser; and at the same instant that he opens the exhausting-valve, the valve is shut at the same time, by which the admission of the steam is cut off, and the cylinder is emptied of steam. This allows cold water to pass through the condenser, and condenses the steam as fast as it arrives from the cylinder, so that in an instant all the steam in the lower part of the cylinder will be drawn off and condensed. The preasure of the steam on the piston being now unbalanced by any thing beneath the piston, it descends and draws up the pump-bucket, and columns of water in the pumps, with a velocity proportioned to the preasure of the steam, and the diameter of the piston, compared with the height of the column of water in the pump, and the diameter of the steam to the boiler: but the piston having descended about one-third of its stroke, a check of the plug-frame, $R$, meets the upper handle $x$, and presses it down, shutting off the steam from the boiler. That part of the handle on which the check acts becomes perpendicular when the valve is shut, the handle being bent for that purpose; and the check can therefore descend farther, and slide against the perpendicular part of the handle, which is straighth, without producing any farther depression of the handle, at the same time that it keeps it down to the same point, so as to hold the valve shut. The piston, therefore, continues its descent by the further expansion of the quantity of steam at first let into the cylinder; but having arrived at the bottom of its stroke, a check on the opposite side of the plug-frame, $R$, seizes the middle handle, $y$, and presses it down, which pulls the rod, 4, until it shuts the exhausting-valve, $K$, and also shuts the injection-valve by the strap and rod 9. When the catch, 1, of this handle, $y$, presses on the upper hook, 4, of the detent 10, it relieves the catch, 3, of the lower axle $z$, and then the weight, $z$, causes the handle, $z$, to fall, and pulling the rod 14, opens the lower steam-valve, 0. Let us now consider the position of the engine: the middle handle, $y$, being held down by its catch, 1, holding in the upper hook, 4, of the detent, so as to keep the exhausting-valve, $K$, shut, and the upper steam-valve, $F$, is also kept shut, by the same means which kept it shut during the latter two-thirds of the descent of the piston.

Under these circumstances the piston is at liberty to rise by the action of the counter-weight $S$, because the opening of the lower steam-valve, $O$, has established a free communication between the top and bottom of the cylinder, and the steam in the top of the cylinder can flow freely to the valve $z$, and enter the bottom of the cylinder, as fast as the piston rises, by the action of the counter-weight.

When the piston has returned to within one-third of the top of the cylinder, the check of the plug-frame quits the upper handle $x$; but this handle cannot yet be thrown up by its weight to open the upper valve, because the rod, 5, from the lever of the middle axis bears up the short lever, 6, of the upper axis $x$; and thus the motion continues, till the piston arrives very nearly at the top of the cylinder: a check on the plug-frame then seizes the lower handle $z$, and lifting it up, shuts the lower steam-valve; and the catch, 2, of the lower axis pulling the lower hook, 9, of the detent, moves it on its centre, so as to release the catch, 1, of the middle axis from the upper hook, 4, of the detent. This being the case, the weight of the middle axis carries its handle, 4, to, up, and by the rod, 4, it opens the exhausting-valve; and by drawing the strap and rod, 9, it opens the injection-valve; at the same time the upper axis, $x$, losing the support of the rod 5, which kept it up, its weight carries up the upper handle $x$, and by pulling the rod, 2, it opens the upper steam-valve, $F$.

The steam from the boiler is now admitted to press upon the upper surface of the piston, while the steam from the lower part of the cylinder behind the piston rushes into the condenser, where being met with the cold injection, it is condensed, and makes a vacuum in the lower part of the cylinder, which brings down the piston to make another stroke.

At one-third of the descent, the plug-frame, as before, presses and holds down the upper handle $x$, to keep the upper steam-valve shut; and when the piston has arrived at the bottom, the plug-frame presses down the middle handle $y$, to shut the injection and the exhausting-valves; and in catching, this discharges the lower axis, and the weight thereof opens the lower steam-valve. The piston then rises by the counter-weight, and when at the top of its stroke, the plug-frame lifts the lower handle $z$, and shuts the lower steam-valve; and in catching, this lifts the two other handles, which open the upper steam-valve, the exhausting-valve, and the injection-valve, and this produces the descent of the piston, as before.

If the air has been fully discharged from all parts of the engine by blowing through, the action of the air-pump does not begin until the injection-water and the air, which are extricated from the water in the boiling, have accumulated in some quantity in the condenser; then at every descent of the bucket, $d$, of the air-pump, it dips into the barrel of water contained in the bottom of the barrel $N$, and the water passes through the valves in the bucket, and then the valves shut when the bucket is drawn up, lifting all that water which is above them up to the top of the barrel, and there it is forced out through the hanging-valve, $g$, into the hot-well $G$. The drawing up of the bucket at the same time makes a vacuum in the pump-barrel beneath it; and if this vacuum is more perfect than that in the condenser, which it will be, if the condenser contains either air or steam, it will press by its elaticity upon the surface of the water in the lower part of the condenser, and force it through the hanging-valve at $m$, into the lower part of the barrel, $N$, of the air-pump; and when all the water is gone from the condenser, the air or elastic vapour which is in the condenser will follow and enter into the pump, until the space of the barrel beneath the bucket is filled equally with the condenser.

This takes place while the pump-bucket is at the top or its barrel; and on the descent of the bucket, the space beneath it is diminished, until it compresses this rarefied vapour so much, that its elaticity will be sufficient to close the hanging-valve, $m$, and to lift the valves in the bucket, $d$, and pass through them into the space of the barrel above the bucket: and when the bucket has descended to the very lowest, the water contained in the bottom of the barrel, not being able to escape through $m$, must pass up through the valves, and rest upon the bucket $d$. When the bucket ascends, it carries
STEAM-ENGINE.

before it this water and air, and as it rises the space of the barrel above the bucket diminishes, and the rare vapour or air in it condenses by being crowded into less space, until at last it becomes equally dense with the atmospheric air, and then the water following it, drives through the valve, \( g \), into the open air.

The descent of the bucket, \( d \), left a vacuum beneath it, as before, and this drew a portion of the air or vapour from the condenser into it, ready to be extracted by the next stroke. As soon as the bucket begins to return, the discharge-valve, \( g \), shuts, and prevents the atmospheric air from entering into the pump. By this we see, that if the vapour in the condenser is so rare that the whole contents of the barrel of the pump will only make a few cubic inches, when reduced to become equal to the pressure of the atmosphere, this small quantity will be effectively evacuated through the discharge-valve, \( g \), because the water reffing upon the bucket follows the air, and will chase every particle of it from the top of the pump, and then follow itself.

The air-pump of Mr. Watt's engine requires to be of large dimensions, and the condenser is generally of the same size, by which means the rarefaction of any elastic vapour contained in the condenser will be equal to half at every stroke; that is, the air-pump will extract half the quantity of the elastic vapour every time; because, supposing the vacuous space which the bucket of the pump leaves beneath it, when it is drawn up, to be equal to the capacity of the condenser, then the vapour in the condenser must expand itself to fill a double space, by which one half of it will enter into the pump, and be drawn out by the succeeding stroke, while the other half will remain in the condenser.

The cylinder at Chelsea is four feet diameter, and eight feet stroke, and the air-pump two feet diameter, and four feet stroke; thus, their areas respectively are as one to four, and their capacities as one to eight. But it must not be considered that this large pump, full of air, is to be drawn out of the condenser at every stroke; for, as we have stated before, the vapour with which it is filled reduces itself to a small quantity before it comes to the density of atmospheric air. At first sight we should be led to conclude, that the pump affects the power of the engine, as a deduction, of as much power as the pressure of the air upon the surface of its bucket; but if we consider its contraction, having a valve at \( g \) to keep off the pressure of the atmosphere, it is certain its bucket can have light weight upon the engine, until the bucket is near the highest height of the stroke; and taking the sum of the resistance, from the commencement of the stroke to its termination, it will be found to be very little in comparison with the power of the cylinder.

An air-pump of one-eighth the capacity of the cylinder is sufficient to keep the condenser empty when it is a single engine. If a smaller air-pump were employed, it must be in action to lift out the air and water, for a greater portion of its stroke.

In fact, whatever the size of the air-pump may be, it will occasion little more resistance to the engine than from the friction of its bucket, except during the time that it has actually opened the valve, \( g \), to discharge the air or water which it contains; before that period, the resistance is only that of condensing the vapour, an operation which begins at nothing, but increases by an ascending proportion reverse to that of the decrease of the pressure of the steam, when acting in the cylinder by expansion, as we have before explained.

In Mr. Watt's early engines, the air-pump and condensing cistern were placed at the outer end of the beam; and there are some reasons to prefer that mode of construction, where the building will admit of it. In this case, the pump-bucket being drawn up by the descent of the piston, the engine requires a less counter-weight than in the form just described, in which the air-pump must be wholly worked by the counter-weight. Alto, it is during the descent of the piston that the action of the air-pump is most necessary; and it is possible that an engine, having the pump worked by the outer end of the beam, may make a better vacuum than when it is worked by the inner end, because there may be some, though a very slight impulse given to the remaining air of the last stroke, by the rush of steam into the condenser at the infant the steam-piston begins to descend, and the air-pump to rise; for no sooner is the exhausting-valve opened, than the steam rushes towards the condenser, and giving a momentary tendency to a plenum therein, may give a pull to the air through the hanging-valve, between the pump and the condenser; and hence it is reasable to conclude that more air will enter the pump by this means, than if it were left to its own expansion.

It is necessary that the parts appropriated to the condensation of steam should be kept as cold as possible, and those intended for the operation, or passage of the steam, as hot as possible; hence the air or discharging pump and condenser are placed in the cistern of cold water, which is kept constantly full by the cold-water pump, and a little running away into the well, to carry off the excess of heat; and if the injection-valve is placed low in this cistern, it will take the water in the coldest state. The injection-valve and cock are shown in fig. 2.

As the condensing apparatus is immersed in water, to be kept cold, so the cylinder should, if possible, be immersed in steam, to be kept hot; for which purpose, Mr. Watt from the first used a casing or jacket round the cylinder, and also at the top and bottom: this was attended with very beneficial effects, although it enlarged the steam surface, and exposed the external jacket to a more rapid condensation than would have taken place from the surface of the cylinder itself. But to have the vacuum as perfect as possible, it is necessary that the cylinder be kept up to such a temperature, as to prevent the least condensation of the steam upon the internal surface, either above or below the piston; because, if the fides of the cylinder were to be wet, as in the common atmospheric engine, the vacuum would be vitiated, as there would be occasioned by this moisture a moiture gradually forming to steam, which the outside casing prevents, when filled with steam from the boiler, and the heat which escapes from the surface of the jacket does not injure the operation of the engine; but if it were possible to cover this outward case again with any sort of substance which would entirely prevent the transmission of heat from the casing, it would supercede the use of the jacket altogether, and would apply with more advantage to the cylinder itself; but we do not know of any substance which will not admit this transmission more or less. Some of Meffrin, Watt and Boulton's best engines we have seen surrounded by a case of polished copper, we believe outside of the jacket.

In small engines, it is common to place the cylinder within the boiler, and it must then be kept partly as hot as the steam which enters it; but this is not practicable in a large engine, nor is it advisable in any case, because the frequent repairs which the boiler requires must damage all parts of the engine.

When the jacket is used, a small copper pipe is conducted from the steam-pipe to keep it full. As the jacket of a large cylinder must be exposed to be heated or cooled less than the metal cylinder to which it is attached, the unequal expansion might break the joints; to avoid this, the jacket is made in two halves, put together in the middle of the
the length, without any other attachment than that of entering into each other for three or four inches, with a cup which is packed with hemp and tallow. The steam-pipe has a similar joint at $b$, fig. 2, which unites it to the box of the exhausting-valve $K$, and will admit of drawing out a little.

**Description of other parts of Mr. Watt's Engine.** In the drawing (fig. 1.) in our plate, the condenser is represented at one side of the air-pump, in which situation it partly conceals the pump. In fig. 2, they are put into a different position for explanation, the condenser being represented beneath the cylinder. The eudiotion-valve is carried sideways from the box in which the eudiotion-valve is situated, so that the condenser can be placed in any situation which is convenient.

13, 13, are the catch-pins, which are firmly fixed to each end of the beam, and limit the motion of the engine by coming down to strike upon the beams of the floor $D$, if the engine makes too long a stroke; and pieces of cork are laid on the floor to soften the blow with which it would otherwise strike. It once happened to this engine, that the valve of the pump-bucket breaking, the engine suddenly loit its load, or reformation, which occasioned the piston to descend, and strike on the spring-beams, or floor $D$, for two or three successive strokes, with such violence as to break one of the beams; and as lift the piston striking the bottom of the cylinder, the momentum of the beam forced down upon the rod for violently, as to bend the great piston-rod quite crooked. To prevent such accidents, a smaller steam-pipe was added at the side of the vertical steam-pipe, communicating with the passage into the outer cylinder; this pipe is kept closed by a valve; but if the engine descends so low as to strike on the spring-beam $D$, the catch-pin, 13, of the beam strikes a small lever 10, and by the communication wire, 11, opens the valve, and lets the steam into the lower part of the cylinder beneath the piston, and this destroys the vacuum, so as to prevent the farther descent of the piston.

There is a small spring-catch or detent, which tends to spring under the lever of the upper steam-valve, and prevent it from descending. This catch is held back by a second catch, which is relieved when the catch-pin strikes the lever 10, and then the first-mentioned detent, by retaining the steam-valve from being opened, prevents any danger of the engine making a repetition of the stroke while it has no load.

**Boiler.**—The boiler of the engine we have not mentioned before; it is set in a furnace, so as to receive the heat of the fire, and the flame passes through a long flue, which goes twice round the bottom part of the boiler, to give as much as possible of its heat to the water before it enters into the chimney. The steam-pipe, $F$, has a throttle-valve in it at 30, which regulates the supply of steam to the cylinder. This valve is not a conical spindle-valve, the same as the other valves of the engine, but is a circular plate of metal, made to fit the bore of the pipe, and is moveable upon an axis, which passes diametrically across the plate; and the end of the axis, where it comes to the outside, has a lever fixed on it to communicate motion to the valve, which being turned endways in the pipe, prevents scarcely any malignance to the passage of the steam; but when turned flat across the pipe, it flops its bore; and although it is not fitted with an extraordinary care, it is sufficient to regulate the steam. This kind of throttle-valve is preferable, because it can be moved by a very slight force.

**Regulator.**—There is a contrivance to regulate the velocity of the engine, by a small pipe proceeding from the air-valve of the pump; it conveys water to the lower part of a small vertical cylinder, into which a piston is fitted, and loaded with a heavy weight; then if the engine works too fast, so as to force more water into the air-valve than the main pipes, $K$, will carry off, it must make a greater preasure and condensation of the air in the air-valve, until the water is forced to run quicker through the main-pipe, and thus the preasure being also communicated by the small pipe to the regulating cylinder before-mentioned, causes its piston to lift the weight and rise up, and this motion is communicated by a wire to the throttle-valve, so as to close it and diminish the supply of steam; or, on the other hand, if the engine works too slow, the preasure in the air-valve must diminish, and then the loaded piston will sink and open the throttle-valve a small quantity, to admit more steam.

It should have been mentioned before, that the weight with which the piston of this regulating cylinder is loaded, is so contriv'd that it will increase in force as the piston ascends, and diminishs as it descends. There are many ways of doing this, but the one adopted, in this case, is to load the piston with a very heavy cast-iron chain, some of the links of which fall upon the ground as it descends, and relieve the piston from their weight; but as it ascends, it lifts other links off the ground, and becomes more loaded, until it finds itself a place where the load will balance the preasure of the water in the air-valve.

It is evident that, by this contrivance, the motion of the engine will at all times be so regulated, as to supply just the quantity of water desired; but these quantities can be made greater or less, by applying a greater or less weight to the piston, so that it will sink more or less into its cylinder, before it will come to an equilibrium with the preasure in the air-valve, and will thus open the throttle-valve more or less. But when the adjustment is once made, it will keep the engine working with regularity at that velocity.

In some of the latest engines erected by Mefira. Watt and Boulton, they have, by an ingenious movement, made the motion of this regulating piston communicate with a long screw, attached to the plug-beam, which regulates the chuck that flushes the upper steam-valve at any required portion of the descent of the piston. By this means, although the screw is in constant motion with the plug-beam, the screw is turned so as to regulate the chuck on the plug, and measure out the quantity of steam which the engine shall have introduced into the cylinder at each stroke, to enable it to fulfil its task.

It is in these properties of the engine, by which it regulates itself, and provides for all its wants, that the great beauties of the invention consist. M. Belidor, 80 years ago, speaking of the old engine, says: "It must be acknowledged, that this is the most wonderful of all machines, and that nothing of the works of man approaches so near to animal life. Heat is the principle of its movement: there is in it a tube circulation, like that of the blood in the veins of animals; having valves which open and shut in proper periods, it feeds itself, evacuates such portions of its food as are useless, and draws from its own labours all which is necessary to its own subsistence." To pursue the idea, we may now lay of the more perfect machine, that it has what approaches the appetite of animals, in taking that kind and quantity of food which its exigencies require, and in rejecting that which is unnecessary. But we must explain these self-regulators more fully.

**Apparatus connected with the Boiler.**—In order to know the exact height of the water in the boiler, two gauge-cocks are employed, one of which reaches to within a little of the height or level at which the water should stand, and another reaches a little below that level. If the water stands at the defired
STEAM-ENGINE.

desired height, the first-mentioned cock, being opened, will give out steam; and the other cock will emit water, in consequence of the pressure of the superincumbent steam on the surface of the water. But if water should issue from both cocks, it will be too high in the boiler; and if steam issues from both, it will be too low. This is the same contrivance which was used in Newcomen's engine; but Mr. Watt applied in his first engine a small vertical glass tube, which has a communication with the boiler by a copper pipe cemented to each end: one pipe, from the top of the glass, enters the boiler above the intended level of the water; and the other pipe, from the bottom of the glass tube, enters the boiler below the surface of the water. In this way, it is evident that the glass tube will always be filled with water to the same level as the water in the boiler, and may be graduated with inches, to inform the engine-man when the boiler requires a supply.

Another contrivance is a pipe defending beneath the surface of the water in the boiler, when at its intended level; and in the upper end of the pipe at the top of the house a whistle or mouth-piece is formed; then, if the water in the boiler sinks too low, the steam will issue at the pipe, and, passing through the whistle, will make such a noise as to call the engine-man to his duty, even if he should have fallen asleep. This contrivance is rendered unnecessary by a subsequent one, by which the boiler will always feed itself, exactly as fast as its evaporation of steam requires.

The boiler is kept constantly supplied with water, to repair the waste of evaporation, by means of a small pump 20, which draws hot water from the hot-well 9, and raises it to such a height, that the water will run through a pipe, schemed by the dotted lines, into the cistern 14, placed over the top of the boiler, at an elevation of some feet. From this cistern a tube, 18, descends into the boiler, and terminates beneath the surface of the water therein, so as to feed the boiler with water. But as it is necessary that the water in the boiler should always be preferred at the same level, this feed-pipe is closed by a valve in the bottom of the cistern 14, which prevents the water running down into the boiler, until the level of the water subsides, and sheaves that it requires replenishing. A crooked arm, which is attached to the side of the small cistern 14, supports the short lever 15, 16, which moves upon a centre-pin. The extremity, 15, of this lever supports, by means of the wire 16, a flont or piece of metal, which hangs just below the surface of the water in the boiler. The wire passes through a small flapping-box in the top of the boiler, to prevent leakage. The other extremity, 15, of the lever is connected by a wire with a valve at the bottom of the cistern 14, which covers the top of the pipe 18; and this end of the lever is loaded with a sufficient weight to balance the flont in the boiler. Now it is a maxim in hydrostatics, that when a heavy body is suspended in a fluid, it loses as much of its weight as equals that of the quantity of fluid which it displaces. When the water in the boiler, therefore, is diminished, by the conversion of part of it into steam, the upper surface of the flont will be above the fluid, and its weight will consequently be increased in proportion to the quantity of its masts that is not immersed. By this addition to its weight, the flont will overcome the balance-weight on the end, 15, of the lever, causing the extremity, 16, of the lever to descend; and in consequence, by elevating the opposite arm 15, will open the valve at the top of the pipe 18, and thus gradually introduce a quantity of water into the boiler equal to that which is carried off by evaporation. This process is continually going on, while the water is converting into steam; and it is evident that too much water can never be introduced, for as soon as the surface of the water coincides with the surface of the flont, it recovers its former weight, and the valve at the bottom of the cistern, 14, shuts the top of the pipe 18, and prevents any more water entering the boiler, until the float or body, 21, descends by the diminution of the water therein.

When the engine is steadily at work, the flont subsides until it opens the valve to admit a regular stream of water, which will just equal the waste by evaporation; and then the operation will go on regularly, without any action of the float, until something is altered.

We have before stated, that the steam in the boiler is no stronger than the atmosphere; but there would still be great danger of the boiler's bursting, if the steam should accidentally become too strong: the boiler is, therefore, furnished with a safety-valve, which is so loaded, that its weight, added to that of the atmosphere, may exceed the pressure of the interior steam, when of a sufficient strength. As soon as the expansive force so far increases as to become dangerous to the boiler, its pressure preponderates over the pressure of the atmosphere, and the safety-valve is opened, when the steam escapes from the boiler, till its strength is sufficiently diminished; and the safety-valve shuts again, by the predominance of its pressure over that of the interior steam. By opening the safety-valve, the engine may be stopped at pleasure; and to effect this, a small rectangular lever, with equal arms, is fixed upon the side of the valve, and connected with its top. To one of these arms a chain is attached, which is conducted into the engine-houset, and palls over a pulley from a horizontal to a vertical direction, so that it hangs like a bell-pull. By pulling it, the valve is opened, and the machine is stopped.

There is also another valve of safety, for the receptor of the object of the first-mentioned safety-valve: it opens internally, and is balanced by a small lever, and a sufficient weight to keep it shut, until the pressure of the steam within the boiler becomes much less than the external air, which then forces open the valve, and enters into the boiler, till the equilibrium is restored. It is evident that this valve can never be necessary so long as the engine is at work; but its use is to prevent the sides of the boiler being crushed in by the weight of the air, when it has done work, and the steam within it cools and condenses.

Self-adjusting Damper.—By another ingenious contrivance, the boiler is made to regulate the heat of its furnace, in proportion to the quantity of steam which the cylinder draws off from it. For this purpose, a damper or iron sliding-door is fitted into the flue, just where it enters the chimney; and a chain is conducted from it, over pulleys, to any convenient situation, where the engine-man can pull it like a bell-pull, to draw up or lower down the damper, and by that means regulate the draught of air through the furnace, and the heat of the boiler.

To make the damper self-regulating, a large pipe of six or eight inches bore is fixed vertically through the top of the boiler: it is open at top and bottom, but the lower end descends nearly to the bottom of the boiler, so as to be always immersed beneath the surface of the water. Now the steam preying on the surface of the water in the boiler, and the atmosphere preying on the surface of the water in the open pipe, it is evident that the relative levels of the water in both will be at all times in exact proportion to the relative elaticity of the air and the steam; and if at any time the preying of steam diminishes, by the heat of the furnace, growing less, or by the engine drawing off more steam, the surface of the water in the open pipe will subside; and there is a flont-float in this pipe, balanced in the same manner.
STEAM-ENGINE.

ner as the feeding-float before described, the deflection of the stone is made to operate upon the chain of the damper, and draw it up so as to increase the draught of the furnace, until, by the accession of heat, the steam recovers the intended preasure, and restores the damper to its place. On the other hand, when the preasure of the steam is on the increase, either from the engine being retarded or stopped, or from the furnace burning too fast, the preasure of the steam on the surface of the water in the boiler raises the water in the open pipe; and the stone-float, then rising by its balance-weight, closes the damper, and diminishes the draught, until the steam subsides to its defined force. By this means, the steam is always preferred to the same intensity; a circumstance very necessary to the regularity of the motion of the engine.

Steam-Gauge.—To ascertain the preasure of steam with a greater degree of exactitude than by the load on the surface of the safety-valve, which is liable to many uncertainties, Mr. Watt employs a steam-gauge, confining of an inverted siphon, or bent tube, of glas or iron; one leg of which is joined to the steam-pipe, and the other is open to the atmosphere. A quantity of mercury being poured into the tube, it will occupy the bent part which joins the two legs; and the surface of the mercury in one leg being exposed to the preasure of the steam, while the external air acts upon the other, it is evident that the difference of level of the two surfaces will express the preasure of the steam in the height of a column of mercury.

When the tube is of glas, this difference of level may be seen and measured on a scale; but when an iron tube is used, a small light wooden rod is made to float on the surface of the mercury in the open leg, and point out the height on a scale of inches, fixed above the tube. But in this scale the divisions, which are numbered for inches, must be only half inches; because, as the mercury descends in one leg as much as it rises in the other, the scale reads double, to shew the difference of level.

Barometer-Gauge.—Mr. Watt has also adapted a gauge, called a barometer, to indicate the degree of vacuum in his engine, an addition which is of important conformance to the good performance of the engine, to the profit of the proprietors, and the credit of the engine; yet in many engines in London, we see this important instrument either out of repair, or wholly laid aside.

The form of this barometer can be understood without a figure: it is a tube of glas, 30 inches long, filled with mercury, and applied to a scale of inches, the lower end being immered in a cup, in the same manner as the common barometer, or weather-glas; it is, in fact, the same thing as a barometer in every respect, except that the vacuum is not made in the top of the tube, in the Torricellian manner, but by the engine. For this purpose, a small copper tube is conducted from the condenser, and cemented to the top of the glas tube, by which means the surface of the mercury in the tube is relieved from the preasure of the atmosphere; and the weight of the atmosphere, which presses upon the surface of the mercury in the bacon, will cause it to mount up in the tube to a greater or less height, according as the vacuum is more or less perfect, or as the atmosphere is more or less heavy; which will be shewn by a common barometer placed at the side of the engine barometer.

The pipe which leads from the condenser to the top of the barometer tube must be provided with a cock, which should be shut when the engine is blowing through, to prevent the steam entering the tube, and blowing the mercury out of it; but the bacon for the mercury must be made large enough to contain all the mercury, because, when the engine is not at work, the air will leak in, and allow the mercury to descend into the bacon.

It has been proposed to make the barometer in the form of an inverted siphon, just the same as the common steam-gauge, one leg being made to communicate with the condenser, and the other left open to the air. In this way, the rise of the mercury in one leg produces a corresponding fall of the mercury in the other; but on this account, if the scale is applied to one leg, the divisions must be only half inches; that is, provided the two legs are of the same bore; but if they are of different bares, the scale must not be half, but of a proper proportion, to shew always the difference between the level of the surface of the mercury in the two legs.

These tubes may be made of glas; but if the quicksilver is not very pure, the alloy with which the vendors of this article adulterate it is by constistant action brought to the surface, and, together with the vapour, make the tube so foul, that no precision can be obtained. Iron is the best material for both parts of the tube, which should be correctly of one diameter, or else the result will be erroneous, as we have before remarked; for it is difficult to graduate a scale by experiment in an iron tube, where the difference of level of the mercury in the legs cannot be seen. This tube must communicate with the condenser by a small copper pipe, and a stop-cock be placed between the gauge and condenser. The index in this instrument is the same as in the steam-gauge, viz., a light deal rod, which is put into the shorter tube; and quicksilver being poured into it within three inches of the end, the rod is put into the tube, and floats on the quicksilver. It is almost needless to remark, that the graduation on this instrument must be inverted with regard to those of a single tube.

The barometer shews the perfection of the vacuum, or the preasure of the atmosphere to enter into the condenser, whilst the steam-gauge shews the preasure of the steam to escape into the air. By adding the height of these two columns together, we have the preasure of the steam upon the piston, provided the throttle-valve is fully open, so that there is no obstruction to the entrance of the steam from the boiler into the cylinder. It would be interesting to have a single gauge made to express this in one; nothing would be more easy than to have a large tube bent to an inverted siphon, and one of the legs being connected with the steam-pipe, and the other with the condenser, the difference of level between the two surfaces would at all times express the preasure on the piston.

Counter.—In many of Mr. Watt's engines, a little apparatus is attached to the beam, to ascertain the number of strokes the engine makes in any given time; this contrivance is called the counter, and is a train of wheel-work, working like clock-work, commonly attached to the beam in such a manner, that every stroke made by the engine moves one tooth, so that the index tells how many strokes have been made since last examined. This is so much up in a box, that no person can gain access to it but the one entrusted with the key. When the box is attached to the beam, the inclination of the beam causes the pendulum to vibrate every time the engine makes a stroke, and thus moves the counter round one tooth for every stroke. In other cases, the box containing the counter is fixed to the spring-beam floor, and at every stroke the beam strikes a small detent, and moves the counter one tooth. It was by the account of this instrument that Messrs. Boulton and Watt charged their portion of the savings for working their engines during the term of Mr. Watt's patent.

Construction of the Valves.—The steam and eduction-valves are of that kind called button or conical spindle-valves.
 STEAM-ENGINE.

valves. Mr. Watt, in his first essays, employed cocks, and also sliding-valves, such as the regulator or steam-valve of the old engine. But he found them always lose their tightness, after a short time. This is not surprizing, when we consider that they are always perfectly dry, and almost burning hot. He was therefore obliged to change them all for spindle-valves, which being truly ground, and nicely fitted in the seats, are not likely to get out of order, or become loose, in any length of time. Other engineers now use them commonly in the old form of the steam-engine; where, however, there is less necessity for them.

The manner of constructing these valves is as follows. Fig. 3, represents a valve, with its seat and box; suppose it one of the steam-valves: the box is at the end of the pipe which introduces the steam, and b b is the upper part of the pipe, which communicates with the lower part of the cylinder, or with the condenser. At e e may be observed a part more faintly shaded than the surrounding parts. This is the seat of the valve, and is a brass or bell-metal ring, turned conical on the outside, so as to fit exactly into a conical part, bored out in cast iron, of the pipe b b. This ring or seat is fitted in by cement; and the cone being of a long taper, the ring fits firmly in it, especially after having been there for some time, and united by ruff. The valve itself is a strong brass plate, D, turned conical on the edge, so as to fit the conical or inner edge of the seat. These two cones are very nicely ground into each other with emery. This conical joining is much more obtuse than the outer side of the ring e e, so that although the joint is air-tight, the two pieces do not stick closely together. The valve has a spindle or round tail, D c, which is freely moveable up and down in the hole of a crook-piece extended beneath the ring or seat e e; and on the upper side of the valve is a strong piece of metal, D G, firmly joined to it, one side of which is formed into a toothed rack.

A is the eccentric of an iron axle, which turns in holes in the opposite sides of the valve-box; and one of these, where it passes quite through the side of the box, is nicely fitted by grinding, so as to be air-tight; and a stuffing of hemp, well soaked in melted tallow and rosin, made to fit the end of the hole, to prevent all ingress of air. The end of this axis projects a good way without the box, and carries a spanner or handle 3, which is connected by a rod with a lever, moved by the plug-frame. To the axis, A, is fixed a strong piece of metal, or sector, the edge of which is formed into an arc of a circle, having the axis, A, in its centre, and is cut into teeth, which work in the teeth of the rack D G, on the valve, and lift the same when the sector is moved. K K is a cover, which is fixed by screws to the top of the box F 3, and may be taken off, in order to get at the valve when it needs repair. From this description it is easy to see, that by turning the handle 3, which is on the axis A, the sector must lift up the valve by means of its toothed rack D G, till the upper end of the rack touches the top or cover K; and turning the handle 3, in the opposite direction, brings the valve down again to its seat.

The force requisite to lift up a large valve from its seat is very great, the valve being kept down by a preasure of the steam upon its upper surface while there is a vacuum beneath it. The valves of the Cheltenham engine are nine inches diameter, and therefore contain (9 x 9 = 81 x .785)= 65.5 square inches, and each being prefixed by at least 13 lbs., makes 826 lbs. weight to keep the valve down; and this should, if possible, be lifted in an instant, to admit the steam to pass off without delay. One method of balancing this weight is by means of a small piston, applied beneath the valve. Thus, the lower part of the pipe or box in which the valve is contained, is bored out to a short cylinder, and a piston is truly fitted therein, as shewn beneath K, fig. 2: a cover or bottom is screwed on to close the lower end of the short cylinder; and there is a small copper pipe from the jacket, which admits steam into the space of the short cylinder beneath its piston, while there is a vacuum in the box in which the valve is contained, and which is open to the upper surface of the piston. The axis of the valve being connected with the piston, it is easy to move it up and down, and, by lifting the piston to ascend will countersink that of the valve to descend; and, therefore, by apportioning the area of the piston to that of the valve, it may be made to lift with the lightest force.

Even without this contrivance, which is only applied beneath the exhausting-valve, as is seen in the section, fig. 2, Mr. Watt invented a very simple and effective method of raising up the valves by levers. The force which holds down the valve is quite momentary; and the instant the valve is detached from its seat the pressure is over, although it has not risen more than a tenth of an inch; the force, therefore, is, therefore, no impediment to the engine, but would be an inconvenient labour to the man who crowds and drops it.

By Mr. Watt's contrivance, the lever is put in such a position when it begins to raise the valve, that its mechanical energy is almost infinitely great. Let fig. 3, represent the valve shank, which is supposed to have been just closed by the chock on the plug-beam in its deficient coming in contact with the handle s s, and depressing it, which is moveable with the axis X: on this same axis is another arm, Z Z, connected by a joint with the back of a 3, which is connected also by a joint with the lever 3 A, fixed on the axis, A, of the sector, contained within the valve-box. Therefore, when the chock of the plug-beam depresses the handle s s, and turns the arm, X Z, round upon its centre, it pushes up the lever, 3 A, by means of the connecting rod, until the valve is closed, as shewn in fig. 3. At that time, the rod 2 3, and the arm, X Z, of the lever, are in one straight line, while the lever 3 A, (on the axis of the sector,) is at right angles to rod 2 3, which moves it; consequently the rod is acting with its greatest power to turn the valve; but, as soon as the valve is kept closed by the catch or detent before explained, which holds down the handle s s, until it is wanted to be opened; the plug-frame then, by lifting the lower handle, relieves the catch, and the weight, a, applied to the axis turns it round into the position of the dotted lines, and the lever, X Z, draws the rod 2 3, and, by depressing the lever 3 A, opens the valve.

From this arrangement, the intelligent mechanic will perceive that, in this position, the force exerted by lever X Z is extremely great to pull down the rod 2 3; and, at the same time, another great advantage arises from this disposition of the levers, which is, that any preasure, however strong, applied upon the valve to open it, would be ineffectual, as that force would be exerted to turn the lever X Z endways, in the direction of the axis X, instead of turning it round, as shewn by the figure, which represents the valve shut, and retained in that position by the lever.

Construction of the Piston.—In Mr. Watt's first attempt, the greatest difficulty which he encountered was to make the great piston tight. The old and inefficient method of sticking it on it, was indissipable. He was therefore obliged to have his cylinders most nicely bored, perfectly cylindrical, and finely polished; and he made numberless trials of different soft substances for packing his piston, which should be tight without enormous friction, and long remain so, in a situation perfectly dry, and not almost to burning.

After many trials, he settled the form of the packing which is now universally employed. The piston has a projecting rim at
STEAM-ENGINE.

at bottom, which is fitted as accurately to the cylinder as it can be, to leave it at full liberty to rise and fall through the whole length. The part of the piston immediately above this is about two inches less all round than the cylinder, to leave a circular groove or channel, into which the hemp, or soft rope which is called gasket, is rammed, to form the packing; then, to keep the packing in its place, a lid or cover is put over the top of the piston, with a ring or projecting part, which enters into the circular groove for the packing, and preventing the air being forced down by pressure. Through part of the groove round the piston being made rounding, with a curve, this pressure on the packing forces it against the inside surface of the cylinder. The piston must be kept supplied with melted grease; for which purpose a funnel is fixed on the top of the cylinder, with a cock and pipe to let the grease down. The stuffing-box in the top of the cylinder, round the piston-rod, is packed with hemp in a similar manner, a collar, with a hole through it for the passage of the rod, being screwed down, to confine the packing in its place.

After all that has been done in this respect, it is probable that the greatest part of the waste of steam which we still perceive in engines, arises from the unavoidable escape of the sides of the piston during its descent. If the piston is packed so tight as to prevent the lofs, the friction is so increased as to fully outweigh the saving. But it is a fortunate circumstance, that the performance of Mr. Watt's engine is not immediately destroyed, nor, indeed, greatly diminished, by a small want of tightness in the piston. In the atmospheric engine, if air enters in this way, it immediately puts at flight the water; but in the new engine, although even a considerable quantity of steam escapes past the piston during its descent, the rapidity of condensation is such, that the diminution of pressure is not considerable, and the waste of steam is the greatest inconvenience.

A great many schemes have been since tried to make better methods of packing a piston, but none of them have been brought into use, except the metallic expanding piston, which was proposed by Mr. Cartwright, as we shall notice in describing his engine. Something of the same kind, but not for steam-engines, is to be found in Leopold's, "Machininarum Hydraulicae"

The actual Performance of Mr. Watt's Engine with respect to Coals.—At the first establishment of their engines, Messrs. Boulton and Watt charged their profits in proportion to the saving of fuel which their engine made, when compared with a common engine burning the same kind of coals. They had one-third of these savings paid them annually, or the payment was redeemed at ten years' purchase. It should be observed, that Mr. Smeaton's improvements were introduced about the same time as Mr. Watt's, and therefore the comparison was not with his engines, but with the former ones. It was Mr. Smeaton's rule, judging from some experiments made before him on some of Mr. Watt's early engines, to cheapen Mr. Watt's engine at one-half the consumption of fuel as his own for the same work, in large engines, or a still greater proportion in small engines, because the waste of steam is greater, and he reckoned his own at only one-half of the common engines, as he found them; therefore, Mr. Watt's will be four times as great in effect as the common engines.

As early as 1778, when Mr. Watt first established his engine, we find his proposals, deduced from experiment, were to raise 500,000 cubic feet of water one foot high with one cwt. of coals. He afterwards adopted the denomination of the number of pounds of water which could be lifted one foot high by a bushel of coals as the scale for engines; if we reduce this to the latter term, it will be 555 lbs. Thus, 500,000 cubic feet × 63.5 lbs.

the weight of a cubic foot of water, is 51,250,000 lbs. of water raised by 112 lbs. of coals. Then say, as 112 lbs. : 51,250,000 lbs. : 88 lbs. the weight of a bushel of coals, to 24,553,571, the number of pounds of water which will be lifted one foot high with one bushel of coals. Mr. Watt was at that time in expectation of making a great improvement by adopting his expulsive method.

Mr. Smeaton, who was defirous of promoting Mr. Watt's discovery, made an experiment in 1778, on an engine on the same principle as that of Mr. Watt's, to see how the water let down by the passage of boats through the locks.

The working cylinder was 20 inches, and the pump also 20 inches, lifting 27 feet, at the rate of 11 strokes per minute, of 5 feet 7 inches length each. It worked for an hour with 65 lbs. of Wednesbury coals.

When reduced, this experiment gives about 15 millions lifted one foot by a bushel of coals. Thus, the area of the pump is (20 × 20 = 400) × 3784 = 3144 square inches, × 434 lbs. = 156.27 lbs. weight for every foot in height, × 17 feet = 2679 lbs. the total weight of the column. The motion per minute is 634 feet (11 strokes of 5 ft. 9 in. each), or 3595 ft. per hour, × 2679 lbs. = 93961,805 lbs. raised 1 foot high per hour. The coals consumed in the hour was 65 lbs.; therefore say, as 65 lbs.: 13,961,805 lbs.: 88 lbs.: 18,902,156 lbs. raised one foot high with each bushel of coals of 88 lbs.; load on the piston 27 ft. of water, or (27 × 434 = 11,7 l. sp. sq. inch.

When the engines were made to work with the expansion, they were enabled to raise as much as 30,000,000 lbs., but this is when the engines are of the best construction, and worked under every advantage of the parts being tight and in the belt order; for these circumstances, when neglected, as they usually are by the engine-keepers, make a most material difference in the result.

In the great scale of practical operations this nicety of management cannot be expected; and accordingly, from reports on the engines now working on the mines in Cornwall, which, with the exception of a few of Woolf's engines, are all on Mr. Watt's principle, and most of them constructed by Messrs. Boulton and Watt, taking the average of the engines, both old and new, and putting them together, they were found in August, 1811, to raise only 13,500,000 lbs. one foot high for each bushel of coals which they consumed.

But when it was known by the engine-keepers that their engines were under examination, they took so much pains to improve the effects, that by gradual increase, the engines, in 1815, lifted 21,500,000 lbs. taking the average of 33 engines. This information we obtain from the monthly reports of the engines which are working for draining the mines; these were begun in the year 1811, by the agreement of a number of respectable proprietors of the valuable tin and copper mines in Cornwall, who resolved to have ascertained the real work which their respective steam-engines were performing, as it was suspected some of them were not doing duty adequate to the consumption of fuel; and for the greater certainty of attaining their object, it was agreed that a counter should be attached to each engine, and all the engines be put under the superintendence of some respectable and competent engineer, who should report monthly the following particulars in columns: namely, the name of the mine; the size of the working cylinder; whether working single or double; the load per square inch upon the piston; length of the stroke in the cylinder; the number of pump-lifts; the depth in fathoms of each lift; diameter of pumps in inches; time during which they worked; consumption of coals in bushels during that time; number of strokes during the time; length of stroke in the pump; load upon the whole area of the piston in pounds; pounds lifted
STEAM-ENGINE.

I employ the steam after it has ascended in the first vessel to operate a second time in the other, by permitting it to expand itself, which I do by connecting the vessels together, and forming proper channels and apertures, whereby the steam shall occasionally go in and out of the said vessels.

Thirdly: I condense the steam, by causing it to pass in contact with metallic surfaces, while water is applied to the opposite side. Fourthly: To discharge the engine of the water used to condense the steam, I suspend a column of water in a tube or vessel constructed for that purpose, on the principles of the barometer, the upper end having open communication with the steam-vessels, and the lower end being immerged in a vessel of water. Fifthly: To discharge the air which enters the steam-vessels with the condenising water or otherwise, I introduce it into a separate vessel, whence it is protruded by the admission of steam. Sixthly: That the condenised vapour shall not remain in the steam-vessel in which the steam is condened, I collect it into another vessel, which has open communication with the steam-vessels, and the water in the mine, reservoir, or river.

"Lastly, in cases where the atmosphere is to be employed to act on the piston, I use a piston so constructed as to admit steam round its periphery, and in contact with the sides of the steam-vessel, thereby to prevent the external air from passing in between the piston and the sides of the steam-vessel."
STEAM-ENGINE.

Lastly, the pump-rods, X, cause the outer end of the beam to preponderate, so that the quiescent position of the beam is that represented in the figure, the pistons being at the top of the cylinders.

Suppose all the cocks open, and steam coming in copiously from the boiler, and no condensation going on in L, the steam must drive out all the air, and at last follow it through the valve Q. Now shut the cocks b and d, and open the valve, S, of the condenser; the condensation will immediately commence, and draw off the steam from the lower part of the great cylinder. There is now no prejudice on the under side of the piston of the great cylinder A, and it immediately descends. The communication, Y, between the lower part of the small cylinder B, and the upper part of the great cylinder A, being open, the steam will go from the lower part of B, into the space left by the descent of the piston of A. It must, therefore, expand, and its elasticity must diminish, and will no longer balance the prejudice of the steam coming from the boiler, and pressing above the piston of B.

This piston, therefore, if not withheld by the beam, would descend till it came in equilibrio, from having steam of equal density above and below it. But it cannot descend so fast; for the cylinder A is larger than B, and the arch of the beam, at which the great piston is suspended, is no longer than the arm which supports the piston of B; therefore, when the piston of B has descended as far as the beam will permit it, the steam between the two pistons occupies a larger space than it did when both pistons were at the top of their cylinders, and its density diminishes as its bulk increases. The steam beneath the small piston is, therefore, not a balance for the steam on the upper side of the same, and the piston B will act to depress the beam, with all the difference of these prejuires.

The lightest view of the subject must throw the reader, that as the pistons descend, the steam that is between them will grow continually rarer and less elastic, and that both pistons will draw the beam downwards. Suppose now, that each one had reached the bottom of its cylinder, shut the cock a, and the eduction-valve at the bottom of A, and open the cocks b and d. The communication being now established between the upper and lower part of each cylinder, the pistons will be press'd equally on the upper and lower surfaces; in this situation nothing, therefore, hinders the counter-weight from raising the pistons to the top.

Suppose them arrived at the top: the cylinder B is at this time filled with steam of the ordinary density; and the cylinder A with an equal absolute quantity of steam, but expanded into a larger space. Shut the cocks b and d, and open the cock a, and the eduction-valve at the bottom of A; the condensation will again operate, and cause the pistons to descend; and thus the operation may be repeated as long as steam is supplied; and once full of the cylinder B, of ordinary steam, is expended during each working stroke.

The cocks of this engine are composed of two flat circular plates, ground very true to each other, and one of them turns round on a pin through their centres; each is pierced with three sectorial apertures, exactly corresponding with each other, and occupying a little less than one-half of their surfaces. By turning the moveable plate so that the apertures coincide, a large passage is opened for the steam; and by turning it so that the forty part of the one apertures of the other, the cock is thus. Such regulations are now very common in the cast-iron flues for warming rooms.

Mr. Hornblower's contrivance for making the collars for the piston-rods air-tight, is thus: the collar is in fact two, placed at a small distance from each other; and a small pipe, branching off from the steam-pipe, communicates with the space between the collars. This steam being a little stronger than the pressure of the atmosphere, effectually prevents the air from penetrating through the upper collar; and though a little steam should get through the lower collar into the cylinder A, it can do no harm. The manner of making this stuffing-box is as follows: on the top of the cylinder is a box to contain something soft, yet pretty close, to embrace the piston-rod in its motion up and down; and this is usually a fort of plaited rope of white yarn, nicely laid in, and rammed down gently, occupying about a third of its depth; upon that is placed a fort of tripod, having a flat ring of brass for its upper, and another for its lower part; and these rings are in breadth equal to the space between the piston-rod and the side of the box. This compound ring being put on over the end of the piston-rod, another quantity of this rope is to be put upon it, and gently rammed as before; then there is a hollow space left between these two packings, and that space is to be supplied with strong steam from the boiler. Thus is the packing about the piston-rod kept in such a state as to prevent the air from entering the cylinder at any time there may be a partial vacuum above the piston.

Mr. Hornblower's description of this engine was followed by a mathematical investigation of the principles of its action, by the ingenious professor Robison, which demonstrates that it is the same thing in effect as Mr. Watt's expansion-engine; but though this is true, there is a considerable difference in the steps by which the effect is attained, which gives an important advantage when it is reduced to practice. We shall give an investigation in a more popular form, using only common arithmetic. Mr. Hornblower assumed, that the power or prejudice of steam is inversely as the space into which the steam is expanded; this is the case with air, and for the present we will grant it to be so with steam, and reason from the same data as the ingenious inventor gives us.

To explain clearly what paffes in the two cylinders, we must deviate from the precise form of the engine, and direct ourselves of one complication of ideas, by reducing both cylinders to the same stroke; therefore, suppose the engine to have two like fig. 2, which represents the two cylinders placed one upon the other, the lower one being double the capacity of the upper one, and both pistons being attached to the same rod, which may be applied to the end of the beam, so that the descent of the pistons must draw up the load at the opposite end of the beam.

Then, if we suppose the small piston to be 10 inches in diameter, the great piston must be 14.14 inches; and to avoid all difficulties of the ratio of the expansion, and the prejudice of steam, we will suppose the engine to be worked by the prejudice of atmospheric air instead of steam, and for the convenience of round numbers in our calculation, we will consider the prejudice at only 10 lbs. per circular inch on the surface of the piston.

The area of the small piston will be 100 circular inches, and being assumed to move without friction, the prejudice upon it will be 10 x 100 = 1000 lbs. The area of the great piston is twice as much, or 200 circular inches, and the prejudice 2000 lbs.

Suppose both pistons to be at the top of their respective cylinders; let the atmospheric air be admitted to press freely upon the upper surface of the small piston; and suppose...
STEAM-ENGINE.

This force would balance a load of 2000 lbs.; but suppose we diminish the load to 1000 lbs., then the pistons will immediately begin to descend; but they will soon stop, because the air between the two pistons must expand itself, to fill the increasing space occasioned by the equal descent of both pistons in the cylinders, one of which is twice the area of the other; and as the air becomes rarer, its pressure on the great piston must diminish. Now as this same diminution occurs the small piston to have a power of descent, we will first consider the pistons separately, and then conjointly, in their power of descent, which with which they draw down the beam.

STEAM-ENGINE.

Now let us consider how Mr. Watt's principle of expansion would operate in the same circumstances; that is, in a cylinder of 14.14 inches diameter; which is to be supplied with air of 10 lbs. pressure per circular inch, until it has completed one-half of its descent, and leaving the remainder of the descent to be accomplished by the expansion of the air already contained in the upper half of the cylinder.

At the beginning, the power of descent will be
At one-fourth, the power will be
At one-half, the power will be
At three-fourths of the descent, the power will be diminished to

\[ \text{Lbs.} \]
\[ 2000 \]
\[ 2000 \]
\[ 2000 \]
\[ 1333 \frac{1}{3} \]

Because the air must occupy one-fourth of the length of the cylinder, in addition to that half of the cylinder which it occupied before the expansion began; therefore the space is one and a half times the former, or as three to two, and the pressure will be two-thirds of 2000.

At the bottom the pressure will be

\[ \text{Lbs.} \]
\[ 1000 \]

Because the air is expanded to occupy twice the space it filled before.

\[ \text{Lbs.} \]
\[ 833 \frac{1}{3} \]

The sum total is very nearly the same as the former, but both are greater than they should be, from the imperfect manner in which we have been obliged to make our calculation, so as to express it in common arithmetic, without having recourse to fluxions, which is the only method of treating quantities that are constantly increasing or decreasing by any given law.

The source of the inaccuracy is easily explained: at first we set out with the pressure at 2000 lbs. in Mr. Hornblower's engine, and did not take into the account that it decreases at all, until the piston has descended to one-fourth, but reasoned as though it diminished all at once at that place; whereas it began to diminish from the very first starting. Here then we have taken a small quantity too much. In the same manner, our process takes no notice of the diminution which happens between one-fourth and one-half of the descent, or between the other points at which we have chanced to examine it; the result is, as if the diminution took place suddenly at each of those points. The remedy for this would have been to have taken the account at a greater number of places, as it is by fluxions alone that we can take an infinite number, so as to obtain a true result. Now in the second calculation of Mr. Watt's expansion-engine, we have taken a still fewer number of steps for the consideration of the expansion, because, although there are four steps in the process, two of them are before the expansion begins.

This is the reason of the apparent difference; for in reality there is none in the sum total of the varying powers exerted through the whole stroke, as will appear to any person who will take the trouble to read professor Robison's investigation. But if we consider the difference of the manner in which the whole power is expended during the stroke, we shall find great reason to prefer Mr. Hornblower's method, from the much greater uniformity of the action; it begins at 2000, and ends at 1500; whilst Mr. Watt's begins at 2000, and ends at 1000; hence the facility of those ingenious contrivances for equalizing the action in Mr. Watt's patent of 1788. Mr. Hornblower's is not uniform, but approaches uniformity more nearly, so that he could have carried the effect of the expansive principle much farther, in employing stronger steam, than we believe he ever proprosed to do.

We have been thus full upon this subject, because the gaining more power by the expansion of air or steam acting in double cylinders, has been a favourite idea with many, and there are no less than five different patents for it, but several of these have been upon mistaken notions; neither Mr. Watt's nor Mr. Hornblower's can have any advantage from shutting off the air, or from a double cylinder, when air is used to press the piston; nor could they derive any advantage from the expansion of steam in their engines, if the pressure of it was inversely as the space it occupies.

The advantage of the expansive principle arises wholly from a peculiar property of steam, by which, when suffered to expand itself to fill a greater space, it decreases in pressure or elastic force by a certain law, which is not fully laid down; that is, the relation between its expansive force and the space which it occupies is not clearly decided; but Mr. Woolf has found that, by applying these properties in their fullest extent to the double cylinder engine, he can make most important improvements in the effects which can be obtained from any given quantity of fuel. Steam is a fluid far different from air, as to have no one property in common with it, except elasticity. This elasticity is wholly derived from the quantity of heat which it contains, and its force increases and diminishes with the quantity of heat; but by what law it increases or diminishes we are uncertain, because we have no measure of the actual quantity of heat which is contained in steam of any given elastic force. All we know with certainty is what is stated in our table of expansion, viz. that water, being converted into steam, and confined in a close vessel, when heated until the thermometer indicates a certain temperature, will have a certain prelude or elastic force. But here we must observe, that the thermometer indicates only the intensity of the heat, without affording a direct measure of its quantity. When steam is suffered to expand itself into any given space, the quantity of rarefied water which will be found to be contained in any given bulk of steam, in its expanded state, must be undeniably proportioned to the quantity of water contained in the same bulk of the steam, before the expansion took place, in the inverse ratio of the space which it originally occupied, and that space which it fills when expanded; but we cannot say that this is the case with heat; and it is the quantity of heat alone which determines the elastic force. The reason.

We believe that in practice Mr. Hornblower was not able to obtain any greater effect from the application of the expansive action in two cylinders, than Mr. Watt did in one cylinder. In 1791-2, he erected an engine in Cornwall, at Tin-Croft mine, of which the large cylinder was 27 inches diameter, and worked with a stroke of eight feet long, and the small cylinder 21 inches diameter, working with a fixed stroke. The only account we have been able to obtain of the performance of this engine, is from a pamphlet published by Thomas Wilton, an agent of Mellis, Boulton and Watt, professedly with a view to prevent the introduction of Mr. Hornblower's engines into that country, in which he makes it appear, that it raised only \(14,223,120\) lbs. of water one foot high with each bushel of coal.

In Mr. Hornblower's own account of his engine, in Gregory's Mechanics, he informs us, that "an engine was erected in the vicinity of Bath, some years since, on this principle, and under very disadvantageous circumstances. The engine had its cylinders 19 inches and 24 inches diameter, with lengths of stroke in each suitable to the occasion: viz. 6 feet and 8 feet respectively. The confessing apparatus was very bad, through a fear of infringement on Mr. Watt's patent; and the greatest degree
of vacuum which could be obtained, was no more than 27 inches of mercury. The engine worked four lifts of pumps to the depth of 376 feet, 4,000 lbs. 14 strokes in a minute, 6 feet each, with a cylinder 6 feet long, and 19 inches diameter, with a great deal of inertia and friction in the rods and buckets: some of the latter of which were not more than 34 inches diameter; and this it did, under all these disadvantageous circumstances, with 70 lbs. of coal (light coal) per hour."

To reduce this to the standard of one foot high, we must put the load 4,000 lbs. x 6 feet stroke = 27,000 lbs. which the engine raised one foot high at every stroke; 27,000 lbs. x 14 strokes per minute = 378,000 lbs. raised one foot high each minute; 378,000 lbs. x 60 = 22,680,000 lbs. raised one foot high per hour, or with 70 lbs. of coal. As the coals are flated to be light, we will take them at only 84 lbs. per bushel, instead of 88 lbs. as Mr. Smeaton did, and say as 70 lbs. = 22,680,000 lbs.; 84 lbs. = 27,316,000 lbs. of water raised one foot high with a bushel of coals, which is a very good performance, but not greater than Mr. Watt's.

In this engine, Mr. Hornblower says that two remarkable circumstances prevented themselves to show the advantages of this application of the principle: the one was, that the man who attended the engine would sometimes detach the smaller cylinder from the beam, and work only with the large one, and then the boiler would scarcely raise steam enough to keep the engine going; but no sooner was the small cylinder-rod attached to the beam, than the engine resumed its wonted activity, and the steam would blow up the safety-valve.

The next circumstance is, that when the detent, which kept the exhausting-valve shut, happened to miss its action, the piston would be checked, as it was, not being permitted to rise through the whole of the returning stroke; and it would, as by an instructive nature, come down again and again, until the detent performed its office, which is a practical argument for the power of the engine at the termination of its stroke.

In 1792, Mr. Hornblower made application to parliament for an extension of the term of his patent, but it was not granted; and he was prosecuted by Meirs. Boulton and Watt for infringement on their patent in using the condenser and air-pump. We believe none of these engines have been erected since the expiration of Mr. Watt's patent in 1800, until Mr. Woolf took up the subject of double-cylinder engines.

Mr. Woolf's Double-Cylinder Expansion-Engine.—In 1804, Mr. Arthur Woolf had a patent for improvements in steam-engines. The specification of his invention states, that he has ascertained by actual experiment, and reduced to practice, the following particulars respecting the expansibility of steam. That, in practice it is found that steam, acting with the expansive force of four pounds per square inch against a safety-valve exposed to the atmosphere, is capable of expanding itself to four times the volume it then occupies, and still to be equal to the pressure of the atmosphere: that, in like manner, steam of the force of five pounds the square inch, can expand itself to five times its volume; and that masses or quantities of steam of the like expansive force of five pounds per square inch, can expand to fix, seven, eight, nine, or ten, pounds pressure per square inch, in atmosphere, and be still equally equal to the atmosphere, or capable of producing a sufficient action against the piston of a steam-engine, to cause the same to rise in the atmospheric engine of Newcomen with a counterpoise, or to be carried into the vacuous part of the cylinder of the improved engine, first brought into effect by Mr. Watt: that this ratio is progressive, and nearly, if not entirely, uniform; so that steam prepping with the expansive force of 20, 30, 40, or 50 pounds the square inch against a common safety-valve, will expand itself to 20, 30, 40, or 50 times its volume; and that generally, as to all the intermediate or higher degrees of elastic force, the number of times which steam of any temperature and force can expand itself, is nearly the same as the number of pounds it is able to sustain on a square inch exposed to the common atmospheric counter-pressure; provided always, that the space, place, or vessel, in which it is allowed to expand itself, be kept at the same temperature as that of the steam, before it is allowed room to expand.

Respecting the different degrees of temperature required to bring steam to, and maintain it at, different expansive forces above the weight of the atmosphere, Mr. Woolf states that he has found by actual experiment, setting out from the boiling point of water, or 212° of Fahrenheit, at which degree steam of water is only equal to the pressure of the atmosphere; that, in order to give an increased elastic force equal to five pounds on each square inch, the temperature must be raised to about 227.9°, when it will have acquired a power to expand itself to five times its volume, and still be equal to the atmosphere, and capable of being applied as such in the working of steam-engines, according to his invention. Various other pressures, temperatures, and expansive forces of steam, are shewn in the following table.

Woolf's Table of the relative Pressures per square Inch: the Temperature and Expanability of Steam at Degrees of Heat above the boiling Point of Water, beginning with the Temperature of Steam of an elastic Force equal to five Pounds per square Inch; and extending to Steam able to sustain forty Pounds on the square Inch.

And
STEAM-ENGINE.

And so in like manner, by small additions of temperature, an expansive power may be given to steam to enable it to expand to 50, 60, 70, 80, 90, 100, 200, 500, or more times its volume, without any limitation but what is imposed by the frangible nature of every material of which boilers and other parts of steam-engines can be made. And prudence dictates, that the expansive force should never be carried to the utmost which the materials can bear, but rather be kept considerably within that limit.

Having thus explained the nature of his discovery, Mr. Woolf proceeds to give a description of his improvements grounded thereon.

If the engine is constructed originally with the intention of adopting these improvements, it ought to have two steam-cylinders of different dimensions, and proportioned to each other, according to the temperature, or the expansive force determined to be communicated to the steam made use of in working the engine; for the smaller steam-vessel or cylinder must be a guide for the larger. For example; if steam of forty pounds the square inch is fixed on, then the smaller cylinder should be at least one-fourth part the content of the larger one. Each cylinder should be furnished with a piston, and the smaller cylinder should have a communication, both at its top and bottom, (top and bottom being here employed merely as relative terms, for the cylinders may be worked in a horizontal, or any other required position, as well as vertical,) with the boiler which supplies the steam; and the communications, by means of cocks or valves of any construction adapted to the use, are to be alternately opened and shut during the working of the engine.

The top of the small cylinder should have a communication with the bottom of the large cylinder, and the bottom of the smaller one with the top of the larger, with proper means to open and shut these alternately by cocks, valves, or any other well-known contrivance. And both the top and bottom of the larger cylinder should, while the engine is at work, communicate alternately with a condensing vessel, into which a jet of water is admitted to hasten the condensation; or the condensing vessel may be cooled by any other means calculated to produce that effect.

Things being thus arranged, when the engine is set to work, the steam of a high temperature is admitted from the boiler to act by its elastic force on one side of the smaller piston, while the steam which has last moved it has a communication with the larger steam-vessel or cylinder, where it follows the larger piston, now moving towards that end of its cylinder which is open to the condensing vessel. Let both pistons end their stroke at one time, and let us now suppose them both at the top of their respective cylinders, ready to descend; then the steam of forty pounds the square inch, entering above the smaller piston, will carry it downwards; while the steam below it, instead of being allowed to escape into the atmosphere, or applied to any other purpose, will pass into the larger cylinder above its piston, which will make its downward stroke at the same time that the piston of the smaller cylinder is doing the same thing; and while this goes on, the steam which last filled the larger cylinder in the upward stroke of the engine will be passing into the condenser, to be condensed during the downward stroke. When the pistons in the smaller and larger cylinder have thus been made to descend to the bottom of their respective cylinders, then the steam from the boiler is to be shut off from the top, and admitted to the bottom of the smaller cylinder. The communication between the bottom of the smaller and the top of the larger cylinder is also to be cut off; and the communication is to be opened between the top of the smaller and the bottom of the larger cylinder. The communication between the bottom of the larger cylinder and the condenser is to be cut off, and the steam which, in the downward stroke of the engine, filled the upper part of the larger cylinder, suffered to flow off to the condenser. The engine will then make its upward stroke from the pressure of the steam in the top of the small cylinder, acting beneath the piston of the great cylinder, and so on alternately, admitting the steam to the different sides of the smaller piston, while the steam last admitted into the smaller cylinder passes alternately to the different sides of the larger piston in the larger cylinders; the top and bottom of which are at the same time made to communicate alternately with the condenser.

In an engine working in the manner just described, while the steam is admitted on one side of the piston into the smaller cylinder, the steam on the other side has room made for its admission into the larger cylinder, on one side of its piston, by the condensation taking place on the other side of the large piston which is open to the condenser; and that waste of steam which takes place in engines worked only by the expansive force of steam, from steam passing the piston, is prevented; for all steam that passes the piston in the smaller cylinder is received into the larger.

In such an engine, where it may be more convenient for any particular purpose, the arrangement may be altered, and the top of the smaller made to communicate with the top of the larger cylinder; in which case the only difference will be, that when the piston in the smaller cylinder descends, that in the larger will ascend, and vice versa; which, on some occasions, may be more convenient than to have the two pistons moving in the same direction.

This engine is exactly the same in its actions as Mr. Hornblower's, which we have before described. The novelty consists in the application of steam of a high pressure thereto, and in proportioning the capacities of the two cylinders to the expansibility of the steam, according to his table. But Mr. W. goes on to state, that effectual means must be used to keep up the requisite temperature in all parts of the apparatus into which the steam is admitted, and in which it is not intended to be condensed; and here it may be proper to state, that instead of the usual means of accomplishing this, by inclining them in the boiler, or in a steam-safe communicating with the boiler, the separate fire may with advantage be made under the steam-safe containing the cylinders, which in that event will become a second boiler, and must be furnished with a safety-valve, to regulate the temperature. By means of the last-mentioned arrangement, the steam from the smaller cylinder or steam-measurer may be admitted into the larger cylinder, when kept at a higher temperature than the steam in the smaller cylinder, by which its power to expand itself may be increased; and, on the contrary, by keeping the larger cylinder at a lower temperature than the smaller, its expansibility will be lessened, which, on particular occasions, and for particular purposes, may be desirable. In every case, care must be taken that the boiler, or cafe in which the cylinder is incloded, the steam-pipes, and generally all the parts exposed to the action of the expansive force of the steam, shall have a strength proportional to the high pressure to which they are to be exposed.

It is not advisable that the proportion of the capacity of the smaller cylinder or steam-measurer, to the capacity of the larger or working cylinder, should in any case be smaller than the proportion of the expansion of the steam which is to be used in it, as we have stated; yet in the making of it larger, considerable latitude may be allowed; for example, with steam of forty pounds the square inch, a small cylinder or measurer of one-twentieth, or even larger, instead of one of fortieth the capacity of the larger or working cylin-
STEAM-ENGINE.

der, and so with steam of any given strength. And in many cases, it may be advisable that this should be the case, because of the difficulty of preventing some waste of steam, or partial condensation, which might lessen the rate of working, if not allowed for in the case of the small cylinder or steam-mesfurier.

In all cases when the engine is ready for working, whatever may be the proportion that has been adopted, or intended to be worked with, it should have its power tried by altering the load on the valve that actuates the force of the steam, in order that the strength of steam belt adapted for the engine may be ascertained, and it may be turned out to be advantageous, that the steam should be employed in particular engines of an elastic force, somewhat over or under what was first intended.

Mr. Woolf also states, that Mr. Watt's engines may be improved by the application of his discovery in making the boiler, and the steam-cake in which the working cylinder is included, much stronger than usual, and by altering the structure and dimensions of the valves for admitting steam from the boiler into the cylinder in such a manner, that the steam may be admitted very gradually by a progressive enlargement of the aperture, so as first to wire-draw the steam, and afterwards to admit it more freely. The reason of this precaution is this, that steam of such elastic force as Mr. Woolf proposes to employ, if admitted suddenly into the cylinder, would strike the piston with a force that would endanger the safety and durability of the engine. The aperture allowed to the valve for admitting steam into the cylinder, or cylinders, should be regulated by the following consideration. If the intention is, that the engine should work wholly, or almost wholly, by condensation, the steam, in passing into the cylinder, should be forced to wire-draw itself only so much, that the piston may perform the whole, or a great part of the stroke, by the time that the intended quantity of steam has been admitted into the cylinder. For example, when steam of forty pounds on the square inch is used, such a quantity of it must be allowed to enter as shall be equal to one-fourth of the capacity of the cylinder, and so in proportion when steam of any other force is employed; and when the requisite quantity has been admitted, the steam is to be shut off till the proper moment for admitting a fresh quantity. But if it is intended that advantage shall also be taken of the elastic force of the steam acting on one side of the piston, while condensation goes on on the other side, then the steam must be admitted more freely, but still with caution at first, for the reason already mentioned.

This latter is the same thing as Mr. Watt's expansion-engine; but with the addition of gradually diminishing the aperture of the steam-valve as the piston descends, instead of stopping it altogether at a certain portion of the descent, by which means the action of the engine is rendered more uniform. We think that, by regulating the descent of the valve by an accurate movement, a very good effect may be produced in this manner, without the complication of two cylinders or other parts; the only objection is, that if at any time the valve should be fully opened by accident, the pressure might suddenly become too great, from the strong steam acting upon the full surface of the piston, as to break the engine to pieces.

In 1805, Mr. Woolf took out a second patent for further improvements, in which he proposes, as before, to apply first to the cylinder itself, to heat the steam after it is thrown into the working cylinder; and this was to be done by a fire being placed beneath the case containing the cylinder: the space between the case and the cylinder was to be filled with oil, wax, fusible metal, or mercury. He also proposes a method of preventing the passage of any of the steam from that side of the piston which is acted upon by the steam, to the other side, which is open to the condenser. In those steam-engines which act as double engines, he effects this by employing upon, or about the piston, a column of mercury, or fluid metals, in an altitude equal to the pressure of the steam. The efficacy of this arrangement will, he says, appear obvious, from attending to what takes place in the working such a piston. When the piston is ascending, that is, when the steam is admitted below it, the space on its upper side being open to the condenser, the steam, endeavouring to pass up by the side of the piston, is met, and effectually prevented by the column of metal, equal or superior to it in pressure; and during the down stroke no steam can possibly pass without first forcing all the metal through.

In working what is called a single engine, a less considerable altitude of metal is required, because the steam always acts on the upper side of the piston; and in this case, oil or wax, or fat of animals, or similar substances in sufficient quantities, will answer the purpose. But care must be taken, either in the double or single engine, when working with thin pistons, that the outlet which conveys the steam to the condenser shall be so situated, and of such a size, that the steam may pass freely, without forcing before it, or carrying with it, any of the metal, or other substance employed, that may have passed by the piston: and at the same time providing another exit for the metal, or other substance collected at the bottom of the cylinder to convey the fame into a reboiler kept at a proper heat, whence it is to be returned to the upper side of the piston by a small pump, worked by the engine, or by some other contrivance. In order that the fluid metal used with the piston may not be oxidated, some oil or other fluid substance is always to be kept on its surface, to prevent its coming in contact with the steam: and to prevent the necessity of employing a large quantity of fluid metal, although the piston must be as thick as the depth of the column required, the diameter need be only a little less than the steam-veil or working cylinder, excepting where the packing, or other fitting, is necessary, or for applying the same, or to such an extent, that in fact, the column of fluid metal forms only a thin body round the piston.

We have seen an engine of an eight-horse power of this kind at work, with a fluid metal on the pistons: it effectually prevented the leakage. But as it required to have the cylinders twice as long as usual, in order to have sufficient room for the long or thick pistons which it required, and as these pistons must be of considerable weight, the method is not at all applicable in practice; and, indeed, the increase of the bulk of the moving parts is such as to counterbalance the advantage, which is confined to the saving of steam by leakage: for the friction must be greater than in another engine, because the piston must be packed as tight as usual, to be able to sustain a column of fluid metal, which must be more than equal in pressure to that of the steam; and when the steam presses upon the piston, the pressure of the fluid metal to leak by the piston must be double that of the steam; also, the friction of so great a surface of fluid metal pressing against the inside of the cylinder is very great.
STEAM-ENGINE.

cylinder, he places a separate vessel, communicating with the lower part of the cylinder by a large pipe or passage from the bottom of each; then steam, being admitted into this vessel, will pass upon the surface of the oil or fluid metal contained in it, and force the same to pass out of that vessel into the cylinder, where it will act beneath the piston to press the same up-wards; a vacuum being at the same time made in the upper part of the cylinder, to give effect to the preasure. The steam is then made to pass upon the upper surface of the piston, which is always covered with a quantity of the fluid; and at the same time a vacuum is made in the separate vessel, so as to relieve the surface thereof from all preasure; in consequence, the piston is made to descend. It is evident that the piston must be packed so tight as to suffer none of the fluid to pass by it; but this is easy, in comparison with the difficulty of making a packing sufficiently tight to refill the passage of steam, particularly when it is so rare as the expanded steam which Mr. Woolf sometimes uses in his engine. The separate vessel of which we have spoken, is in some cases to be the jacket or space which surrounds the cylinder, which is then to be open at both ends.

This contrivance is ingenious, but we think the necessity of an additional cylinder is an objection which will prevent its adoption in large engines; and for small engines the advantages are not so great.

Performance of Mr. Woolf's Engine.—Since his first patent, Mr. Woolf has erected several small engines, which performed well, and with an evident economy of fuel. But these engines were employed to turn mills, of which the operations do not afford so exact an estimate of the power as the operation of pumping water. Mr. Woolf's engines did not come to a direct and indisputable comparison with those on Mr. Watt's principle, until 1815, when two large engines were set to work in Cornwall, at Wheal Vor and Wheal Abraham mines, for pumping water; and these have since been regularly reported in Mefirs. T. and J. Leans reports, of which we have before spoken, and of which one of the objects was to ascertain the comparative merit of the double and single cylinder engines.

The report for May, 1815, states the average performance of these two engines at 99,862 lbs. lifted one foot high for each bushel of coals; and since that time they have done more than 50,000,000 lbs.

The engine at Wheal Vor has a great cylinder of 53 inches diameter, and 9-feet stroke; and the small cylinder is about one-fifth of the contents of the great one. The engine works six pumps, which, at every stroke, raise a load of water of 37,952 lbs. weight 7½ feet high, which is the length of the stroke in the pumps. This makes a preasure of 14.1 lbs. per square inch on the surface of the great piston, and it makes 7.5 strokes per minute. With respect to its consumption of coals, it raised, in March, 1816, 48,432,702 lbs. one foot high with each bushel; April, 1816, 44,000,000 lbs.; May, 1816, 49,500,000 lbs.; and in June, 1816, 43,000,000 lbs.

From the same reports we learn, that the engine at Wheal Abraham mine has a great cylinder of 45 inches diameter, working with a 7-feet stroke, at the rate of 8.4 strokes per minute, under a load of 24,450 lbs., which it raises 7 feet at each stroke. Its performance during the above four months was 55,000,000 lbs.; in May, 4,909,000 lbs.; in May, 56,917,532 lbs., which, we believe, is the greatest performance ever made by a steam-engine; and in June, 51,500,000 lbs.

We have before given a similar account of Mr. Watt's engines, but at the same time we must observe, that the variation in the performance of different steam-engines, which is a construction upon the same principle, and working on the same advantages, is the same as would be found in the produce of the labour of so many different horses, or other animals, when compared with their consumptive food; for the effect of different steam-engines will vary as much from small differences in the proportions of their parts, as the strength of animals from the vigour of their constitution: and, again, there will be as great differences in the performance of the same engine, when in bad or good order, from all the parts being tight and well oiled, to move with little friction, as there is in the labour of an animal, from his being in good or bad health, or excessively fatigued; but, in all cases, there will be a maximum which cannot be exceeded, and an average which we ought always expect to attain.

Plate V. fig. 3, is a sketch to show the arrangement of the valves and cylinders of these two engines: A is the large cylinder, and B the little cylinder, each inclosed in its steam-case. The steam is admitted from the boiler into the steam-case of the large cylinder A, by a communication at C; and there is a communication between this steam-case and that of the small cylinder so that all the steam for the supply of the engine passes through both of the steam-cases, which therefore become part of the communication between the boiler and the little cylinder, into which the steam is first admitted. D furnishes a communication for carrying back to the boiler any water which may be produced by condensation in the steam-case, before the engine is heated to the proper temperature. E is the pipe from the steam-case to supply the engine; it has a regulating-valve. F is the valve-box of the small cylinder, the spindle of the one valve working through that of the other; and the passage for the steam from the case into the small cylinder is situated between the two valves. G is the valve that opens the communication between the bottom of the small cylinder B, and the top of the large cylinder A, when the pistons thereof are to be pressed down. H is the valve that returns the steam from above to below the large piston, when the piston is to ascend. And I is the exhaustion-valve, to carry off the steam to the condenser.

When the engine makes its down-stroke, the upper valve at F is opened, and admits the steam from the case to press upon the small piston, the valve G being opened at the same time, which suffers the steam to pass from the under side of the small to the upper side of the large piston; and the valve I is opened to make a passage from beneath the great piston to the condenser. These upper valves, F, G, I, open at the same instant of time.

When both pistons arrive at the bottom of their respective cylinders, these three valves are shut all together, and the lower steam-valve at F is opened, to return the steam from above to below the small piston; the valve H doing the same to the large cylinder, and both pistons return in equilibrio by the counter-weight; but the upper valve at F can be shut off at any part of the stroke, according to the load of the engine.

Those who are conversant with steam-engines will perceive, from the passing of the steam, as above described, from the upper to the lower side of each of the pistons respectively, that the engines at Wheal Vor, and at Wheal Abraham, are all of them perfect working with a single stroke. Were these engines working double, the steam would, on the down-stroke, be made to pass, the same as before described, from the under side of the small, to the upper side of the large piston, steam from the boiler in the mean time coming in upon the small piston, and the under side of the large piston being open to the condenser.
STEAM-ENGINE.

condenser; but on the up-stroke, the action would be different from what we have described, for the steam would pass from the top of the small cylinder to beneath the large piston, while steam would be admitted from the boiler under the small piston, the top of the large cylinder being open to the condenser.

Mr. Woolf's Boiler for raising Steam of a high Pressure with Safety.—The boilers which Mr. Woolf employs in his engines are different from those of other engines which work with steam of a low pressure, the water being contained in several cylindrical tubes of cast-iron, which are filled with water, and exposed to the flame nearly in an horizontal position, at right angles to the axis of the boiler.

Mr. Woolf has a patent for this boiler, which the specification states to consist of two or more cylindrical vessels, properly connected together, and so disposed, as to constitute a strong and fit receptacle for the water intended to be converted into steam of a temperature and under a pressure uncommonly high, and also to present an extensive portion of convex surface to the current of flame and heated air from a fire; likewise of other large cylindrical receptacles placed above the former cylinders, and properly connected with them, for the purpose of containing some water and the steam.

These cylindrical vessels are set in a furnace so adapted to them, as to cause the greater part of the surface of each of them, or as much of the surface as may be convenient, to receive the direct action of the fire, or heated air or flame.

Plate V. figs. 4 and 5, represents one of these boilers in its most simple form. It consists of eight tubes, marked a, made of cast-iron, or any other fit metal, which are each connected with the larger cylinder A, placed above them, as is shown in the side view, fig. 5, in which the same letters refer to the same parts as in fig. 4. In fig. 5, is also shown the manner in which the fire is made to act. The fuel rests on the grate-bars at B, and the flame, and heated air, being reverberated from the part above the two first smaller cylinders, go under the third, over the fourth, under the fifth, over the sixth, and partly over and partly under the eighth small cylindrical tube, all which tubes are full of water. The direction of the flame, until it reaches the last-mentioned tube, is shown by the dotted curved lines and arrows. When it has reached that end of the furnace, it is carried by the flue, O, to the other side of a wall, built beneath the main cylinder A, in the direction of its length, and the flame then returns under the opposite end of the seventh smaller cylinder over the sixth, under the fifth, over the fourth, under the third, over the second, and partly over and partly under the first, when it passes into the chimney. The wall before-mentioned, which divides the furnace longitudinally, answers the double purpose of lengthening the course which the flame and heated air have to traverse, giving off heat to the boiler in the passages, and also of securing the flanges, or other joints, of the frames, employed to unite the smaller tubes to the main cylinder, from being injured by the fire. The ends of the small cylindrical tubes rest on the brick-work which forms the sides of the furnace, and one end of each of them is furnished with a cover, secured in place by screws and a flange, but which can be taken off at pleasure, to allow the tubes to be cleared, from time to time, from any incrustation or sediment which may be deposited in them.

To any convenient part of the main cylinder, A, a tube is affixed, to convey the steam to the steam-engine. In working with such boilers, the water carried off by evaporation is replaced by water forced in by the usual means of a high-pressure boiler, that is, a forcing-pump; and the steam generated is carried to the place intended by means of pipes connected with the upper part of the cylinder A. In the specification, means are pointed out for applying this plan to the boilers of steam-engines already in use, by raising a row of cylinders beneath the present boiler, and connecting them with each other, and with the boiler. Directions are also given for constructing boilers composed of cylinders disposed vertically. In every case the tubes composing the boilers should be so combined and arranged, and the furnace so constructed, as to make the fire now act at right angles to the sides of the boiler, or to embrace the largest possible quantity of their surface. It must be obvious to any one, that the tubes may be made of any kind of metal; but cast-iron is the most convenient. The size of the tubes may be varied; but in every case, care should be taken not to make the diameter too great: for it must be remembered, that the larger the diameter of any single tube is in such a boiler, the stronger it must be made in proportion, to enable it to bear the same expansive force of steam as the smaller cylinders. It is not essential, however, to the invention, that the tubes should be of different sizes; but the upper cylinders, especially the one which is called the steam-cylinder, should be larger than the lower ones, it being the reservoir, as it were, into which the lower ones send the steam, to be thence conveyed away by the steam-pipe. The following general directions are given respectning the quantity of water to be kept in a boiler of this construction; viz. it ought always to fill, not only the whole of the lower tubes, but also the great steam-cylinder A, to about half its diameter, that is, as high as the fire is allowed to reach; and in no case should it be allowed to get so low as not to reach the vertical neck of the boiler, which joins the smaller cylinders to the great cylinder, full of water, for the fire is only beneficially employed when applied, through the medium of the interposed metal, to water, to convert it into steam; that is, the purpose of the boiler would in some measure be defeated, if any of the parts of the tubes which are exposed to the direct action of the fire, should present a surface of steam in their interior, instead of water, to receive the transmitted heat. This muff, more or less, be the case, whenever the lower tubes, and even a part of the upper, are not kept filled with the water.

Respectning the furnace for this kind of boiler, it should always be so built as to give a long and warming course to the flame and heated air, forcing them the more effectually to strike against the sides of the tubes which compose the boiler, and so to give out the greatest possible portion of their heat before they reach the chimney. Unless this be attended to, there will be a much greater wafte of fuel than necessary, and the heat communicated to the contents of the boiler will be less from a given quantity of fuel.

When very high temperatures are not to be employed, the kind of boiler just described is found to answer very well; but where the utmost force of the fire is desirable for producing the most elastic steam, the parts are combined in a manner somewhat different, though the principle is the same. In the Philosophical Magazine, vol. xxvii. p. 40, are a description and drawing of a boiler of this kind, two of which were erected in 1803 at Medirs. Meus's brewery.

In every case Mr. Woolf uses two safety-valves, at least, in his apparatus, to prevent accidents; a precaution which cannot be too strongly enforced, as it may happen, when
but one is employed, that by some accident it may get locked, and the engine and people about it be exposed to the danger of an explosion.

In those engines of Mr. Woolf's which we have seen, he employs boilers like the one described, viz. with two small tubes beneath, which are full of water, and exposed to the immediate action of the flame, communicating by perpendicular necks or branches with the large cylinder above, which has water in the lower part, and steam in the upper. The only difference from what we have above described is, that the lower and upper tubes are placed in the same direction, instead of being at right angles to each other, as in the flame, and the flame, instead of being inclined, is rather inclined upwards. The metal of these tubes is made very thick, with a view to strength and durability.

The idea of making boilers for raising strong steam, by a number of small tubes, which can be made stronger than one large vessel, is not original with Mr. Woolf; Mr. Blakney, of whom we have before spoken, having proposed it in a small tract which he published in French, at the Hague, in 1796. But his tubes were to be placed over each other in an inclined direction; and the water being admitted at the upper end, ran down within the heated inclined tubes, and became converted into steam.

**Woolf's Regulating Steam-Valve.**—Besides the common safety-values, Mr. Woolf has also introduced a valve of a new construction into the flame-pipe itself, to regulate the quantity that shall pass from the boiler. In fact, it is a self-acting flame-regulator, and extremely ingenious. A (fig. 6.) is a part of the great or flame cylinder of one of Mr. Woolf's boilers; B B, the neck or outlet for the flame, furnished by the box; C, the flame-pipe is tied to the neck of B B, by the flanges a a. The top or cover of the flame-box C, marked with the letter D D, is well secured in its place, and has a hole through it for the rod of the valve to pass through; and the interior of the hole is formed to a box to hold a stuffing, and make the rod work up and down, flame-tight; the stuffing being kept in its place by means of a collar, screwed down in the usual way, as shown in the figure. By means of a pin δ δ, and the two vertical pieces e e, the stuffing-valve is made fast to m, which is a collar contiguous to the inner end of the flame-tube. The cover covers the inner end of the collar o o, which is made fast to the flange a a, and descends into the neck of the boiler, forming a barrel, in which the cylinder fits close. The cylinder, n, is open at bottom, having a free communication with the flame in the boiler A A; and it has three vertical flaps cut through the sides, one of which, S, is shown in the plate. The lumen of all these flaps or openings is equal to the area of the opening of the seat or collar o o, in which the cylinder, n n, works.

When the flame acquires a sufficient degree of elastic force to raise the valve, that is, the cylinder n n, with its cover m m, and the rod R R, together with whatever weight the rod may be loaded, then the openings S, rising above the flame-tight collar or seat o o, allow the steam to pass into the flame-box C C, and to flow off to the engine through the pipe N N. But the quantity of steam that passes is proportioned to the elastic force it has acquired, and the weight with which the valve is loaded; because the rise of the openings S, above the collar o o, will be in that proportion.

This valve may be loaded by applying weights in any of the usual methods; but Mr. Woolf prefers the one shown in the drawing, in which the upper part of the rod, R R, is joined by means of a chain to a quadrant of a circle Q Q, with an arm projecting from it, as represented in the plate, for the purpose of carrying a pendulum weight Z Z, that admits of being moved nearer to or farther from the centre of the quadrant, according as the pressure of the valve is wished to be increased or diminished.

As the valve rises, the weight moves upwards in the arc n n, giving a continually increased resistance to the farther rising of the valve, proportioned to the horizontal distance of the weight from the centre of Q Q, of which the weight attains a continual increase by its rise in the arc, and the flame proceeds in the horizontal distance measured by the line Q Q, passing through the centre of the weight by perpendiculars from the horizontal line.

Thus, if the weight Z Z presses down the valve n n, with a force equal to 20 lbs. on the square inch of the aperture in o o, in its present position, when it rises to the position at s, it will press with a force equal to 30 lbs.; and at r, with a force equal to 40 lbs. on the square inch; so that the rod, Z Z, may be made to serve at the same time as an index to the person who attends the fire, nothing more being needed for this purpose than the descriptions given by the end of the rod Q Q, by experimental trials. In the side of the flame-box C C, there is an opening N N, to allow the steam to pass from it by a pipe to the flame-engine.

It is plain that the adjustment of the positive pressure on this valve can be determined by sliding the weight, Z Z, of the pendulum to a greater or less distance from the centre of motion. Again, to adjust the rate of the increasing forces, so as to correspond with the increasing force of the flame, the radius of the quadrant, Q Q, must be proportioned to the atmosphere of the valve, radius of the open flaps S S, so that the ascent of the weight, Z Z, in its quadrant will be correspondent to the varying pressure. This adjustment must be made as nearly as it can be done before the valve is fixed, and to bring it afterwards to an exact regulation, the chain is attached to the rod, R R, by a nut and screw; by means of which, any part of the arc can be used that is found most correspondent with the varying pressure, because the rate at which the resistance of the lever increases is more rapid when the pendulum is near to the perpendicular, than when it approaches the horizontal position. The valve is shown in the side of the cylinder narrower at the lower part of the cylinder, instead of being parallel.

**Edelcrantz's Safety-Valve.**—The chevalier Edelcrantz contrived a safety-valve, some years ago, which has the same properties as Mr. Woolf's, and is worthy of notice, as being more simple in its construction. A small brass cylinder is fixed on the boiler, and fitted with a piston, which moves with very little friction, in order that it may descend by its own weight, after it has been raised up, without, however, permitting the steam to pass between it and the cylinder in any quantity. The lower part of the cylinder communicates with the boiler, and the upper part is closed by a small cover screwed on to it, and perforated with a hole, through which the piston-rod paffes easily. This cover serves the double purpose of guiding the rod, and preventing the piston from being blown out. The piston-rod is furnished with a shoulder, which serves to support different weights which are placed upon it, and they can be changed at pleasure. The side of the cylinder is pierced with holes opening to the air; the holes are very small, and placed above each other at the distance of about a line, but...
STEAM-ENGINE.

This distance, as well as the number of them, is a matter of indifference.

To give an idea of the effect of this small apparatus, let us suppose the piston lowered, and loaded with any weight, and that a fire is kindled under the boiler. When the vapour has acquired sufficient elasticity to raise the weights, the piston will ascend and have raised the first hole; if the steam were escape, it will remain in that position, and in a state of oscillation; if not, it will ascend above the second, third, &c. hole; and if the intensity of the fire is sufficiently strong, above the last, which must be made large, that, by giving the proper means of escape to the vapour, all accidents may be prevented. It is here evident, that though the greater or less elevation of the piston, as well as the number of the holes open, depend on the variations and different intensities of the fire, these variations, however, have no influence on the interior heat, and the elasticity of the vapour contained in the digester, since their force is always proportioned to the weight with which the piston is loaded, and which is constant. This safety-piston seems likely to afford, for delicate experiments, greater exactness than the usual safety-valves hitherto employed, with levers charged with weights; for in the whole course of the space which the cylindrical piston passes over in ascending, the state of the elasticity of the vapour is the same; whereas, when the conical valve is common use, none rises up by nothing prevents whether or how much the present state of the vapour fur- passes the first effort it made to open the valve. Besides, the diameter of the piston being once known, the force of the vapour requisite for each experiment can be easily regulated and determined: if we suppose, for example, that the lower surface of the piston is 4/9 of a square inch, each ounce of weight placed on the shoulder of the piston-rod will be equivalent to the pressure of a pound on each square inch of the surface, and so on in proportion. As this pressure then remains constant, the experiment will be more exact, and consequently more comparative.

The application of this piston to the boiler of the steam-engine needs no farther explanation, except that, in this case, the diameter of the piston must be considerably increased. It seems here to offer the same advantage of greater uniformity in the force of the steam, especially if the motion of the piston be employed to regulate the fire of the furnace, and to prevent the useless dispersion of the vapour, by preventing an excess in the intensity of the fire. The following apparatus may be used for this purpose. Let the aperture of the due for the current of air which maintains the combustion of the fuel be provided with a register, which, by rising and falling, will open or shut that passage of air: if the motion of the safety-piston be combined by any means with the register, in such a manner that when the former ascends, the latter descends, so that when the piston is at its greatest elevation, the register shall be entirely shut, it is evident that since the heat produced depends on the access of the air, the elasticity of the vapour, being determined by the weight on the piston, will not only remain within the bounds prescribed for it, but will regulate itself, by preventing any more air from entering the furnace than is necessary to maintain its force. A figure, representing this useful apparatus more minutely, may be found in the 17th volume of the Philosophical Magazine, p. 162.

Before quitting the subject of double-cylinder engines, we shall notice some others beside those of Mr. Hornblower and Mr. Woolf.

Messrs. James and John Robertson had a patent for one in 1800. The proposed object of the double cylinder was to have that portion of the steam, which in the best constructed steam-engines escapes past the sides of the piston in the time of working, and is lost without producing any motive effect whatever, so Mr. Robertson's intention was to prevent so great a quantity of steam from escaping, and in making the steam, which actually did escape, act on another piston, and add to the power of the engine. There are two steam-cylinders, with a piston fitted to each; the one cylinder of a smaller, and the other of a larger size. These two cylinders act together in producing the effect, and are furnished with a condensing vessel and air-pump, similar to other engines. The same patent contains the description of the smoke-burning furnace, which has been very extensively used.

Mr. William de Vereell obtained a patent in 1805, for improvements in the steam-engine. He proposes to have two working cylinders, placed near to one another, each having a pipe of communication, with a large vessel, in which the steam, after passing from the small cylinder, is suffered to expand itself, before entering the large cylinder. The pistons in the two cylinders work alternately up and down by means of valves or cocks, opening and shutting as in the common engine. Suppose the small piston has just made a stroke, and a passage is opened to the steam-vessel at the end of the stroke; at a certain beginning to work the engine, the vessel will be full of steam of about 18 lbs. pressure, admitted from the boiler, but afterwards will only be supplied by the steam thrown into it from the small cylinder. The vessel should be about twenty times larger in capacity than the smallest working cylinder; and the larger it is, the more regular will be the pressure on the great piston, which is worked by the steam coming from the steam-vessel. If the steam in the boiler be of 54 lbs. pressure per square inch, the ratio of the two working cylinders may be as 1 to 3, for then the smaller one will supply the larger with steam of about 18 lbs. pressure; the proportion, however, may be varied, though these are thought best by the patentee. The improvements here are represented to consist in the steam going from the smaller working cylinder to the steam-vessel, and then from the steam-vessel to the larger working cylinder, from which it is afterwards drawn off, and condensed. By these means the engine will be very regular in its operations. Suppose the steam in the boiler is at 54 lbs., the smaller cylinder will, at the end of the stroke, be full of steam of the same or nearly the same force; and the steam-vessel being full of the steam delivered to it by the former stroke of the small cylinder, at about 18 lbs. pressure, the communication is opened between this vessel and the smaller cylinder, and the steam in each of these will be brought to nearly 20 lbs. pressure, which steam will be used in the great cylinder at the next stroke. But at the end of each stroke of the pistons, before the opening is made between the smaller cylinder and the steam-vessel, the steam in the smaller cylinder will be, as before stated, at about 54 lbs.; in the steam-vessel it will be at about 18 lbs., and in the larger working cylinder at about 18 lbs. also. Hence the medium pressure on the piston of the smaller cylinder will be about 55 lbs. on the inch, while the medium pressure of the steam on the piston of the great cylinder will be about 19 lbs. on the inch; for it will be about 20 lbs. at the beginning, and about 18 lbs. at the end of the stroke. If the steam-vessel be made larger, the difference at each end of the stroke will not
not be so great. If the steam was let out at 5 lbs. from the smaller cylinder to the open air, there would be but 39 lb. upon each inch of the piston, in consequence of the re-action of the atmosphere, equivalent to about 15 lb. per inch; thus, by letting the steam pass from the smaller cylinder to the steam-vessel, instead of letting it out to the open air, it loses about 4 lbs. on the inch of the small piston, but it gains about 12 lbs. on the inch of a piston three times as large; and there being but half the steam required in the common way to condense, there must of necessity be a considerable gain. If the friction and loss of force be equal to 6 lb. on the inch on the piston of the smaller cylinder, there will be about 30 lb. on the inch next power, when the larger one will work about 12 lb. on the inch. Here too, if the large cylinder, or piston, or air-pump, or condenser, should be out of order, the small piston may still be worked, by diffracting the large piston from the beam; on the other hand, if the smaller piston be out of order, the large one may still be worked, while the other is diffracted. The steam-vessel is to be made of wood, that it may transmit the heat slowly; and the cylinders may be placed within it, if found convenient.

We have examined two engines of Mr. Deverell’s which worked with great regularity, but the nature of the work they were performing did not admit of any accurate estimate of their power. The quantity of fuel they consumed was but small. We are disposed to think the addition of the steam-vessel has prevented the engine from the advantage of regulating the pressure, provided the heat is kept up; and for this purpose, the steam-vessel is in one of the engines we speak of was included in the boiler, and we think would, in that case, receive a confluent addition of heat to the expanded steam within it, which we believe is essential to all these kinds of engines. See the specification at large in the Repertory of Arts, vol. viii. p. 81.

Messrs. Fox and Lean also have a patent, dated Dec. 10, 1801, for improvements on steam-engines, the principal part of which is a double-cylinder engine, very much resembling those which we have described. See the Repertory, vol. xxii. p. 200.

Application of Reciprocating Engines to produce a rotative Motion for turning Machinery.—We have hitherto considered the steam-engine as being confined to the operation of working pumps for raising water; except in the flight notice which we have taken of the application of the crank to the atmospheric engine. This was a thing so obviously in imitation of the foot-lathe, as to be scarcely considered an invention; but the difficulty of applying it to use arose from the want of regularity in the action of the old engine. An engine to work a crank, must at all times make exactly the same length of stroke; and to perform well, all these strokes must be performed in an equal period of time. The old engines had very little exactness in either of these particulars. From the nature of the detent which opened the injection-cock, and the great friction of turning it, the degree to which it was opened was not constantly the same in the succeeding strokes; and a very small difference of opening would materially influence the quality of injection, and consequently produce a greater or less vacuum, and velocity with which the piston would descend. The boilers also of the old engines were always made too small, so that the leaf alteration in the intensity of the fire made the engine vary its speed.

At present, in all countries the atmospheric engines are made to work machinery by means of a crank, and perform very well, but they are lightly loaded, and move very quickly. The steam in the boiler is made much stronger than formerly, to enable it to fill the cylinder with a sudden puff, and thus to displace the air and water in an instant, because the rapid motion of the piston will not allow sufficient time for the discharging to be performed with weak steam, as is usual. All these circumstances reduce the performance of the engine with respect to coals, and the consumption is very great in comparison with the work they perform. Such engines act very well when the work or resistance is constantly the same throughout the day; but the engine cannot work regularly, except when the counter-weight of the connecting rod is equal to half the descending force of the piston, so as to make the stroke upon the crank of equal force in ascending and descending. In breweries, and those works which demand attention to varying resistance, this cannot apply: for instance, when the machinery for grinding is disengaged, or thrown off, if something does not operate to retard the effect of the counter-weight, the engine will increase in its velocity beyond all bounds, so as to work itself to pieces; and as the only remedy is to check the quantity of steam at the returning stroke, the discharge of the air will be interrupted, and the engine must stop. Mr. Watt’s single engine accommodates this circumstance, from the mode of discharging being constant, and not possible to be effectual by the work applied to it, whether it be uniform or variable; hence, to lessen the momentum of the counter-weight, it is only to check the entrance of the steam by any constrivance that will prevent the steam from entering at above the piston, from opening to its greatest limits.

Mr. Watt, for some years after the first introduction of his engines, was so fully occupied in substituting them for the large atmospheric engines at mines, where the expense of fuel was threatening to put a stop to their proceedings, that he found no leisure for new speculations; and although the advantages of applying engines on his principle to agricultural machinery had early occurred to him, he did not seriously set about reducing his ideas to practice until the year 1778 or 1779. In the first model he then made, in order to equalise the power, he employed two cylinders, acting upon two cranks fixed upon the same axis, at an angle of 180° from each other, and a weight was placed upon the circumference of the fly-wheel at an angle of 120° from each of the cranks; which weight was to be so adjusted, as to turn the wheel when neither of the cranks could do so, and consequently to render the power nearly equal. This model performed satisfactorily; but Mr. Watt having neglected to take out a patent immediately, the essential part of the contrivance was communicated, as we are informed in the Edin-burgh Review, by a workman employed to make a model, to the persons engaged about one of Mr. Walshbrugh’s engines, of which we have before spoken, and a patent was taken out for the application of the crank by the engineer there employed. This did not deter Mr. Watt from proceeding; and without attempting to dispute a patent which, so long as it continued attached to the common atmospheric engine, could not rival him, he set about other modes of effecting the same thing, and took out a patent for several new methods of applying the vibrating or reciprocatting motion of steam-engines to turn a coupled rotary motion round an axis, one of which was that beautiful contrivance of the revolving motion of one wheel round the other, called the fun and planet wheels, from the resemblance to the motion of those laminaries. Mr. Watt’s patent is dated Otober 1783, and entitled, a new method of applying the vibrating or reciprocating motion of steam-engines to produce a continued rotary or circular motion. It contains six different methods; but the two which have been since brought into use are
STEAM-ENGINE.

are the crank, and fun and planet wheels. The crank is applied in the best manner to produce a regular motion, when a single acting engine is the moving power: this was to apply an iron wheel on the end of the axis of the fly-wheel for a crank, and with a pin projecting from it, to which the connecting rod is jointed: one half of the wheel is made solid, of cast-iron, in order to be heavy on that side in which the pin is fixed, in or to be moved by that side in the return stroke of the engine; the other half of the wheel is made light, that it may not oppose this weight.

Soon after this patent, Mr. Watt erected some engines in London at the large breweries; the first was at Mr. Goodway's, a spirited encourager of improvements, and the next at Mr. Whitbread's. A sketch of the latter engine, which is still working, is given in our plate Porter-Brewery. In these engines he employed the fun and planet wheels, and used a maltese connecting rod, of sufficient weight to actuate the fly during the returning stroke, for these engines had not the advantage of the double action.

Double-acting Steam-Engines.—The advantage of a double-acting engine, which shall urge the machinery equally in ascending and descending, is obvious. The first double-acting steam-engine was proposed in 1779, by Dr. Falcet, who published an account and description of an improved steam-engine, which will, he says, with the same quantity of fuel, and in an equal space of time, raise double the quantity of water raised by any lever-engine of the same dimensions; but he does not appear to have proved the assertion, or constructed even a working model of this proposed engine, which was on Newcomen's principle. The chief improvement which he suggests is to use two cylinders, into which the steam is alternately admitted by a common regulator, which always opens the communication of the steam to one, whilst it shuts up the opening of the other. The piston-rods are kept (by means of a wheel fixed to an arbor) in a continual ascending and descending motion, in the same manner as the rods of the common air-pump, by which they move a common axle, to which is affixed another wheel, moving the pump-rods in the same alternate direction as the piston-rods, by which alternate motions of the two pistons the pumps are kept in constant action. Since the improved engines of Mr. Watt have been introduced, this method of combining the alternate action of two single engines has been applied to work machinery. We have seen both the atmospheric engine and the single engine of Mr. Watt working in this manner, but his double engine is much preferable. Mr. Watt saw that this was necessary, in order to perfect the application of his steam-engine; he therefore applied the power of the steam to press the piston upwards in its cylinder as well as downwards, by forming the vacuum alternately above and below the piston, and the counter-weight then becomes unnecessary. The only change in the machine beside the arrangement of the valves and their mechanism, was in applying a double chain to the arch-head of the beam, in the same way that the pumps of old extinguishing engines were worked; or he employed a rack and fector at the end of the beam.

This he called the double engine, as in fact it doubled the power exerted within the same cylinder. He had long had in his mind the idea of this improvement, and had even produced a drawing of it to the house of commons, in 1774, at the time he procured the act to prolong his original patent for 25 years; but the first he executed was, we believe, at Soho, in the year 1781 or 1782, and the first public exhibition of it at the Albion mills a few years later.

About the same period, finding double chains, or racks and fectors, very inconvenient for communicating the motion of the beam, he invented and applied what has been called the parallel motion, one of the most ingenious and most perfect contrivances in mechanics. To prevent irregularities in the speed of the engine, arising from variations in the quantity of power used at different intervals in the works to which it was applied, he made an application of the centrifugal force of what is called the governor (before used in wind-mills), to regulate the admission of the steam; by this means keeping the engine always at an uniform velocity, and diminishing the consumption of steam, in proportion to the power exerted. This gave the finishing stroke to the perfection of the motion of the machine, and rendered its regularity nearly correspondent with that of the pendulum of a clock. These inventions are detailed, among many other contrivances, relative both to steam-engines and the application of their power, in two patents, dated 1785 and 1784. The steamers are highly ingenious; a few may have been first ideas, not reduced to practice, and others were no doubt inferred for the purpose of guarding against evation.

Miffet's, Boulton and Watt's Double-acting Engine for turning Mills.—Plate VI. contains a general elevation of the whole engine, and Plate VII. fig. 1. is a section of the cylinder, inclosed in its steam-cake or jacket, the outside of which is coated with platter, to keep in the heat; the internal structure will be described hereafter: a is the piston-rod, connected to the great working beam B C E, by a system of levers: C D E. Each of these levers consists of a parallel motion, the property of which is, that the rectilinear motion of the piston-rod, a, is preserved, though the end, C, of the beam describes an arc of a circle when it rises and falls upon its centre of motion, B. At the opposite end, E, of the beam is jointed the connecting rod D, and at the lower end of this is Mr. Watt's contrivance for communicating the force of the steam-engine to any machine of the rotatory kind. G represents the rim and arms of a very large and heavy cast-iron fly-wheel; on the extremity of its axis is fixed the concentric toothed wheel H, called the fun-wheel. The connecting rod, D, is a strong and stiff iron rod, D y of sufficient weight to balance the piston: to the lower end of it, a toothed wheel, I, is firmly fixed by three bolts, so that it cannot turn round. This wheel is called the planet-wheel, because it revolves round the fun-wheel; it is of the same size and in the same vertical plane with the wheel H, and an iron link or strap (which cannot be seen here, because it is on the other side of the two wheels) connects the centres of the two wheels, so that the one cannot cut the other. The engine being in the position represented in the figure, to explain the action of this movement, suppose the fly, G, to be turned once round by any external force, in the direction from G towards K; it is plain, that since the toothed wheels, being kept together by the link, cannot quit each other, the outer half of the fun-wheel (that is, the half farthest from the cylinder) will work on the inner half of the planet-wheel I, so that at the end of the revolution of the fly, the planet-wheel must have arrived to the top of the fun-wheel H, because the circumferences of the wheels are equal, and the outer end, E, of the beam must be raised to its highest position. The next revolution of the fly will bring the planet-wheel, and the beam connected with it, to their first positions, and thus every two revolutions of the fly will make a complete period of the beam's reciprocating movements. Now, instead of supposing the fly to drive the beam, let the beam drive the fly, the motions must be precisely the same, and each ascent or descent of the piston will produce one revolution of the fly. For
STEAM-ENGINE.

For instance, when the piston-rod, \( a \), is caused to ascend by the preflure of the steam beneath its piston, it raises one end of the beam and depresses the other; and by the communication of the connecting rod \( D \), causes the planet-wheel \( I \), to turn the wheel \( H \), and the fly-wheel, round with a double velocity. As soon as the piston-rod arrives at the end of its stroke, it receives a new impulse, which brings it down again, and consequently raises the connecting rod \( D \), and planet-wheel \( I \), so as to continue the motion of the wheel \( H \), and fly-wheel \( G \), always in the same direction. The use of the fly-wheel is to acquire an impetus from the force communicated to it, at the time that the centre of the planet-wheel, \( I \), is on the same horizontal line with the centre of the sun-wheel \( H \), at which time the connecting rod exerts all the force of the engine upon the wheel \( H \), to turn it round. This momentum is preserved by the rapid motion of the fly-wheel, which continues to turn all the rest of the machinery, when the planet-wheel, \( I \), is at the top or bottom of its motion, for the centres of the two wheels being in a line with the connecting rod, it has no tendency to turn them round.

To describe the manner in which the power of the steam is given to the piston-rod \( a \), we must turn to the section in Plate VII., fig. 1, where \( A \) is the jacket of steam-cape containing the cylinder, which is of cast-iron, and truly bored; it is closed at top by an iron lid \( l \), screwed on by screw-bolts, passing through a projecting rim or flange at the top, and a similar flange is formed at the lower end of the cylinders, to fall on the bottom. In the end, the top lid is a stuffing-box \( L \) for holding a packing of hemp, through which the piston-rod, \( a \), passes, perfectly air and steam tight; \( 20 \) is the piston, packed with hemp in a channel round its edge, so that the packing lies between its circumference and the inside surface of the cylinder; and while it can move up and down in the cylinder easily, it will not allow any steam to pass by it. The piston is fitted to the rod, \( a \), with a cone, and fast keyed in: the cylinder has a flange or projecting ring round it, a little below the top flange, by which it is held into the jacket \( A \), which is constantly supplied with steam from the boiler of the engine, by a small pipe branching off from the steam-pipe.

The steam-pipe cannot be seen in the elevation, except by the small dark circle near \( g \); and in fig. 9, it is marked as it introduces the steam from the boiler, at all times, through a throttle-valve, \( 35 \), into a box \( g \), called the upper steam-box. In the bottom of this box is the upper steam-valve, which being opened by depressing the end of the lever \( 7 \), admits the steam to the short passage \( 14 \), which leads to the top of the cylinder. A branch, \( 13 \), descends perpendicularly from the steam-pipe, just before it enters the upper steam-box, and conveys steam to the lower steam-box \( 8 \); and in the bottom of this is a valve, which can be opened by lifting the end of a lever, \( 10 \), to admit the steam into the passage \( 15 \), which leads into the bottom of the cylinder. These two valves govern the entrance of steam into the cylinder; and they both open upwards.

The valves for carrying off the steam are situated in two other boxes, \( b \) and \( k \), in which a vacuum is always maintained by their open communication with the condenser \( M \), by the exhausting-pipe \( 13 \), which descends from the upper box \( b \), and where it passes by the lower box \( k \), has a small branch leading into it.

These two exhausting boxes are situated immediately beneath the passages, \( 14 \) and \( 15 \), which lead to the top and bottom of the cylinder, and the exhausting-valves are situated in the horizontal plate of the partition between the boxes and the passages, in the same manner as the steam-valves are in the partitions between the steam-boxes and the steam passages, as is clearly shown in fig. 3. On opening the upper exhausting-valve, by depressing the lever \( 8 \), the steam from the top of the cylinder will be drawn off to the condenser; or by elevating the lever \( 9 \) (fig. 2.), the lower exhausting-valve will be opened, and the steam will pass off from the lower part of the cylinder to the same end.

The steam and eduction-valves, \( 7, 8, 9, 10 \), are opened and shut by the levers called spangers, whose handles, \( 1 \) and \( 2 \), are alternately moved by the plugs fixed to the piston-rod of the air-pump \( N \). This part of the machinery has been called the hand-gear, because it is so contrived that the steam and eduction-valves can be worked either by the hand or by the piston of the air-pump.

The valves are connected in pairs to levers upon the axle of the two handles \( 1 \) and \( 2 \), which are actuated by the pins \( f \) and \( 24 \), projecting from the rod, \( f \), of the air-pump, and this arrangement is this: the lower steam-valve \( 10 \), and the upper exhausting-valve \( 8 \), are connected by rods with levers upon the axle of the lower handle \( 2 \), and when that handle is depressed it will open both those valves at once, to admit steam below the piston, and exhaust it from above, which will cause the ascent of the piston. A lever and rod \( 6 \), (see the elevation) are applied to the axis of this handle, with a sufficient weight in the ciften to cause the handle to fall and open the valves suddenly; but when the valves are to be kept shut, the handle, \( 2 \), is held up by a catch, and dentet \( 34 \), the end \( 4 \), having a hook to receive the catch, and detain the handle when lifted up, as in the figure.

In the same manner, the upper steam-valve \( 7 \), and the lower exhausting-valve \( 9 \), are united by rods to levers upon the axis of the upper handle \( 1 \); and when this handle is raised, as in the figure, it opens both valves at once, so as to admit the steam above the piston and exhaust it from beneath it, as is shown by the arrows in the section, which will cause the piston to descend.

Like the former spindle, a lever, \( 5 \), and rod are applied to it, with a weight which will lift up the handle, \( 1 \), and open the two valves; but when the handle is depressed, so as to shut the valves, it is held down by the catch entering the hook, \( 3 \), of the dentet \( 34 \). As this dentet moves upon a centre-pin, it must be observed, that when one lever catches into the hook it pushes back the dentet, and this motion releases the other catch from the hook at the opposite end of the dentet, so that moving one handle to shut one pair of valves releases the catch, and the weights immediately open the opposite pair of valves.

The exhausting-pipe, \( 13 \), descends to the condenser \( M \), which is a cylindrical vessel of cast-iron, immerced in the cold water of the condensing ciften \( L \); it communicates by the valve \( m \), with the air-pump \( N \), which has valves in its bucket opening upwards, and is covered by a lid, through which the rod paffes in a stuffing-box ; also at the top of the pump is a short pipe of discharge, opening into the hot-well \( n \), and this has a valve to prevent the return of the air and water into the pump.

All these parts are exactly the same as those of the single engine, before described, except the injection-cock \( 16 \), which is constantly running a small jet of cold water into the condenser, when the engine is at work. There is no necessity for an injection-valve in the double engine, and the use of the cock is only to regulate the quantity, and to stop it when the engine is not at work; it is moved by a handle \( 17 \), and there is a divided plate and index, to shew the degree of opening.
STEAM-ENGINE.

The cylinder is bolted down to two strong beams, which cross over the top of the condensing cistern L, and these are united at the ends to two vertical polls S, which are framed into another piece situated beneath the cistern, and supported upon a pier of brick-work R: by this means the whole weight of the water in the cistern is applied to hold the cylinder firmly down. X are beams which support the flain of the beam-centre, by bearing up the floor F, on which the centre bearing rests; and the narrow dark line up the middle of the frame K, is a large iron bolt, which ties the frame down to the long groundills, on which the cistern rests, and with which the beam T, for the centre of the fly-wheel, is connected by oblique legs and tie-bolts: by this means the external walls, W, W, are relieved from any material strain occasioned by the working of the engine. X X is the staircase to ascend to the beam-floor. The boiler is not represented, but may be considered the same as that of the single engine.

Operation of the Double Engine.—Supposing every thing in the position of the fiction, the operation of the engine is as follows. When the water in the boiler is heated by the fire made under its bottom, the heat which enters into combination with the water causes it to expand, and form steam: in this state it rises and fills the boiler; and thence passing through the pipes 21, enters the upper steam-box g; it then passes into the cylinder; and by the descending branch, 12, of the steam-pipe, enters and fills the lower steam-box 2. Before the engine can be worked, the steam must be heated, until it is expanded so much, that it will rush forcibly out of the boiler when permitted.

The person who attends the engine must now open all the four valves at once, by elevating the handle i, and depressing the handle 2; this admits the steam from the boiler to pass through the boxes and the cylinder to the condenser, when it rushes through the pipe 13, into the condenser M, and the air therein contained, through the valve n, and the valves in the bucket of the air-pump, which it opens, and passes into the cistern m, through the discharge-valve, where it is open to the atmosphere, the lid of that cistern being only laid on, and not setting tight. This operation (called blowing through) being continued for a few seconds, expels all the air from the condenser, and fills it with hot steam. All the four valves are now closed, by depressing down the upper handle i, and lifting up the lower handle 2; and the injection-cock 16, of which 17 is the handle, is opened; this allows a small stream of cold water from the condensing cistern L, to enter into the condenser, and condenses the steam or cools it, when it instantly contracts into the same space it originally occupied in the boiler, before it was heated. As the valve, m, closes, to prevent the return of the atmospheric air, a vacuum will be caused in the condenser, because there will be nothing in it but that small quantity of water produced from the steam, and the cold water injected into the condenser.

The engine-man now opens the upper condensing valve 8, and lower steam-valve 10, by allowing the lower handle, 3, to fall down. The communication to the condenser being thus opened, the mixture of air and steam in the upper part of the cylinder will expand itself into the condenser through the passage 14, and valve 8, by the exhausting-pipe 15; as it occupies more space than it did before, it will be considerably rarefied, and press lightly upon the upper side of the piston. The steam from the boiler entering through the open valve, 10, is all the while preying with its full force against the lower side of the piston, and will perhaps, now a rarefaction is made above it, overcome the resist ance of the work and friction, and cause the piston to ascend, the air-pump rod and bucket moving with it. When the pin 24, upon this rod, reaches the handle 2, it raises it up, and shuts the lower steam-valve 10, and the upper exhausting-valve 8; and by means of the catch preying back the hook at the lower end of the detent 4, it relieves the catch of the upper handle from the hook 3, of the detent; in consequence of which, the weight applied to the lever 5, throws up the handle 1, and opens the upper steam-valve 7, and lower exhausting-valve 9, while the hook 4, of the detent, receiving the catch of the lower handle 2, holds it up. This is the situation represented in the section in fig. 1.

The operation is now reversed; the steam from the boiler going through the valve 7, and passage 14, into the cylinder above the piston, as shown by the arrow, fig. 1; and that steam which is beneath the piston going through the passage 15, and valve 9, to the condenser, where the steam will be condensed, and a vacuum will be formed beneath the piston: the steam now preys it down, moving the beam, and turning the fly-wheel and other machinery which it has to drive. When the piston is at the bottom, the pin, f, on the air-pump rod arrives at the handle 1, and preys it down; this shuts the upper steam-valve 7, and lower exhausting-valve 9; and when they are completely shut, the catch of the upper handle, in entering the upper hook of the detent 4, disengages the lower hook thereof; and the weight 6, which is applied to the lower handle 2, immediately throws open the lower steam-valve 10, and the upper exhausting-valve 8: the steam entering at the lower passage 15, the piston will be driven up again.

At each stroke of the engine, when the piston rises, the valve in the bucket of the air-pump will shut, and all the air and water contained above the bucket will be lifted through the valve, n, into the cistern or hot well; at the same time, a vacuum being made beneath the bucket, which is more perfect than that in the condenser, the valve, m, will be opened by the water and air in the condenser, which will enter the pump. On the descent of the piston, and air-pump bucket, the valve m, and the discharging-valve, n, will be shut, because the pressure which opened them is removed; and the water and air in the pump preying upon the valves in the bucket will open them, and pass through the bucket as it descends. At its return, it raises and discharges the water and air above it at the valve m, as before.

In this manner, when the engine has made two strokes, all the air which was contained in the cylinder, and mixed with the steam at the commencement of the operation, which was the only part from which it could not be expelled by blowing through, will be pumped out. The operation of the engine is now more perfect; the instant the exhausting-valve is opened, so as to establish a communication from the cylinder full of steam to the condenser, the elasticity of the steam causes it to rush through the valve, down the pipe 13, into the condenser; when it arrives there, it meets the steam of the injection-water, which condenses it, the remaining steam in the cylinder following it surprisingly quick; and in an instant, an almost perfect vacuum is formed in the cylinder, so that the steam acts with its whole force upon the piston to give it motion, all resistance upon the other side being removed.

The air-pump has now only to draw off from the condenser the water injected into it, the water produced by the condensed steam, and that small quantity of air or gas which goes from the boiler with the steam, and will not be condensed by the cold water. These are delivered by
STEAM-ENGINE.

by the air-pump into the hot-well, $a$, from which the air escapes; and the water, which still continues hot, runs off, when at a certain level, by a waste-pipe, which is not represented.

The water which is boiled off in steam from the boiler, is conveyed from the hot-well by means of a small pump, $p$, in the elevation, which draws the water from it by a pipe $o$, conducted up the side of the great frame $k$, which stands at the end of the condensing cistern $l$, and supports the bearing for the centre of the great beam. The water is conveyed from the pump by a pipe, to a cistern placed at the top of a vertical pipe, which descends into the boiler. The top of this pipe is closed by a valve in the cistern, which valve is raised by means of a lever, and the other end has a wire hooked to its going through a small stuffing-box into the boiler, where a flange is hung to it. This flange is balanced by a weight suspended at the other end of the lever, so that when the flange is covered with water, the weight keeps the valve shut, and prevents any water getting down into the boiler; but as the water sinks in the boiler by the evaporation, the weight of the flange overcomes the weight, and opens the valve: the water in the cistern then runs down the pipe into the boiler, and raises the water therein, and the balance-weight lifts up the flange, so as to close the valve.

The water being constantly supplied with hot steam, which gives out its heat, it would at length render the water surrounding it in the cistern so hot, that it would condense no more. To prevent this, it is constantly supplied with cold water from a pump $o$, worked by a rod $p$, from the great beam. The water from the condening cistern runs off by a waste-pipe at the back of the cistern, but not seen in the figures. The safety-valve is placed in a short pipe fixed upon the boiler, with a lid and a stuffing-box, through which a rod passes to open the valve within, and discharge the steam when the engine is not to be worked any longer. When at work, the valve is pressed down by a lever and weight. If at any time, when the engine is not at work, the steam should be heated, so as to be in any danger of bursting the boiler, the valve will lift up the weight, and allow the steam to escape through the pipe which opens into the chimney.

Other Particulars of the Double Engine. — Mr. Watt's mode of regulating the engine is a most beautiful contrivance, and so perfect, as to put the steam-engine on an equality with a water-wheel, in the regularity of its motion, even when the refraction is very variable. The throttle-valve, which regulates the supply of steam, is placed in the steam-pipe at $25$ (Plate VII. fig. 2): it is a thin circular pipe in the valve, turning on a pivot across its centre, which comes through the pipe, and has a small handle fixed on the end of it; by turning this handle, the spindle and valve within the pipe are turned also. When the valve is set, so that its plane is perpendicular to the axis of the pipe, it nearly fills the circular passage, and offers little steam, if any, to pass by it; but when the valve is turned edgewise, it presents a very small surface, and the steam passes by without obstruction to the steam-box and $i$. By turning the handle of the throttle-valve, the engine-man can at any time regulate the speed of the engine, the friction of the axis being sufficient to retain it as it is placed.

This method of regulation is sufficient for many engines; but when the steam-engine is employed to drive machinery, in which the refraction is very variable, and where a determinate velocity cannot properly be dispensed with, Mr. Watt has applied the conical pendulum, which is represented in the elevation (Plate VI.) at $b$, for procuring uniform velocity. (See also Regulator and Mill-Worke) This regulator has two pendulums, consisting of heavy balls, $b, s$, suspended by iron rods, which move on a common joint, $v$, at the top of the vertical axis $w$, which is put in motion by an endless rope, $g$, passing round a pulley on the axis of the fly-wheel, and round another pulley upon a small horizontal axis, from which, by means of a pair of bevelled wheels, $r$, the motion is communicated to the vertical axis $w$, which is caused to revolve, and carry the pendulum with it. In this motion, their balls, $b$ and $s$, describe a horizontal circle, and the velocity is sufficient to make the balls fly out by their centrifugal force, the arms of the pendulums moving upon their centres: in this motion, the upper ends of the arms $v, w$, draw down a collar, $u$, which slides on the square part of the axis, and operates on a lever $m$, and by another lever $n$, and rod $a$, communicates with the steam or throttle-valve. The action of this beautiful contrivance is this: as the velocity of the fly-wheel increases and diminishes with the quantity of steam that is admitted into the cylinder, let it suppose that too much is admitted; then the velocity of the fly-wheel is increased, and the velocity of the vertical axis $w$, will also increase, and the balls $b, s$, will recede from the axis by the augmentation of their centrifugal force. By this reces of the balls, the extremity, $a$, of the lever is depressed, its other extremity rises, and acting upon the lever $g$, cause the rotation of the throttle-valve to increase, and to close the passage a little, and diminish the supply of steam. The impelling power of the engine being thus diminished, the velocity of the fly-wheel and the flying balls decreases in proportion, and the balls resume their former position, and the engine works regularly.

The advantage of the sun and planet wheels has been alluded to in making the fly-wheel revolve with a double velocity to that which would be produced by a simple crank, by which means a fly-wheel of smaller dimensions becomes sufficient to regulate the motion of the engine. Of late years, this ingenious contrivance has been laid aside in favour of the simple crank, because it has been found that the cogs of the two wheels, when they become worn and loose, act with a disagreeable jerk at every change of the motion from the ascents to the descents. As it is in many cases an advantage to make the fly-wheel revolve with a double or triple velocity, a large cog-wheel is applied upon the axis of the crank, and this turns a pinion of only one-half or one-third of the size, fixed upon the axis of the fly-wheel. Here the fame defect of the jerk, by the loosening of the cogs, will be experienced; but the wheels being larger than can be used in the sun and planet wheels, a greater number of cogs are brought into action, and the weight upon each will be less: also, this form of the engine can be included in less room, because the centre of the large fly-wheel may be brought beneath the middle of the beam.

The power of the engine, when transmitted by the crank, is extremely variable throughout the different periods of the stroke: at first beginning, the crank being in a line with the connecting rod, the force of the piton has no action at all to begin the motion of the joint, $d$, but by turning the handle of the throttle-valve, the engine-man can at any time regulate the speed of the engine, the friction of the axis being sufficient to retain it as it is placed.

A Table
A Table shewing the force which the connecting rod of a steam-engine has to turn round the crank at different parts of the motion. The parts of the engine are supposed to have the following proportions: length of the stroke, 1; length of the beam, 2; length of the crank, 3; length of the connecting rod, 5.

</table>

The third column of this table shews the force which is communicated to the fly-wheel, expressed in decimals, the force of the piton being 1.

The above table explains itself by the titles of its different columns, and it is only necessary to remark, that the variations of force are not to be considered as an absolute loss of power, because, when the crank has but light power, on arriving towards the top or bottom of the stroke, the whole force descends proportionally; and, in consequence, the steam has more time to flow into the cylinder, and press upon the piton with a greater power; therefore, what the piton loses in force upon the crank, it makes up in some degree by an increase of its force; and, from moving forward, it consumes less steam than when moving with its whole velocity, and acting with full force upon the crank. Hence both the power and velocity of the piton in the cylinder are to be considered as varying continually; and if the fly is sufficiently heavy, it will be found that the rotative motion is very nearly regular, while the ascent and descent of the piton are accelerated from nothing at the top of the cylinder, to its greatest velocity at the middle, or near the middle, and from that point it is retarded till it comes to nothing at the bottom of the motion. The table shews the exact increments and decrements.

It has been considered desirable to have such a motion, that the power and velocity communicated to the fly-wheel shall be at all times equable and constant. This was one of the first attempts to produce a rotatory motion, as we have mentioned, by Mr. Fitzgerald, at Hartley colliery, in 1768; it has been repeatedly attempted since that period. The most practicable form in which it has been tried was by Mr. Matthew Murray, who, in a patent dated 1799, for the improvement of steam-engines, describes a very ingenious movement for the purpose. The defect of all these contrivances for obtaining equal power on the rotative axis is, that the piton must act upon it all at once with a sudden shock, which is course of time destroys the best constructed mechanism.

In the Philosophical Journal is a description of a contrivance by Mr. Samuel Clegg, for producing a rotating motion from a reciprocating one, which not only simplifies the machine very much, but exceeds the power of the common crank one-third, in consequence of its acting being always perpendicular to the radius of the wheel, which is done by a vertical double rack and wheel. The two vertical ends of this rack are joined by a semicircle at the top, and both parts are toothed on the inside, so that the teeth of the vertical wheel are constantly in contact with some of the teeth of the fork formed by the two vertical bars and the semicircle uniting the double racks. The wheel and rack are constantly kept in gear by means of a small roller, a sliding-bar, and a plate, serving, instead of a groove, to keep the roller from deviation in this way. Although the change from the upward to the downward motion of the piton-rod will be great, the change from the downward to the upward motion must be instantaneous; or at least the piton-rod must be brought to rest at once, from an uniform motion downwards, and then receive instantaneously a finite velocity in the opposite direction.

A mode of giving a more uniform action to the crank, was attempted in an engine erected by Mr. Hornblower about 1795, at the brewery of Meux and Co., where the alternate power of two single cylinders was applied by chains acting upon circular arcs, at a constant distance from the centre of the lever; while the end of the lever which was connected to the crank; by the connecting rod continually varied in its action, and consequently in its force on the crank, nearly in an equal proportion to the alteration of the leverage of the crank. (See the sketch of this contrivance at fig. 7. Plate V.) The two cylinders A, B, of this engine made an alternate action on a band-wheel, D, by means of two chains. The lever which carried the connecting rod, F, was a wheel fixed on the same shaft with the band-wheel, and had a pin, E, near its periphery, to which the connecting rod, F, was attached. This pin traversed about one-fourth of the whole circle, and may be designated by the symbol 2 of the lever, which, in its action upward to 4, and downward to 2, ascended and receded to and from the centre of motion; and had it traversed through the remainder of the semicircle, it would then have pressed on the crank, G, proportionately to the sine of every angle it made in its revolution. But considering the great pressure on this pin in the crank-wheel, it would have demanded a degree of strength in that part which would have been preponderous, compared with the rest of the work.

This engine has its merits and its defects; it is subject to much more friction than a double-acting cylinder, by having two cylinders and their appendages; and unless the communication between the cylinders is clothed with the best materials for that purpose, a great loss of heat must ensue; because the surface exposed in two cylinders, compared with one double-acting cylinder, is as 2 to 1, and the friction of the pistons will be nearly in the same proportion.

The air-pumps in this engine (for it had two, though only one condenser) were worked by a small band-wheel, upon the same axis as the great band-wheel D; and from the opposite sides of this, the rods, 14, were moved by chains. The air-pumps were open at top, and the pressure of the atmosphere always refelt upon their pistons; but as the two were acting in opposite directions, they balanced each other as to power;
power: in this the inventor adopted the common double-barrelled air-pump of Haukbee, instead of the more perfect air-pump of Smeaton, which Mr. Watt employs. This engine was considered of 36 horse's power, and for many years performed all the work of the brewery. We have also seen some smaller engines built on the same plan, one of them with atmospheric cylinders.

It may be considered an advantage in this engine, that it has a double air-pump, whereas the double cylinder has only a single air-pump, which draws out the air from the condenser while the piston is making its ascending stroke; but during the descent of the piston the air-pump is inactive. We have seen many proposals for double-acting pumps.

Mr. Murray, in 1801, had a patent for a new air-pump, (see the specification in the Repository of Arts, fifth series, vol. xvi.); but we have not had an opportunity of ascertaining the performance of an engine so constructed; and as the ingenious inventor does not now adopt it in the steam-engines which he makes, we may presume it is not of great importance.

The proportion usually given to the air-pump of a double engine is about two-thirds the diameter of the cylinder, and half the stroke, or from one-fourth to one-fifth the capacity of the cylinder: the condenser is of the same size. Whether it is owing to the circumference of the single air-pump or not, we are unable to determine; but it appears that double-acting engines do not in general produce as great an effect from the fuel they consume as single engines of the same dimensions.

In Meflops' reports of the engines in Cornwall, generally contain the accounts of 20 or 25 engines, there are several enormous double engines for pumping the mines, with cylinders of 66 and 67 inches, and four of 63 inches. The belft of these appear to be on Williams' mine; cylinder 67 inches diameter, and working with a stroke of 8 feet 9 inches, under a pressure of 16.0 lbs. per square inch: it works 10 pumps, which are a load of 70,411 lbs., at the rate of 33 strokes per minute, of 6 feet 9 inches stroke; its performance with respect to coal was, in June 1816, 30,074.507 lbs. lifted one foot high for each bucket consumed. This is a very good performance; but all the other double engines are less, one of the 63-inch cylinders is 27 millions, the others 25, 22, 21, and even 17 millions.

The advantages are all on the side of the double engine; the diminution of surface which is exploited to condensation, the vis inertie of the parts in motion is much less, and the friction of the piston is very much reduced, although the friction of the pump or air-pump should affect the amount of power to be increased, because they must be bound tight, so as to have no shake or looseness; but this must be inconsiderable.

Before quitting the subject of double engines, employed to give a rotative motion to machinery by a crane, we must notice the remarkable difference, shown by Meflops' reports, between the performance of the small engines employed in drawing the matter out of the mines, and those in pumping water.

We should think the loss of power from friction in drawing up buckets by a rope, could not be greater than the friction of pump-buckets, and of the water moving in the pipes; therefore all the difference must be attributed to the application to the rotative motion, and to the smallness of the engines: these are usually 14, 16, and 24 inches in diameter, but their performance, with respect to coal, is only 3, 3 1/2, 4, and 5 millions. The best engine they have has only from 9 1/2 to 11 million pounds one foot high for each bucket of coal, which is only one-third of the produce of the best large engines employed in pumping.

One of Woolf's double engines at Wheal Fortune mine, in May, 1816, drew only three million pounds one foot high with each bucket; but another at Wheal Vor mine drew six millions.

Estimation of the Force of Steam-Engines in Horse's Power.

The method of estimating the mechanical power of any machine by the weight of water or other matter which it will raise to a given height, in a certain period of time, or with a given quantity of fuel, is the most unequivocal expression that can possibly be obtained; but as steam-engines are frequently substituted in the room of horses, it has been customary to calculate their mechanical energy in horse-power, or to find the number of horses which could perform the same work. This, indeed, is a very vague expression of power, on account of the different degrees of strength which different horses possess; but still, when we are told that a steam-engine is equal to sixteen horses, we have a more distinct conception of its power, than when we are informed that it is capable of raising a given number of pounds weight through a certain space in a certain time.

Prior to Mr. Watt's application of the steam-engine to produce rotative motion, the great manufactories of the kingdom had their mill-work put in motion by the agency of water, of wind, or of horses; and the latter had for many years been almost exclusively employed in the breweries and distilleries of the metropolis. It was, therefore, natural for those who wished to substitute the power of steam for that of horses, to state the number of those animals, to which the new power, under given conditions, ought to be equivalent; and it is probable that Meflops, Watt and Boulton felt, that such a mode of comparison would be more intelligible to common apprehensions, than a more accurate and scientific formula: it gave the power of an engine expressed in numbers, of which the ordinary strength of a horse is the unit. This, no doubt, is not in itself very exact, the unit being large, and subject to considerable variation. Relative to the purpose for which it was used, it was, however, sufficiently correct; and on this subject many similar occasions, a more minute measurement would have been less useful. But to give this unit all the accuracy which can be desired, they have assumed, from the result of experiments made with the strong horses employed by the brewers in London, that the standard of a horse's power is a force able to raise 33,000 lbs. one foot high in a minute: and this, no doubt, was meant to include an allowance of power sufficiently ample to cover the usual variations of the strength of horses, and of other circumstances that might affect the amount of power, according to the estimate just mentioned, we think the power of a horse is rated above the ordinary average, a circumstance which cannot be complained of by the public, as it tends to represent the advantage of the engines less than it will be found in real practice.

Dr. Brewster, in his edition of Ferguson, states that Meflops, Watt and Boulton suppose a horse capable of raising 33,000 lbs. avoiduplous one foot high in a minute; while Dr. Defaguillers makes it 27,500 lbs. and Mr. Smeaton only 22,916. If we divide, therefore, the number of pounds which any steam-engine can raise one foot high in a minute by these three numbers, each quotient will represent the number of horses to which the engine is equivalent, according to the estimate of these different engineers. We will take, for example, an engine having a double-acting cylinder, on Mr. Watt's plan, 24 inches diameter, and which makes 20 strokes per minute, each stroke being five feet long, and the force of steam being equal to a preasure of 10 lbs. per square inch. Required the number of horse-power of such an engine.

The square of the diameter of the cylinder being multiplied by the decimal number .7854, will give the area of the piston:
STEAM-ENGINE.

piston; thus, 24 × 24 = 576 × 7854 = 4534 square
inches, which are exposed to the pressure of the steam.
Now, if we multiply this area by 30 lbs., the pressure upon
every square inch, we shall have 4524.4 × 10 = 4524 lbs.
the whole pressure upon the piston, or the weight which
the engine is capable of raising with a certain velocity. To
find this velocity, we say that the engine performs 20 double
strokes, each of five feet long, in a minute; the piston
must, therefore, move through 20 × 5 × 2 = 200 feet in
the same time; and, therefore, the power of the engine will
be represented by 4524 lbs. and 200 yards, raised through
200 feet in a minute, or by 94 1/2 hogheads of water, or
measured, raised through the same height in the same
time. Now this is equivalent to 4524 × 200 = 904,800 lbs. or
94 1/2 × 200 = 18,948 horseheads raised through the height
of one foot in a minute. This is reduced to the horse-power
of Mefire. Boulton and Watt, by dividing by 32,000, their
estimate of the horse-power: thus, 904800 ÷ 32000 = 28 1/2
horsepower.

According to Smeaton, 904800 ÷ 22916 = 394 horsepower.

According to Defaguglins, 904800 ÷ 27500 = 33
horsepower.

In this calculation, it is supposed that the engine works
only eight hours a day, so that if it worked during the
whole 24 hours, it would be equivalent to thrice the
number of horses found by the preceding rule.

Other Constructions of Mr. Watt's Double Engine.—A great
mass of matter must necessarily be put in rapid motion at
every stroke of the reciprocating engine, and the motion must be
flapped and returned at the end of the stroke. This is
an evident disadvantage under which the double engine
labors; so though all objections to the reciprocating, on
account of the irregularity of motion, is done away by
the application of a fly-wheel, the regularity thus attained
is at the expense of the power, as we have shown in the
practical results of the large engines for pumping, and
the engines for drawing from the mines. The most ob-
vious improvement in this particular, is to lighten the masts
of the great working beam, or to dispense with it alto-
gether. The enormous strain exerted on its arms requires a
proportional strength, and this requires a vast mass of matter,
not less indeed (in an engine with a cylinder of 32 inches
diameter) than three tons and a half; moving with a veloc-
ity of three feet in a second, which must be communicated
in about half a second, so that this mass must be brought
into motion from a state of rest, and must again be brought
to rest, again into motion, and again to rest, to complete
the period of a stroke. This consumes much power; and
engineers have not been able to load an engine with more
than 10 or 11 lbs. on the inch of the piston, and pre-
serve a sufficient quantity of motion, so as to make 12 or
15 seven-feet strokes in a minute. Many attempts have
been made to lessen this mass, by using a light fly-wheel,
or a light frame of carpentry, in place of a solid beam.

As an example of this is shewn in the beam of New-
comen's engine (Plate II.), a method which was intro-
duced by Mr. Smeaton; and another is shewn in Mr. Horn-
blower's (Plate V. fig. 1.) The form of this beam is such,
that it would be stronger than a solid beam containing a
great many times the quantity of timber, as there is scarcely
any part of it which is exposed to a transverse strain, but
every piece is either pulled or pushed in the direction of its
length. The only evident improvement of which it ad-
mits, is to apply a strong tie-bolt along the whole length
of the upper beam; because when tie-beams of wood are
used, it is very difficult to connect the iron flaps to the
ends of them in such a manner, that they will not become
loose in time. This is an objection to framed working
beams, for although they are abundantly strong at first,
yet, after being some time employed, the flaps and bolts
with which the wooden parts are connected, cut their way
into the wood, and the framings become loose in the joints,
and, without giving any warning, are liable to break to pieces
in an instant. A solid, massive beam of sufficient
strength bends, and feebly complains, (as the carpenters
experise it,) before it breaks. In all great engines, there-
fore, Mr. Watt at first employed such solid beams as were
found the most durable, and least likely to break in a long
course of work.

They were sometimes strengthened, in a very simple and
effective manner, by placing a king-post perpendicular to
the length of the beam, over its centre, and extending iron
tie-bolts from the top of the king-post to the two exter-
mities of the beam, so that the beam thus framed forms a
triangle, of which the beam is the base, the king-post the
perpendicular, and the iron ties the sides, meeting the per-
pendicular at the vertex of the triangle.

There was an expenient generally referred to, when the
beam was found to yield from a load, it could not stand.
There is, perhaps, no example, except the mast of a ship, in
which a piece of timber is exposed to such a severe strain as
the beam of an engine, because it is necessarily made as small as
possible; and it is relieved from the strain 15 or 20 times
every minute, so that all the fibres are tried to the utmost;
we accordingly see old beams, full of cracks lengthwise
from the fibres, separating laterally, and after this the beam
loses its strength.

Of late years, wooden beams have been altogether disused,
and iron beams substituted. We have already described
the mode of making the beam for the largest engines, by
two plates or slitsches put together parallel, and leaving a
space between them. For double engines, which are not
of the very large dimensions, it is usual to have the beam
cast in one piece, of a form best adapted to give the greatest
strength in the least weight. (See Plate IX. Steam-Engine,
Parallel Motions.) The extremities of the beam are turned in a
lathe to form cylindrical pins, and upon these pins are fit-
ted sockets or pieces, which have other pins projecting from them
to form the joints of the parallel motion and connecting rod;
so that when the sockets are fixed on the ends of the beam, the
pins will project from the beam in a direction perpendicular to
its length, and parallel to its axis of motion. There are two pins
thus projecting from each end of the beam, that is, one pin on
each side of the socket: the two links of the parallel motion
are fitted to the two projecting pins at one end, and the
double joint of the connecting rod is fitted on the two pins
at the other end of the beam. The advantage of this con-
struction is, that the joints at the ends of the beam become
universal joints, having liberty of motion in all directions;
but, in the direction in which the joints of the parallel
motion and connecting rod are to bend for the motion of the
beam, as shown in the figure, the motion will be
upon the projecting pins of the sockets; but if, from the axis
of the beam not being rightly placed, or from any other cause,
a lateral flexure is required in the motion of the beam, the
sockets of the joints will turn a little sideways upon the end
of the beam, and allow the deviation, without any strain on
the moving parts: were it not for this contrivance, the
smallest possible deviation from the perpendicular direction
of the cylinder would cause a great friction in the stuffing
box and joints. In Mr. Murray's best engines, the crank-
pin is also jointed to the connecting rod by a universal joint.

See Plate VIII. fig. 4.

All the joints of the parallel motion, the connecting rod,
O a

and
and crank, in short, all the moving joints of a double engine, must be fitted with brass sockets, which can be tightened round the pivots, so as to prevent all shake or looseness, which, in an engine that works both in ascending and descending, would be destructive of its action. The two great links of the parallel motion are each carried on a piece of a strap or loop of iron, bent so as to make a double link, in the upper bend of which are two brasses for the pivots at the end of the beam, and at the lower end are two others, for the pivots which project on each side from a socket, which is fixed on the top of the piton-rod. The brasses of the latter joint are held in by wedges, or cross-keys, put through the two links at the lower end, so that by driving the wedges farther, the brasses can be drawn tight at pleasure. The two inlaid brasses, that is, the lower brasses of the upper joint, and the upper brasses of the lower joint, are kept extended to their proper distance by a piece of wood, or a light frame of iron, fitted in between them.

But we have not yet satisfactorily explained the action of the parallel motion. It is plain that the piton-rod must ascend and descend in a perpendicular right line, and also that the end of the beam must ascend and descend in the arc of a circle. When the beam rises into the position of Plate VI. from a horizontal one, it gives the piton-rod a tendency to move from its perpendicular towards the centre of the beam, which must move towards it, was not the link, b, fastened to the beam and piton-rod by flexible joints; and while the lower end of the link, b, rises, the end of the bar or lever m, dotted, which is movable on a fixed centre m, also rises at the same time, and the angle between m and c increases, and likewise the angle between b and c increases slowly; so that the vertex of the angle between b and c would move towards B, if the bar, m, was not confined to move round the fixed point or centre m, while the other end rises along with the rod c. While m, therefore, rises upon its centre, the adjoining bar a, moves round the joint at its upper end, and draws c, and the lower end of b, from the centre of the beam, the angle between d and e increases, and the joint between d and c recedes from the centre of the beam; and as it cannot approach nearer to the joint between b and c, because of the rod c, it keeps a, and the bottom of b, in a perpendicular position; so that whatever tendency the joint between b and c has to approach towards the centre of the beam by the increase of the angle between b and c, is corrected by an equal tendency of the lever, m, to draw the angle between d and c in a contrary direction; but as the beam, B, falls into a horizontal position, in all these motions are reversed. In adjusting the parallel motion for work, when the piton-rod, a, is found to rub most upon the side of the collar of the stuffing-box nearest to m, the fixed centre point, m, must be shifted a little in the contrary direction, viz. to remove it nearer to the centre of the beam, and in an opposite direction if it is found to rub on the other side.

That the nature of this parallel joint may be better understood, it is proper to observe, that the bars which have been mentioned as made double, which cannot be shown in the figure, and that the two levers, m, m, are placed at a sufficient distance afdner to allow the links b, and the rods c, to descend between them.

Of late years, the framing for the support of the engine has been wholly made of cast-iron. A very good form is to make the cister, L, of cast-iron, all in one solid piece, and to fix the cylinder A upon it with four feet; a single column is then erected upon the end of the cister L, to support the centre of the beam: the fly-wheel is supported by small cast-iron standards rising from the ground; and the centre of the lever m, of the parallel motion, is supported by a small bracket or standard erected from the flange of the cylinder. By this arrangement, all the parts of the engine are so united, that they cannot deviate in the least from their position, unless the parts are actually broken. An engine of this plan is fully described in the British Encyclopaedia, vol. vi.

The engine represented in Plate VIII. fig. 4. is perhaps the most complete of all. It is of the form in which Meftra. Murray and Wood construct their engines, when they are not of a very large power.

Steam-Engines without Beams.—These have been made in a variety of forms. The simplest of all is to connect the piton-rod at once with the connecting rod, and to place the crank over the centre of the cylinder: the piton-rod must be guided by a parallel motion, or by sliders. The objection to this is, that the fly-wheel becomes elevated to too great a height for the communication of its motion, except in very particular circumstances, without shortening the connecting rod, which occasions the irregularity of the action of the crank to be greater than that of our table, in which the length of the connecting rod is supposed to be six times that of the crank, or three times the stroke of the engine, as a shorter cannot be made to work well. There is also a difficulty in balancing the weight of the piton-rod, connecting rod, and crank, and in giving motion to the air-pump. The balance-weight is usually placed on the rim of the fly-wheel; and the air-pump is either worked by a second smaller crank upon the axis of the fly-wheel, or by a short beam.

Engines of this kind are frequently placed with the cylinder horizontally, and for small engines this answer very well; but in large ones, the weight of the piton-acting always at one side bears the cylinder irregularly. Mr. Murray included this plan in his patent of 1799, which we have before mentioned, for producing the rotary motion without a crank; and he proposed to place rollers in the piton to bear it up.

Steam-engines with horizontal cylinders are used with the greatest advantage in steam-boats, as they can be made to lie low beneath the deck of the boat. Mr. Symington, we believe, first introduced this plan.

We have seen several engines working without a beam, in which the crank was placed immediately over the cylinder, and with the axis of the crank little more than its length above the top of the cylinder. For this purpose, the piton-rod is prolonged upwards to a length of three or four times the stroke of the engine, and the top is guided in a groove, or by a friction-wheel; near the upper end of it is jointed the connecting rod, which descends down to the crank-pin, situated behind the rod, and as close above the cylinder as it can turn round clear of its top. By this means, the ascent and descent of the piton-rod produce the rotation of the crank, the lateral deviation of the crank from the perpendicular being allowed for in the angle which the connecting rod makes with the prolonged piton-rod.

In this way the crank must be placed behind the piton-rod, or out of the line of it; but it is not then thought to work so well.

To remedy this the crank is made double, and the prolonged piton-rod has an opening in it for the crank-pin to pass through, and a connecting rod is placed on each side of the piton-rod, so that it is worked between the two. It is evident that the opening through the piton-rod must be a groove, equal in length to the stroke of the crank, so that the whole of the motion of the crank-pin, from one side to the other, can be admitted in the openings, without influencing
STEAM-ENGINE.

influencing the piston-rod, except in its perpendicular ascent and descent.

The groove must be made wide, so that the pin cannot touch the sides of it. The pin is always retained in the middle of the groove by the connecting rods, of which there is one on each side, extending from the crank-pin to the top of the rod, which is prolonged in the line of the piston-rod, and is part of the frame forming the opening through which the piston passes. It is evident, that in this way the opening cannot be a straight line, but must be formed to a portion of a circle, of which the centre is the joint that unites the connecting rods with the rod which prolongs the piston-rod, and in a line with it.

Another plan for applying the connecting rod immediately to the piston-rod, without the intervention of a working beam, is to have the axis of the crank placed immediately beneath the cylinder bottom, and a crank formed on it at each side: a cross-bar is placed upon the top of the piston-rod, long enough to reach over beyond the flanges of the cylinder; and from each end of it a connecting rod is suspended, the lower ends of which are joined to the two cranks before-mentioned. This arrangement is, perhaps, the best of its kind, because the connecting rods are of a considerable length, without taking up any room.

Mr. Maudslay, of London, had a patent in 1807 for an engine of this kind, of which he has constructed a great number. Plate VIII. fig. 3, is a sketch of one of these.

The specification states the invention to consist in reducing the number of the parts of the common steam-engine, and in arranging and connecting them, as to render it more compact and portable, every part being fixed to, and supported by, a strong frame of cast-iron, perfectly detached from the building in which it stands: it is not, therefore, liable to be put out of order by the finking of the foundations. A is the cylinder, placed upon a frame of cast-iron plates B, B, which, at the same time that it elevates the cylinder to a sufficient height, forms the support for the axis of the fly-wheel D D. This axis has two cranks formed in it. E is one of the connecting rods, which, as before-mentioned, works upon the cranks up and down of the cross-bar, which is fixed at the top of the piston-rod, and which is guided in its ascent and descent by friction-wheels R, fitted upon it, and running in grooves N, N, formed in iron frames, which are placed in a perpendicular situation above the cylinder, and supported by a light iron framing O. Beneath the great frame, B, are placed two circular cisterns F, G, communicating by a pipe, which are for the condensing water: one has the cold-water pump in it, and the other contains the air-pump and condenser. These two pumps are worked alternately from the end of a short beam, H I, (fig. 3), placed beneath the cylinder, and put in motion by a small crank, or eccentric circle, which is formed on the axis of the cranks, in the middle between the two cranks, and acts in a groove or opening made in a projecting arm, \(X\), of the beam, a small parallel motion being applied to that end of the beam which works the air-pump. Instead of valves for supplying steam to the cylinder, a single cock, with four passages in it at L, performs the office of all the four valves: the lever of the cock is worked by a rod of communication from a handle, which is moved up and down every stroke by the rod of the air-pump.

The condenser is a hollow cylinder, and the air-pump is placed within it, so that there is no necessity for a pipe of communication from the air-pump to the condenser: a small cistern, \(r\), is fixed over the pump, to form the hot-well, and the discharge-valves of the pump are made in its lid or cover, and therefore in the bottom of the cistern.

A very ingenious method of converting the reciprocating motion of the piston-rod at once to a rotatory motion is represented in Plate IX. fig. 5. Parallel Motions. A toothed wheel, \(C\), of a diameter equal to half the stroke of the engine, is made to roll round within a ring or fixed wheel \(A\), having interior cogs, and being of a diameter equal to the whole stroke, or twice as great as the internal rolling-wheel \(C\), which is carried round in a circular orbit, so as to work in the cogs of the ring, by having the crank-pin, \(K\), for its centre of motion. By this means, every half turn of the crank will produce half a revolution of the centre of the small wheel in its orbit; and as it is all the time engaged by the cogs of the ring, it makes, during this motion, a whole revolution upon its own centre. The consequence of this is, that a point taken in the circumference of the small wheel, will travel up and down, across the centre of the interior ring, in every revolution of the small wheel in its orbit; that is, it will describe a right line, which is a diameter of the ring. A pin, \(P\), being placed in a proper position of the circumference of the small wheel, and the top of the piston-rod being attached to it as it ascends and descends, will produce a rotation of the crank, upon the axis of which the fly-wheel is fixed.

This parallel motion is described in the article Parallel Motion. It has been employed by Mr. Murray in many of his engines: the objection to it is, that the cogs in time grow loose, and it then makes a very noisy and unsteady motion.

Bell-Crank Engine.—This is a very compact form of the steam-engine, which Messrs. Boulton and Watt began to make soon after the expiration of their patent.

The cylinder is supported by brackets from the cast-iron condensing cistern, and is placed over one end of it. The beam is formed like a bell-crank, that is, a right-angled triangle, the centre of motion being at the right angle, and the axis of it is supported by bearings screwed to the cistern at the lower side; and at the end opposite to that upon which the cylinder is placed, the horizontal arm of the triangle forms the working arm of the beam, to the extremity of which the power of the cylinder is applied. At the upper end of the perpendicular arm the end of the connecting rod is jointed, and extends to the crank, which is supported in bearings screwed to the cistern at the same end at which the cylinder is placed, the centre of motion being at the same level with the top of the cylinder beneath the cylinder, the hypothesis of the triangle of the beam forms a brace to strengthen it. Two of these beams are used, and are applied on opposite sides of the cistern, upon the same axis of motion, and are united together by cross rods, so that they move together in the same manner as if they were one. There are, therefore, two connecting rods and two cranks; but they are formed upon one common axis of motion, which is prolonged, to carry the fly-wheel. To connect the piston-rod with the ends of the arms of the beam, or what we have called the base of the right-angled triangle, a rod is fixed upon the top of the piston-rod, across the fame, at right angles; and to the two ends of these two rods are links, which defend to the beam, and are jointed to it at the ends. By this means, the ascent and descent of the piston-rod produce a corresponding motion of the beam upon its centre of motion, and the upper end of the perpendicular arm moves backwards and forwards, and by means of the connecting rods turns the crank. The perpendicular arms of the beam are shorter than the arms to which the cylinder-rod is attached, so that the motion of the connecting rods, and the sweep
STEAM-ENGINE.

Sweep of the cranks are less than in an engine where the arms of the beam are equal.

The rods which descend from the bar which is fixed across the top of the pinion-rods to the ends of the beams, are of such lengths, that the obliquity which is occasioned by the circular motion of the ends of the beams is small, and the engine does not require any parallel motion to keep the pinion-rods perpendicular. The fame of the air-pump, which is placed in the middle of the cistern, and is worked by two gears connected to the horizontal arms of the beams, at half the distance from the centre of motion at which the cylinder-rods are applied.

In these engines, valves are not used for admitting and taking away the steam from the cylinder; but to perform this office, a slider, invented by Mr. Murdoch, and represented in Plate VII., fig. 9, is used: the motion is communicated to the slider by an eccentric wheel or rim, fixed on the fly-wheel. The bell-crank engine is very compact, and is well adapted for temporary use, as it stands wholly upon the cistern, and requires no fixing. We have seen it used in a steam-boat.

Different Methods of admitting Steam alternately into the Top and Bottom of the Cylinder.—The arrangement of the four valves invented by Mr. Watt has been described. This is now almost universally laid aside, in favour of more simple contrivances, though we think there is not any method so complete in its action, or so durable. For large engines, four separate spindle-valves are still used; but the method of lifting them is changed, the spindles of one valve being formed like a tube, for the spindle of the other to pass through. This plan is described in the specification of Mr. Murray's patent of 1801, the same which was for the improved air-pump.

The arrangement of the pipes and passages is the same, and the valves are situated in the same places; but the boxes which contain them, instead of being square, are cylindrical, and the spindles of the valves are placed concentric with the axis of the cylindrical box. The spindles of the two steam-valves are perforated through the centre, in the manner of tubes, and rise through a flushing-box in the top of the box, and conveyers and the cylinders, and are lifted, instead of the lever or sector within the box, as described in the first engine. Through the tubular axis of the upper valves a small rod is conducted, which forms the spindles of the lower valves; and this junction is made tight by a flushing-box formed at the top of the tubes. The operation of the valves is in every respect the same as the former; the only difference is in the mode of communicating motion to them from the outside, and at the top of the steam-box, both pair of valves being moved by rods through an opening in the lid of the box. See Plate VII., figs. 4 and 5.

This method is neat in its appearance, and answers equally well with the other when properly made, but it is not easy to make it like the other; for if the lid of the steam-box, when fastened on, deviates in the smallest degree from the central position of the valve-spindle which passes through its flushing-box, both the valves will be prevented from applying themselves exactly to their seat. It is necessary for the two valve-feats, and the flushing-box through the lid, to be made precisely on a common centre, line, or axis; and for this purpose, the upper part of the cylindrical box which contains the valves is bored out correctly within, and the conical sockets in which the bell-metal feats for the valves are to be placed, are bored at the same time; then the lid of the box which has the flushing-box in it, being turned in the lathe, with a small projection beneath its flange to drop into the top of the cylindrical box, it will be certain to apply itself exactly in the centre of the box, and also perpendicular, when it is screwed fast down in its place, because the under surface of the lid, and the upper surface of the steam-box, have been accurately formed each of them concentric with, and perpendicular to, the axis of the valves; but it is necessary to use great caution in applying packing between these two surfaces, because it will yield unequally, if the screws at one side are screwed down more forcibly than those on the other side, and thus put the flushing-box out of the perpendicular.

To prevent this, Mr. Murray makes the lid of the box without any flange, but it is exactly fitted into a small reces or rebate, formed for it all round at the top of the steam-box, by enlarging the diameter thereof a small quantity, as shown in fig. 15. There is no packing applied to the joint, and it is then certain that the lid of the box will come to its true place. To prevent leakage, an iron ring is applied all round with a packing beneath it to cover the joint; and this packing and ring being screwed down by four screws makes the joint tight, and at the same time stops the lid from; but by relaxing the ring, the lid can be lifted out, and the valves with it, to repair them. Mr. Murray's patent was first by a writ of ceive facius, at the instance of Meffrs. Boulston and Watt, who had previously practised some things contained in the patent; but we believe Mr. Murray was the first who made valves in the manner represented in the figure.

In small engines, the machinery now employed for opening and shutting these four valves is different from Mr. Watt's original engine, and much more simple. The motion is given by a rotative motion from the main axis of the fly-wheel; a wheel is fixed on the axis of the fly-wheel, and communicates motion by other wheel-work to a horizontal axis (Plate VII., figs. 4 and 5), upon which are two eccentric wheels, which open and shut the valves alternately. Each of the boxes may be considered as being divided into three compartments by the two valves, and the steam is always admitted into the top of the upper box, where the upper steam-valve is situated; its use is to admit steam which comes from the boiler through the steam-pipe into the middle compartment of the box, which is the passage, 14, communicating with the top of the cylinder. In the same manner, the condensing-valve, which is moved by a rod passing through the rod or spindle of the upper steam-valve 12; the valve 8 is for opening a passage from the top of the cylinder to the condenser, through the exhausting-pipe 13. In the same manner, the upper valve, 1, of the lower box is called the lower steam-valve, and is for the purpose of admitting the steam which descends through the pipe, 12, into the bottom of the cylinder, below the piston. The valve 9 is for connecting the bottom of the cylinder with the condenser, and therefore called the lower condensing-valve.

The two rods, L, M, connect the four valves together in pairs; thus, the rod L has an arm projecting from it at each end, one at its top, fastened to the stem of the upper condensing-valve, and the lower steam-valve is connected with it at its bottom; it will consequently, when it is lifted up by the eccentric wheel, which is contained within an opening in the rod, open those two valves, and, by causing a vacuum above the piston, and a preasure of steam beneath it, will force it upwards to the top of the cylinder. The rod M is connected with the upper steam-valve at the top, and with the lower condensing-valve at the bottom. When it is lifted up by the eccentric wheel, which works in an opening in the rod, it admits steam above the piston, and causes a vacuum below, in which situation the piston will descend. One of the rods which connect the valves must be allowed to descend by its weight an instant before the other is lifted,
STEAM-ENGINE.

Lifted, otherwise the steam will have a free passage from the boiler to the condenser; a fault which is called blowing through, but is an operation practised every time at setting the engine to work, after having been some time at rest, for the purpose of expelling the air from the condenser. To blow through with this engine, all the four valves must be opened at once, which is done by lifting up the two rods, L, M, both together.

Fig. 16 represents an ingenious form in which Mr. Murray makes the eccentric movements for working the valves, so that they will work all at once, and not have the liberty of returning until the proper time.

The eccentric triangle, A B, has its sides formed by arcs of circles: the axis of motion is made to coincide exactly with one of the angles, A, and the arc, B, is described from that centre. The eccentric triangle is included within a parallel groove, C D, in an iron frame, in which it exactly fits, as in the figure. In this position, it is evident that the frame is immovable; it cannot ascend, because the circular part, B, bears against the lower side, D, of the groove; nor can it descend, because the angle, A, bears against the middle of the upper side, C; at the same time, the eccentric leading can move round a certain part of a revolution before the rod will be moved at all, and then it will rise at once; so that the middle of the lower side of the groove, D, will bear against the angle or centre of motion, A, and the upper side, C, will be borne by the arc, B, of the eccentric triangle.

Four-passaged Cock.—Of late years, instead of the four valves invented by Mr. Watt, cocks and flaps have been much used for alternately admitting the steam into the cylinder above and below the piston; they have the advantages of simplicity and cheapness, as one cock or flider is made to answer the purpose of the four valves.

What is called the four-passaged cock is the most readily applied to practice. This is represented in Plate VII. fig. 6, which is the cylinder of an engine made by Mr. John Dickson, who erected a great number exactly the same; the cylinder and its piston, with the lid and stuffing-box for the rod, are evident from inspection. The cylinder has a flange or projecting ring round it, a little below the middle, by which it is held in a jacket or case of cast-iron c c e, which is constantly supplied with steam from the boiler by the pipe e: the pipe e is cut off at the top, and the steam is received at the bottom of the jacket. The steam in the jacket is conveyed into the cylinder by the pipe P, and thence into the passage k, which advances horizontally forwards, as represented by the dark circle b, fig. 6, and turns into the cock; the short pipe has a thin circular vane in it, turning upon a pivot to form the throttle-valve, as we have before described.

When the steam is not made to pass through the jacket, the circular passage, b, may be considered as the continuation of the steam-pipe coming immediately from the boiler; and then the throttle-valve is placed in SOME part of the same pipe; p p is the pipe conveying the steam away from the cylinder to the condenser, which is of the ordinary construction. K is a handle fixed upon a spindle, on which is a rack, turning a cog-wheel upon the end of the cock E; this rack is partly seen in the drawing, but the pinion is concealed. There are two pins fixed upon the rod of the air-pump, which take the handle K, as they move up and down, and thus turn the cock a portion of a turn each time; there is also a lever fixed upon the spindle of the handle K, the ends of which stop against the ends of a crooked steel-spring screwed to the iron frame supporting the bearings for the spindle of the rack; so that the motion allowed thereby to the handle, K, and the rack, will turn the cock one-fourth of a whole turn; but no more. N is a cock communicating (when open) from the jacket c e c to the pipe p p, and thereby to the condenser, for the purpose of blowing through at first starting the engine. Now, suppose the steam flowing through the steam-pipe, s, from the boiler, it enters between the jacket, c e c, and the cylinder, p a s, through the short pipe and throttle-valve into the opening b, thence through the crooked passage in the cock E, to the pipe j j, leading to the top of the cylinder, thus causing the piston to descend. The steam in the lower part of the cylinder escapes, by the pipe g, through the other passage of the cock E, and by the pipe p p, into the condenser. When the piston descends, the pump rod carries down the handle, K, which, with its rack a r, in the pinion on the end of the cock E, turns it into the position seen at fig. 7. The operation is now reversed, the steam enters from the jacket at b, through the cock E, and by the pipe g, into the bottom of the cylinder, forcing the piston to the top; at the same time the steam contained above the piston escapes through the opening j j, and the cock E, by the pipe p p, into the condenser. When the pin on the air-pump rod reaches the handle, K, in its ascent, it returns the cock to the position at fig. 6, when the operation is repeated.

Nothing can be more simple, or appear more perfect, than this contrivance, which was originally used by Papin in his air-cylinders; and Leopold, in his Theatrum Machinarum Hydraulicae, vol. ii. has shewn the manner of its application to a high-pressire steam-engine.

In practice it has several objections. The pipe leading from the top and bottom of the cylinder to the cock is so much added to the volume of the cylinder, and the quantity of steam which they contain must be weighed every stroke without any advantage; but in the four valves, there is no further loss than of the small quantity of steam which is contained in the passages 14 and 15, Plate VII. fig. 1, which are purposely made as narrow as they can be to admit the steam freely. Secondly: The passages cannot conveniently be made large enough to admit a full supply of steam, though it should be understood, that, in the other direction, they are three or four times as wide as they appear in the section, fig. 6.

In these engines the steam is always wire-drawn in passing through the passages; hence the steam in the boiler must be made stronger than it is intended to be used in the cylinder, to which, however, there is no objection, as it gives it something of the expansive action. Thirdly: These cocks do not wear equally, because there is much less surface exposed to friction in the part where the passages are; and as the surface which is interposed between the passages is so small, they leak immoderately from one passage to the other, unless the fitting of the cock is perfect. For these reasons, the four-passaged cocks have been confined to small engines, and principally those which work with high-pressire steam, because that will pass through very small openings.

Mr. Bramah has made several steam-engines, in which he employed a four-passaged cock on a construction somewhat different from the above. The steam from the boiler is made to enter into a hollow at the large end of the cone,
of the cock, and to pass away to the condenser by a passage at the small end of the cone of the cock, which, by this means, is always prefixed into its seat by the force of the steam acting upon a surface equal to the small end of the cock, from which the pressure is relieved. This keeps the cock always tight; and to prevent the moveable part from being fixed fast by the pressure, the cone is made much more obtuse than usual. The passages for the steam between the cock, and the top and bottom of the cylinder, are nearly the same as in fig. 6. Mr. Bramah had a patent for this in 1802; and another improvement was, that he made the cock to turn continually the same way round one-fourth at a time; by which means the same effects are produced as by turning it backwards and forwards, but the wear is rendered more equal.

Mr. Maudslay has adopted in his engines a four-paffaged cock, in which the steam is made to pass the cone into its seat.

**Sliding-Valves by Mr. Murray.** With a view of remedying the inconveniences of the four-paffaged cock, the same effect has been attained by a plate sliding upon a flat surface, in which the passages are formed. A cylinder, with a slider upon this construction, is represented in Plate VII. fig. 8. It is used by Mr. Murray in small steam-engines, and found to answer the purpose extremely well, from the simplicity of its construction, and its durability, but, above all, from not being subject to wear or get out of order. A, B represent the cylinder, inclosed in a cast-iron jacket, and surrounded with steam; it is furnished with a piston, and a stuffing-box, for the rod to pass through in the usual manner; C is the passage for the steam to enter the top of the cylinder; and D is the passage into the bottom, to admit steam below the piston. The steam is conveyed by the boiler by the pipe B, passes through the throttle-valve C, and into the steam-box D, from which it is distributed to the cylinder by its different passages, as required. This steam-box is screwed by a flange against the flat surface of a pipe D, extending from the top of the cylinder to the bottom, and attached by dove-tailed joints to the two necks, A, B, of the cylinder. In the flat surface of the pipe D, there are three openings, ma, n, o: the upper one, m, communicates with the top of the cylinder; the middle one, n, communicates with the condenser by passing out sideways to the eduction-pipe, as at the dark circle at p; and the lower opening, o, communicates with the bottom of the cylinder by the passage b: r is the slider, made in the form of a box or cover, and ground round its edges, so as to fit exactly flat against the surface of the steam-pipe D, in which the three openings are made, and which is ground also. This pipe is moved up and down by the small sector s, acting in the teeth of a rack, fixed to the back of the slide. The spindle of the sector passes through a stuffing-box in the side of the steam-box, and is moved on the outside by an eccentric wheel on the axis of the fly-wheel. The motion of the slider, r, up and down, either connects the openings of the two passages m and n, or the two openings n and o. In the drawing, it is represented as connecting the upper passage m with n, which leads to the condenser, at the same time leaving the opening o uncovered; to receive the steam from the steam-box; and consequently the steam enters below the piston, through the neck a, causing it to rise, and escapes from the top of the cylinder through the neck a1, and by the connection of the opening m with n, it passes out at p into the condenser. Now if the slide is moved down, by turning the sector s, so that the lower passage o is connected with s, which leads to the condenser, the top opening m will be open to the steam-box, and the steam will enter at the top of the cylinder, and cause the piston to descend, while the steam in the bottom of the cylinder will rush through the opening b, and by the connection of the passage o with n, it will pass into the condenser. In this manner, by alternately moving the slide up and down, this action is repeated, and the engine kept going.

In the figure of Mr. Murray's small engine (Plate VIII. fig. 4.) the eccentric circle B is plainly seen upon the axis of the fly-wheel; it operates exactly the same as a short crank, and has an iron frame or collar embrace it. By this a motion backwards and forwards is communicated by the rod B S to an axis, upon which are levers, giving motion to the lever of the sector, which moves the sliding-valve. The whole of the engine is upon an excellent construction: the air-pump is worked by the rod R, at the outer end of the beam.

In 1799, Mr. William Murdoch of Redruth, in Cornwall, obtained a patent for several improvements in steam-engines, amongst which is a simple construction of the steam-valve, or contrivance by which the steam is distributed to the cylinder, or withdrawn from it at the proper period.

This contrivance is a sliding-valve, which performs all the offices of the four-valves which we have described for the double engine. Mr. Murdoch's patent has been adopted by Melliss. Watt and Boulton in most of their small engines, for many years past; and they have lately, with some alterations, introduced it into large engines. In Plate VII. fig. 9. A is the steam-cylinder of the engine; B, the piston, and C, the piston-rod; D is the upper opening of the steam-way into the cylinder; F is the steam-cake; in this is applied the sliding-valve, which performs the office of all the four steam-valves in the manner following. G G is a semicylindrical steam-pipe, (but which may be cylindrical, triangular, or of any convenient form,) communicating with the steam-cylinder both at its upper and lower openings, and firmly fixed or connected to the steam-cake, or with the cylinder itself, where no steam-cake is used.

This tube has an opening, H, on its side, with a regulating valve for the admission of steam from the boiler; and an opening, I, at bottom, which leads to the condenser. At the top it is covered with a plate T, having a hole and stuffing-box to admit the sliding-rod K, which is jointed to, or connected with, an inner moveable pipe or tube L M, open at both ends. To one side of the sliding-tube are affixed the solid plates or valves L, M, intended to slide upon the plates at D and E, and occasionally to cover and uncover the upper and lower openings D and E of the cylinder. Opposite to these plates the remaining circumference of the tube, L M, is furnished with projections or flanges of brass, or other metal, with an interface between them, to receive a packing of hemp, or other proper substance, which will permit the tube, L M, to move up and down, steam-tight, in the fixed tube G G. There are openings provided in the steam-pipe G G, which are shut with plugs or plates, screwed or otherwise fixed to it, which may be removed to repair the packing.

When the sliding-tube, L M, is in the position shown in the figure, the steam enters through the steam-pipe HI, and fills the interstices between the steam-tube G G, and the sliding-tube L M, passes into the cylinder at the upper opening D. As the lower opening, E, is open to the condenser, a vacuum will be formed within the sliding-tube L M, and also below the piston, through the passage E, which is uncovered by the rise of the sliding-rod. In consequence, the piston descends; and when it has got near the bottom of
of the cylinder, a bracket, attached to the top of the piston-rod C, strikes a projection upon the sliding-rod K, and causes the tube, L M, to defend a small quantity in the steam-pipe G. The sliding parts, L, M, by this motion, slide past the openings D and E of the cylinder, so as to be beneath them; and the steam, which is above the piston, issues at the upper opening, and pales down the inside of the tube L M, into the condenser. At the same time, the steam passing from past D E, through the pipe H, and the interface between the steam-pipe and the sliding-pipe, enters the cylinder by the lower opening E, and forces up the piston and piston-rod, with its bracket, which, near the end of the ascending stroke, encounters another projection of the sliding-rod K, and raises the tube, L M, into its former position of the figure. The operations are then repeated. This is the plan used in Melfra. Watt and Boulton's bell-crank engine, and it is very good, because no steam is lost, as in all other constructions, where only one cock or slider is used.

If the sliding-plates, where they apply together, are made of steel, and hardened, they then wear extremely well. In some of Melfra. Watt and Boulton's latest engines, they have used similar sliders for large engines; but, in this case, they make the two sliders separate, being moved only by a rod of communication; because, if they were applied to a strong moving pipe, there would not be so great a certainty of their complete action, as the least deviation of the two sliders at the top and bottom of the cylinder would cause a great leakage.

There are many other methods of distributing the steam alternately to the top and bottom of the cylinder; but as we have described those which are brought to such a degree of perfection as to be commonly used, it is unnecessary to pursue the subject any farther.

Regulation of the Velocity of an Engine.—This is a matter of considerable importance. The most common method, as we have noticed, is by the governor or revolving pendulum; but there are others which, in particular circumstances, are very applicable. One is to have a small pump worked by the engine, and raising up water into a cistern, from which it runs out again in a constant stream. By this means, the water will accumulate and rise in the cistern, if the engine works rapidly, so as to pump more water into the cistern than will flow out of it in the same time; and, on the other hand, the surface of the water will fall in the cistern, if the engine works slowly; and a float being placed in the cistern, and connected with a wire to the throttle-valve, will regulate the motion of the engine. See Regulator.

In 1805, Mr. Job Rider obtained a patent for improvements in the steam-engine. These improvements consist, first, in lining the steam-cylinder with a soft metal, of a sufficient thickness to admit of finishing the inside of the cylinder of such metal, by drawing, boring, or otherwise; secondly, in applying a hollow piston-rod, anwering the purpose of an eduction-pipe; thirdly, in the order of opening and shutting the valves; and fourthly, in regulating the speed of the engine by a pendulum. The nature of this latter contrivance is very ingenious, and may perhaps be understood from the following description. Upon an horizontal arbor, which we will denominate the main arbor, are placed three wheels, a drum or barrel, and a pinion; one of these wheels, that is to say, the main wheel, is fitted by means of a socket upon the main arbor, so as to turn round upon that arbor, and has teeth both upon the exterior and interior periphery of its rim. Within the circle of the interior egs of this wheel a pinion is fixed to the arbor, its diameter being one-third of the interior diameter of the main wheel; and this pinion has teeth surrounding its convex surface. The moveable barrel turns freely upon the main arbor; its diameter is rather less than the exterior diameter of the main wheel, and it carries a cord, with a weight hanging at its end, acting like a clock-weight. Besides this, the ends of the barrel are pierced with two orifices, each at about half the exterior radius of the main wheel from the arbor; these holes serving as bulges or pivot-holes, wherein an arbor turns, carrying a wheel, of which the diameter and number of teeth are equal to those of the pinion; the latter wheel may be called the barrel-pinion; its teeth work in the teeth of the pinion, and also in the interior teeth of the main wheel. By these means, the barrel may be turned round upon the main arbor, while the arbor itself is turned by the pinion, which is asked upon by the barrel-pinion, at the same time that this pinion acts upon the interior teeth of the main wheel. The external teeth of the main wheel turn the pinion of a crescent-wheel and pallets, nearly similar to those in Graham's dead-beat. Near one end of the main arbor there is a ratchet-wheel, and wheel and click; and near the other end a wheel, which is asked upon by an endless screw upon a horizontal shaft, worked by the general operation of the steam-engine.

This arrangement serves to regulate the rate of the engine's motion; for the turning of the worm-wheel, by the general motion of the engine, causes the weight to be raised which hangs to the cord that winds upon the barrel; and this weight is connected to one end of a lever, the other end of which is attached to the cistern in such a manner, that the degree of opening of that valve depends upon the altitude to which the weight is raised. The aperture of this valve is formed like an inverted cone; and while this valve shuts and opens twice at every stroke, the lever does not prevent such opening and shutting, but merely limits the extent of the opening by the springing up of a rod connected with it. By this contrivance it happens, that when the weight is highest, the valve is least open; and when the weight is lowest, the valve is most open. Hence it is evident, that should the engine wind up the weight, by turning the worm faster than the pendulum permits it to defend by the turning of the barrel, the aperture of the valve will be contracted; and vice versa. Little power is lost by these means, and the speed of the engine can be accurately regulated by properly adjusting the length of the pendulum, and the numbers of teeth in the wheels and pinions. As to the ratchet-wheel and click, their sole use is to prevent the weight from drawing the line off the barrel, when the worm-wheel is thrown out of gear. We have not had an opportunity of seeing one of these machines at work, but think it would operate very well.

Mr. Cartwright's Engine.—In giving the history of Mr. Watt's inventions, we mentioned that the condensation by external cold was one of his first ideas, and given up, because he found it better to employ injection. We have also described his single engine, in which the piston rises to vacuo. In 1797, Mr. Cartwright took out a patent for improvements in the construction of steam-engines, in which the condensation is performed by the application of cold to the external surface of the vessel containing the steam.

The manner Mr. Cartwright effects this is by admitting the steam between two metal cylinders, lying one within the other, and having cold water flowing through the inner one, and surrounding the outer one. By these means, a very thin body of steam is exposed to the greatest possible surface of cold metal. By means of a valve in the piston, there is a constant communication at all times between the condenser and the cylinder, either above or below the pisto...
STEAM-ENGINE.

ton; so that whether it ascends or descends, the condensation is always taking place, in the same manner as Mr. Watt's engines, where the piston rides in vacuo. But what was probably esteemed one of the most important circumstances attending the mode of condensation, was the opportunity it afforded of subduing ardent spirit, either wholly or in part, in the place of water, for working the engine. For as the fluid, with which it is worked, is made to circulate through the engine without mixture or diminution, the using alcohol, after the first supply, would be attended with no very great expense; on the contrary, the advantage was expected to be great, even equal to the saving of half the fuel. If, indeed, the engine could be applied, as Mr. Cartwright occasionally purposed, both as a mechanical power and as a still at the same time, the whole fuel would be saved.

Mr. Cartwright has been very attentive in simplifying all the other parts of the engine, his engine having only two valves, and those as nearly self-acting as may be; in consequence, the engine is rendered applicable to purposes requiring only a small power, and for which any other engine would be too complicated and expensive. See a figure of Mr. Cartwright's engine, Plate V., fig. 8, where $a$ is the cylinder, which is supplied with steam from the boiler through the pipe $b$; $c$ is the piston in the act of going up; $d$ is the attention-the pipe constructed within the condenser $e$, which consists of two cylinders, one within the other, leaving a small space between them, into which the steam is admitted; while the inner cylinder is filled with cold water, and also the external cylinder surrounded by the same; so that, by this means, a very large surface of steam is exposed to the cold of the water, though no water is suffered to come in actual contact with it.

To the bottom of the piston $c$ is attached a rod, with another piston $f$, working in the barrel $d$, which is in reality the air-pump of the engine, and has a pipe, $f$, to the condenser. When the piston $c$ arrives at the bottom of the cylinder, a valve, $r$, which is in the piston is opened, by its tail prefling against the bottom of the cylinder, which opens the communication from above the piston to the condenser, while the spring $k$, fixed to the rod of the piston, preffes down the tail, and shuts the steam-valve $s$, which admits the steam from the boiler. The steam therefore within the cylinder, both above and below the piston, being condensed, runs through the lower pipe, $f$, to the air-pump, and the piston, being relieved from all preflure, is drawn up in the cylinder by the fly-wheel. The piston of the air-pump arriving at the top of the barrel, in which it works at the same time with the working piston $c$, draws the air from the condenser, and on its return at the next stroke, prefles upon the condensed water, shuts the valve $f$, and forces the water up the pipe $g$, into the box $h$; the air which is difengaged from the water rides to the top of the box, and by its elastic forces forces the water through the pipe $i$, which carries it back again to the boiler. When the air accumulates in the box to such a degree as to depress the water, the ball-cock falls with it, and empties the valve of the top of the box, which fufers some of the air to escape.

When the piston arrives at the top of the cylinder, it prefles up the steam-valve $s$, which admits the steam again from the boiler, to force it down as before; and the valve, $r$, in the piston shuts by prefling up beneath the top of the cylinder. The preffure of the steam is now above the piston, and a vacuum beneath; the piston therefore descends, and when at the bottom, shuts the steam-valve $s$, and opens the valve, $r$, in the piston.

When all the steam in the upper part of the cylinder is condensed, the motion of the fly attached to the machine brings the piston up again, its valves now remaining shut by their weight.

If and $m$ are two cranks, upon whose axes are two equal cog-wheels working in each other, for the purpose of converting the perpendicular motion of the pinion-rods into a rotary motion for working the machinery attached to it.

As it is evident, from its construction, that the whole of the steam is brought back again into the boiler, it affords the means of employing ardent spirit instead of water, and thus having a great deal of fuel.

Cartwright's Metallic Piston.—The most valuable part of this engine is in the construction of the piston, which Mr. C. made wholly of metal, so as by means of springs to fit the cylinder very exactly.

This not only saves the expense and trouble of packing, which must be frequently renewed in all other engines, but also a great deal of steam, on account of the more accurate fitting of the piston. This piston is made in the following manner: Two metal rings are ground, by means well known to good mechanics, into the cylinder, so as to fit it as perfectly as art and industry can make them; that is so well, that no steam can pass between them and the cylinder; their upper and under sides are also ground perfectly flat, and applied one upon the other. Though the absolutely necessary, for greater security two other rings are fitted to the inside of these. On the upper rings is placed a plate of metal, also ground perfectly flat, and of such a diameter as almost to fit the cylinder. A similar flat plate is placed below the under ring; and the two plates, with the rings between, are attached firmly to each other by means of the pinion-rods that pass through them, and they thus form a shell, in which the other rings are contained.

It is plain then, supposing neither the outside rings nor the cylinder are able to wear one another, that such a piston would remain steam-tight; but as constant friction must inevitably tend to enlarge the cylinder, and diminish the diameter of the rings, the piston, after some time, would cease to fit, if a contrivance had not been made to remedy the evil. The rings are each of them cut into three pieces, and in cutting them, such a portion of the metal is taken away as to leave room to introduce, between two of the pieces, a spring in form of the letter V, the open end of which is placed outwards, almost close to the circumference; by which means the two pieces against which the two fides of the spring act are prefled, in the direction of the circumference, against the ends of the third piece; so that the three pieces are kept so uniformly in contact with the cylinder, that the longer the machine is worked the better the rings muft fit.

To prevent steam passing through the cuts in the rings, the solid parts of the upper rings are made to fall upon the divisions and springs of the under ones, so as to form a break joint.

The stuffing-box round the pinion-rod was proposed to be done in the same manner.

The metallic piston has been found advantageous, and Mr. Wolfe uses it in his engine, which is the greatest trial of a piston, because of the rarity of the steam. Plate VII., figs. 10 and 11, represent a piston of a four-horse engine, which was made by Meffrs. Lloyd and Ofcel. A is the pinion-rod, and BCC the solid metal of the piston, firmly fitted and keyed to it; the lower edge, C, of the plate, B, is made very nearly to fit to the cylinder; but for the actual fitting, dependence is placed on the four rings, D, fitted one upon another, and each divided into four segments, as shown by fig. 10. The interior surface of these rings is made rather conical, and a second set of smaller rings, $E$, is accurately fitted.
fitted withinside of them. These rings are divided, like the former, each into four segments, and the springs are applied behind them, as shown in fig. 10, in a better manner than the original, which were like the letter V. E E is the cover-plate, which is screwed over all the segments, to confine them; it prevents down the interior rings into the exterior, and the contact between them being by a conical surface, the effect is to spread the outer rings small quantity, and enlarge them till they exactly fill the cylinder. The dark mark beneath the lowermost interior ring E, is a piece of felt or pasteboard, which sustains the rings, and prevents them from descending, except when the screws are tightened, or the rings would expand with too much force into the cylinder.

**Woolf's Improvised Piston.**—The common method of packing the piston of a steam-engine with hemp, will be so well understood after what we have said, that a particular description of it in this place is not necessary; suffice it to say, that the hollow part round the piston is filled with rounds of hemp, loosely twined into a soft rope, which is pressed into a pretty compact form by a ring, and worked down by screws distributed round the ring, which work into the body of the piston; by this means the packing is made to fill the diameter of the cylinder pretty closely, and to prevent, while the packing remains found, any steam from palling between the piston and the cylinder. In the usual method, whenever the piston, by continued working, becomes too easy, and so occasions a waste of steam, it is necessary to remove the top of the cylinder, even when rent hemp or packing is not wanted, merely to get at the screws, which serve to force the upper ring nearer to the bottom of the piston, by which means the packing is forced outwards against the side of the cylinder.

This being heavy laborious work, it is generally deferred, by the man that attends the engine, as long as the engine can possibly be made to work without taking this trouble; and in consequence of this neglect, a great and unnecessary waste of steam is occasioned, and a waste of fuel in proportion.

Mr. Woolf's improvement on the piston is such as to enable the engine-man to tighten the piston, without the necessity of taking off the cover of the cylinder, except when new packing becomes necessary. He accomplishes this by either of the two following methods. He fastens on the head of each of the screws a small cog-wheel, c, c, c, (Plate VII. figs. 12 and 13.) which wheels are all connected with each other by means of a central wheel d d, which works loose upon the piston-rod in such a manner, that if any one of the small wheels and its screw be turned, it turns the central wheel, and the latter turns all the other three wheels and screws. That one which is to be first turned is furnished with a projecting square head e, which rises up into a recess in the cover of the cylinder. This recess is surmounted by a cap or bonnet, which being easily taken off, and as easily put again in its place, there is little difficulty in screwing down the packing at any time, by applying a key to the square head of this screw. The parts are so clearly expressed in the plates, that no further description is necessary to make any person comprehend it.

Mr. Woolf contrived another method for small pistons, which is familiar in principle, but a little different in construction. Instead of having several screws, all worked down by one motion, there is in this but one screw, and that one is cut upon the piston-rod itself; on this is placed a wheel of a convenient diameter, the centre of which is furnished with a female-screw. This wheel is turned round, i.e., screwed down by means of a pinion, which is furnished with a square projecting head, rising into a recess of the kind already described. The upper ring of the piston is prevented from turning with the wheel by means of two fixed pins.

**High-Pressure Steam-Engine.**—The operation of the high-pressure steam-engine is effected solely by the expansive force of steam, which is not condensed in the manner of the atmospheric or Watt's engine. The steam being raised in the boiler, and heated far beyond the boiling point, is made to acquire a great expansive force before it is allowed to escape from any vessel in which it is confined, even as great as four or five times the pressure of the atmosphere. This steam being allowed to enter into one end of a cylinder, while the other end of the same communicates with the open air, it will exert a force upon the piston of the cylinder, and move it from one end to the other. This is the principle of the high-pressure engine, which has been much introduced of late, on account of some advantages which it possesses in particular situations over other engines: first, from the simplicity of its construction and cheapness; secondly, the small space which it occupies; thirdly, it requires no condensing water, which in some situations is very difficult to procure, and in one instance is altogether impracticable, viz., for drawing of carriages, for which purpose this engine has been successfully used. To get against these advantages, the high-pressure engines are extremely liable to blow up, if not attended very carefully, for they are frequently worked with a pre-pressure of from thirty to eighty pounds on the square inch. These engines require a greater quantity of coal, in proportion to the force exerted, than the engines of Mr. Watt, and consequently are not worked with advantage in a situation where coals are dear.

The first application of high-pressure steam to an engine, is what we find described in 1724, by Leupold, in his Theatrum Machinarum Hydraulicorum, vol. ii. p. 93. He describes the invention to Papin, on account of his having given him the idea of applying the expansive force of steam for the purpose of raising water, and also because he took the construction of the four-paffaged cock, to communicate alternately with two cylinders, from Papin's air-machine, which had been described in the former part of this article. The engine described by Leupold consists of two single cylinders, placed at some distance from each other, with a piston fitted to each, and applied to two separate beams, which at the opposite ends work two forcing-pumps. Between the two cylinders is the four-paffaged cock, the same as described in Plate VII. Steam-Engine, fig. 6, for admitting the steam from the boiler alternately into the bottom of each cylinder, or allowing it to escape from the cylinders into the air. The boiler is situated beneath the two cylinders, and communicates with the cock by a short upright pipe. The action of this engine is very simple: the steam being raised very strongly in the boiler, is allowed to enter through the cock into the bottom of one of the cylinders, at the same time that the air or steam escapes from the bottom of the other, through the other passage of the cock into the open air. In this way, the pre-pressure of the steam causes the aforesaid of the first-mentioned piston, and the other descends by its counter-weight. By turning the cock round one-fourth, the operation is reversed, so that the steam enters the bottom of the second cylinder, and the steam which was contained in the first escapes through the passage of the cock into the air.

The next proposal for a high-pressure engine is Mr. Watt's patent of 1769. See the fourth particular of his specification, which we have given, but we do not know that he ever practised it, finding his own invention so much superior.

The high-pressure engines at present in use were introduced by Mr. Trevethick, in conjunction with Mr. Vivian, who obtained a patent for the same in 1803: this was particularly
STEAM-ENGINE.

...ally for their application of the engine to the purpose of driving of carriages upon rail-roads.

This engine containing no material parts which are not used in other engines, and before described, it may be explained without a drawing. The boiler consists of a large cylinder of cast iron, made very strong, and placed upon its horizontal axis upon short feet or pillars, so that the boiler has a flange at one of its ends, to screw on the end or cover, which has the requisite openings for the fire-door, the man-hole, the exit for the smoke, and the gauge-cocks. The fire is contained within the boiler, in a cylindrical tube of wrought iron, which is surrounded with water on all sides, in the same manner as the fire in Mr. Smeaton's portable engines, of which we have given the description; but there is a little difference in the application: one end of this tube is flanged to the end or cover of the boiler, and is divided into two parts, by having the fire-grate extended across it: the fire-door closes the opening in the upper half, which is the fire-place, the lower half forming the ash-pit: the tube extends nearly to the end of the boiler, where it is reduced in size, then doubles, and returns back in a direction parallel to the first tube or fire-place to form the flue or chimney, till it arrives at the end or cover of the boiler, through which it pusses at the side of the fire-door, and a flue is then conducted from it into the chimney, to carry off the smoke.

At the part where the flue enters the chimney is a small door, to pass through any fuel that may have accumulated there. On the top of the boiler is a safety-valve, kept down by a lever and weight, to allow the steam to escape if it becomes so strong as to endanger the burning of the boiler. The steam-cylinder stands in a perpendicular direction, and is inclosed within the boiler, except a few inches of its upper end, at which the four-passaged cock is situated, and the flange which screws on the lid, with the stuffing box for the piston-rod to pass through. The boiler has a projecting neck, into which the cylinder is received, and it is fastened in its place by a flange round the upper end of the neck of the boiler, which is united by screws to a flange projecting from the cylinder at about one-third from its top flange. The upper end of the piston-rod is fastened to the middle of a cross-bar, which is placed in a direction at right angles to the length of the boiler, and guided in its ascending and descending vertical motion, by sliding upon two perpendicular iron rods, fixed to the boiler, parallel to each other, being connected together at top, and firmly supported there by two diagonal slats, extending from the other end of the boiler, and secured to the flange, which screws on the end of the boiler. At the ends of the cross-bar of the piston-rod the two connecting rods are jointed, and the lower ends of them are connected with two cranks, fixed upon an axis, extending across beneath the boiler, and under the centre of the cylinder: the axis is supported in bearings made in the legs which support the boiler, and the fly-wheel is fixed in it. One of the cranks is formed by a pin which is fixed into the arm of the fly-wheel, at the same radius as the opposite crank. The fly-wheel is situated close to the side of the boiler, and the pin for the other crank is fixed into the arm of a large cog-wheel, fixed on the axis of the fly-wheel, at the opposite side of the boiler. This cog-wheel communicates the power of the engine to other cog-wheels. As the piston is alternately forced up and down by the pressure of the steam, it carries the cross-bar with it, and by the connecting rod turns the two cranks, together with the fly-wheel and cog-wheel.

It now remains to shew the means by which the steam is brought to act alternately on different sides of the piston. On one side of the cylinder, just above the flange which fixes it into the boiler, and beneath the top flange, which fastens down its lid, is a protuberance of cast iron, to contain the four passages and the cock, similar to that shewn in fig. 6 and 7. One passage rises directly from the boiler, and brings steam to the cock at one side, to be distributed either to the top or bottom of the cylinder, according to the position in which the cock stands. A second passage is at both ends of the upper side of the cock, and proceeds to the top of the cylinder, for admitting steam above the piston. The third passage from the under side of the cock connects with the bottom of the cylinder by a pipe cast close to the side thereof, and descending to the bottom. The fourth passage from the cock is on the opposite side to where the steam enters from the boiler, and this passage is open to the waite-pipe, which carries the steam into the external air, and allows it to escape after it has passed through the engine. Now suppose the passage leading to the top of the cylinder, and that one which brings steam, from the bottom of the cock to be connected with the cock, and the passage from the bottom of the cylinder to be connected with the waite-pipe, the steam will enter above the piston, and force it down, at the same time that the steam in the bottom of the cylinder will escape by the connection of the waite-pipe with the open air.

When the piston arrives at the bottom of the stroke, the cock is turned one quarter round, by means of a rod jointed to the cross-bar of the piston-rod, and descending perpendicularly, being guided by pieces of iron screwed to the flange of the cylinder: this rod has two pins projecting from it, which move the handle of the cock up and down alternately; by this the cock is turned on the completion of the descending stroke, so that the passage to the bottom of the cylinder is connected with the boiler, and that from the top with the open air: the steam in consequence enters below the piston, and forces it up, passing out from the upper part of the cylinder into the open air at the same time. In this manner the motion of the engine is kept up by the pins alternately turning the cock, first at the top of the stroke, and then at the bottom.

The boiler is supplied with water, as fast as it evaporates, by means of a small force-pump worked by the engine; but as it would be a great loss of heat to inject cold water at once into the boiler, it is first rendered nearly or quite boiling by a very simple contrivance. The waite-pipe, which conveys the steam away from the cylinder after having performed its office, is inclosed within an external pipe or jacket, leaving a space of about an inch all round; through this space the cold water is forced to enter at one end by the small force-pump, and the boiler is supplied with water by a branch from its other extremity. By thus carrying the water some distance in contact with the hot waite-pipe, through which the steam pusses, it is heated, and a considerable quantity of heat is saved, which would otherwise be lost.

The velocity of the engine is regulated, or its motion can be entirely flopt, if required, by a cock situated in the first passage from the boiler to the four-passaged cock, so as to regulate the passage between the boiler and the cock. The handle of this cock may be connected with a governor, similar to those used in other engines. The construction of the four passages and the cock is exactly similar to what is represented in fig. 6, Plate VII., except that it is placed near the top of the cylinder, because all the lower part of the cylinder is contained in the boiler, and also that the axis of the cock is directed to the centre of the cylinder. High-pressure engines have been sometimes made with beams and parallel levers; but more frequently the cylinders have been placed horizontally, and the piston-rod jointed at once to the connecting rod.

Several very terrible accidents have occurred from the burstling
STEAM-ENGINE.

burthing of high-pressure boilers, either from their being made too weak to resist the force they are intended to bear, or from some mismanagement, as loading the safety-valve too much. Some years ago, an engine that was employed to drain water from the tide-mills, while building between Woolwich and Greenwich, was blown up by overloading the safety-valve, when several people were killed. Many provisions have been made to guard against these accidents by Mr. Trevithick, who first brought the high-pressure engines into use; at first he proposed inclining the safety-valve in such a manner, that no one could get access to it to increase the load beyond what was intended to be employed. Secondly, he drilled a hole in the boiler, which he plugged up with lead, at such a height from the bottom, that the boiler could never boil dry without exposing the lead to be melted, and consequently making an opening for the steam to escape. This contrivance is calculated to prevent the boiler being burst by suddenly forcing water into it, when it has been allowed by carelessness to boil dry, and become red-hot. A metal plug should always be riveted into such a boiler, as a plug should be made of brass, as the fusing metal, that it will melt whenever the contents of the boiler attain that degree of heat which produces steam of a dangerous elasticity. Another precaution which should always be taken, is to have two safety-valves fixed in different parts of the boiler; so that if by any accident one of them becomes fixed fast in its seat by rust or other means, the other will be in a state to act, thereby diminishing the chance of an accident to half; and the larger the safety-valves are made, the more certainly they will operate. The mercury steam-gauge used in most engines is a long curved tube, or inverted siphon, in which the mercury rises by the force of the steam, and indicates the pressure. If this kind of steam-gauge is applied to the high-pressure engine, it requires a very long tube, which is an additional security against the burthing of the boiler, because the mercury will be blown out of the tube, and permit the steam to escape when the pressure is too great.

Before the boiler of a high-pressure engine is set to work, it should be proved effectually, by drilling small holes through it at different places, so as to try the strength of the metal, and ascertain that it is equal throughout; and then it should be proved by injecting water into it, until the pressure lifts the safety-valve, when loaded considerably more than it is intended to be when the engine is set to work; but this proof should not be too severe, because the metal may be weakened, although it is not burst, by the proof; and, in consequence, may afterwards burst with a much less pressure of steam. At the same time, the engineer who undertakes to make these engines, should fully inform himself of the real strength of metal boilers of determinate thicknesses, which could be easily done, without danger, by injecting water into the boilers until they actually burst. We do not know if such experiments have ever been made; and in those boilers which have been burst by the explosion of steam, the pressure at the moment of the accident has not been known.

We have an account of a trial of a small high-pressure engine made in 1804, in Wales, to ascertain its powers to raise water: the cylinder was 8 inches in diameter, and 4 feet stroke; it worked a pump 183 inches in diameter, and 44 feet stroke, which raised 28 feet high. It worked at the rate of 18 strokes per minute, and consumed about 80 lbs. of coal per hour: this, when reduced, is about 17½ million pounds raised one foot high for each barrel. Thus, the weight of the column is 3266 lbs. for the area of the pump (18.3 x 18.5 = 332.25 x .7854 =) 268.8 square inches x .434 lbs. = 116½ lbs. the weight for every foot of the column x 28 feet = 3266.5 lbs. the total weight of the column. The motion of the piton per minute is (4 x 18 =) 81 feet, or 4860 feet per hour x 3266.5 lbs. = 15,875,160 lbs. raised one foot high per hour. The coal consumed in the hour is 80 lbs.; therefore, as 80 lbs.: 15,875,160 lbs. :: 88 lbs.: 17,462,676 lbs., the number of pounds raised one foot high for each barrel of coal. The area of the piston is (8 x 8 = 64 x .7854 =) 50½ square inches, and the load 3266.5 ÷ 50½ = 65 lbs. preûre per square inch on the surface of the piston.

Manufacture of Steam-Engines.—The great demand for these machines, which has taken place since their value has been so fully understood, has occasioned them to be manufactured in the large way by several engineers, who adopt the same system as is pursued in making of watches and clocks, viz., that of having workmen instructed in making the separate parts, and employing machines and tools for every operation which admits of such aid. The first of these manufactories is that of Melfris. Watt and Boulton, at Soho, near Birmingham, for the manufacture of the inventions and his associate, who established the factory about 1775; and until the expiration of Mr. Watt's patent in 1800, it was the only place where his engines were made. It has continued ever since to furnish the greatest proportion of engines, as well for this country as abroad. There are now other manufacturers who approach the original in the beauty and perfection of the workmanship.

Since the expiration of the patent, there has been a total change in the manner of constructing and putting together every part of the engine, and many advantageous improvements have been made, as far as respects the durability and accurate performance of the machine; though nothing, except the second cylinder of Hornblower and Wooll, has been added to Mr. Watt's engine since he first brought it to a standard, by which its powers are at all increased, with respect to the consumption of fuel, but rather the contrary. At the first establishment of these manufactories, on the expiration of Mr. Watt's patent, many ingenious mechanics attempted to improve the structure of the machine, and the records of the patent office contain more upon this subject than any other. All kinds of parallel motions have been tried; cylinders have been inverted, placed horizontally, made of long and short proportions; large air-pumps have been used; and for the minor parts, such as valves, and the machinery for actuating them, scarcely two following engines were made alike for many years, until by the result of a vast deal of invention and experience, those methods which we have described became settled into established forms; but none of them are superior to the original of Mr. Watt's. Respecting parallel motions, and the proportions of the parts, no methods have been found so good as the original engine; and we accordingly find, that all the most established and experienced manufacturers make engines which are not altered in any great feature from Mr. Watt's original engine, with a beam and parallel motion acting on a simple crank; and they give them all the advantages which can be derived from superior workmanship, and improved methods of putting the parts together, which experience has pointed out.

Melfris. Fenton, Murray, and Wood, of Leeds, Yorkshire, are the manufacturers of the most established reputation after Melfris. Watt and Boulton. The engines they found cannot be excelled in beauty and perfection of workmanship, and they perform as well as any others. Their factory at Leeds is very extensive, and provided with every convenience for making all the parts of the engine in the best manner, and with the least labour. They have three
STEAM-ENGINE.

Steam-engines in the works, one for boring cylinders, and turning large lathes; a second for turning small lathes, grinding, drilling, the centres of wheels, tapping screws, &c., and blowing the furnaces of the foundry; and a third engine for working a great forge hammer, by which the heavy wrought iron work is forged. The boring machines for cylinders, of which they have three in number, are very capital, as by an ingenious movement, invented by Mr. Murray, for drawing the borer through the cylinder, it is made to advance regularly from one end to the other, without any interruption. These machines are worked by a separate steam-engine, which is never stopped during the operation of boring a cylinder, since it is found to make a tenfold mark on the ring if the motion is stopped. The best means are also taken to prevent the cylinder from changing its figure by its weight, or by the preasure of the parts which hold it in its position. The whole of the factory is lighted by gas lights in winter time. The boilers are manufactured by the aid of several machines to cut out the plate, pierce the holes, and bend the joints. Before any of the smaller engines are sent away, all the parts are put together in a building on purpose, where there are boilers fixed and they are actually tried, to ascertain that every part is perfect; they are then taken to pieces, with a view to instructions for putting them together, and packed up for carriage, which is very easy, as there is a canal at the gates, which has communication by water to every part of England. For such engines as are too large to be put to work at the factory, workmen are sent out with them, to assist and direct in setting them to work.

In London, Mr. Maundley has made many very excellent steam-engines upon the plan represented in our sketch; but his best engine, which is in the saw-mill at Woolwich, is with a beam upon Mr. Watt's plan. He has lately made a large engine, in which he has added an iron frame, in the cold shed, in the iron shed, in the iron shed, and for pieces, with a view to instructions for putting them together, and packed up for carriage, which is very easy, as there is a canal at the gates, which has communication by water to every part of England. For such engines as are too large to be put to work at the factory, workmen are sent out with them, to assist and direct in setting them to work.

Some engineers of Manchester make very good steam-engines, chiefly for the great cotton-mills. At most of the ironworks in the country, and in some of them very capital engines, as at Butteley in Derbyshire, Low Moor in Yorkshire, and others. Their workshops are in general managed by engineers who have been educated at Soho, or at Leeds. Mr. Woolf's engines are made in London by Mr. Edwards, and by himself in Cornwall.

Rotative Steam-Engine. — The reciprocating motion of a steam-engine has always been considered as a great defect; for though all irregularity of motion can be obviated by connecting it with a fly-wheel, yet a great mass of matter must always be kept in a constant succession of changes from rest to motion; and the irregularities which this would produce, can only be governed by putting a great mass of matter in the fly-wheel, and causing it to move with a rapid motion, so that its momentum or vis inertial shall be vastly greater than that of all the reciprocating parts together. With a view of obviating this objection, and of obtaining the action of steam by more simple machinery than a cylinder and piston, many attempts have been made to produce a circular motion at once by the steam, which has been made to blow on the vanes of a wheel of various forms. But the rarity of steam is such, that even if none is condensed by the cold of the vanes, the impulse is exceedingly forcible, and the

experience of steam, so as to produce any serviceable impulse, is enormous. Mr. Watt, among his first speculations on steam-engines, made some attempts of this kind; but he has not given such a description of the valves for this purpose, as to enable an engineer to construct one of them. From any guesses that we can form, we think the machine very imperfect. One of Mr. Watt's first trials was uncommonly ingenious; it consisted of a drum, turning airtight within another, with cavities so disposed, that there was a constant and great preasure urging it in one direction. But no packing of the common kind could preserve it airtight with sufficient freedom of motion. He succeeded by immersing it in the recovery or in an arm, which remained fluid in the heat of boiling water; but the continual action of the heat and steam, together with the friction, soon oxidated the fluid, and rendered it useless. He then tried Parent's or Dr. Barker's mill, inclining the arms in a metal drum, which was immered in cold water. The steam rushed rapidly along the pipe which was the axis, and it was hoped that a great reaction would have been exerted at the ends of the arms; but it was almost nothing. The reason seems to be, that the greatest part of the steam was condensed in a drum kept boiling hot; but the impulse was very small, in comparison with the expense of steam: this must be the case.

Mr. Watt has described in his specification of 1782, lodged at the patent office, some more perfect contrivances for producing a circular motion by the immediate action of the steam. One of these produces alternate motion upon a centre, and is analogous to the double engine; another produces a continued motion. See his first specification of 1769.

We do not find that Mr. Watt has ever erected a continuous circular engine: he has doubtless found all his attempts inferior to the reciprocating engine with a fly. A very crude scheme of this kind may be seen in the Transactions of the Royal Society of Dublin, 1787.

Mr. Cartwright, in a patent of 1797, proposes some improvement of Mr. Watt's rotative engine, but it was never brought into use. Mr. Jonathan Hornblower had a patent in 1783 for a rotative engine, which is the most ingenious of all the speculations on this subject, but too complicated to be carried into execution; and in 1805 he had another patent, for a machine which is quite different from the former, and is ingenious, but still less likely than the first to answer the intended purpose.

Mr. Samuel Clegg has made a rotative engine, the pivot of which makes a complete revolution in a channel at a distance from the centre of motion. We have seen this engine at work, which acted in a very regular manner, but we think the friction must be greater than that of a common engine, although it gets rid of the reciprocation. Mr. Clegg had a patent in 1809 for his invention.

Mr. Turner has lately obtained a patent for a rotatory steam-engine, the principle of which the same as Mr. Clegg's, but each of them has its peculiar advantages in the manner of fitting up, and in the arrangements of its parts. Mr. Turner's is packed in all the moving parts with metallic packings instead of hemp, and we have been informed that his engines operate very well, and without any fly-wheel. Mr. Clegg's engine only requires a small fly at one part of its movement. We think, that if ever rotative engines are brought to perfection, it will be by something of the nature of these two engines, which are the most practicable, and produce greater probability of success than any before invented.

For the application to steam-boats, and to the purpose of drawing carriages, or locomotive engines, as they are now called, rotative engines would be so advantageous, that they would
would be very useful, even though they should consume rather more fuel than reciprocating engines of the same power, provided they were certain in their action.

Cement for making Joints in Steam-Engines.—In joining the flanges of iron cylinders, and other parts of hydraulic and steam-engines, a strong and durable cement is required. The following are receipts for cements proper for such purposes.

Mix boiled linseed oil, litharge, red and white lead, together to a proper consistence: this cement is to be applied on each side of a piece of flange, previously shaped to fit the joint, and then interposed between the flanges, before they are brought home to their place by the screws or other fastenings employed, which will make a close and durable joint. The quantities of the ingredients may be varied without inconvenience, only taking care not to make the mass too thin with the oil. It is difficult, in some cases, to make a good fitting of large pieces of iron work at once, and this renders it necessary sometimes to join and separate the pieces repeatedly, before a proper adjustment is obtained. When this is expected, the white lead ought to predominate in the mixture, as it dries much slower than the red. A workman knowing this fact, can exercise his own discretion in regulating the quantities; but it is safe to have too much rather than too little white lead in the mixture of the cement is not so strong as necessary, only a longer time is required for it to dry and harden. When the fitting will not admit of so thick a substance as flanged being interposed, linen may be substituted, or even paper or thin pasteboard, the only reason for employing any thing of the kind being the convenience of handling.

This cement answers well also for joining broken flanges, however large. Cifererus built of square pieces put together with this cement, will never leak or want any repairs; in the case the flanges need not be entirely bedded in it, for an inch or even less of the edges that are to lie next the water need only be treated, and the rest of the joints may be filled with good lime.

Another cement, which is preferable to the former for withstanding the action of steam, is compounded as follows: Take two ounces of sal ammoniac, one ounce of flour of sulphur, and 16 ounces of caft iron filings or borings; mix all well together by rubbing them in a mortar, and keep the powder dry. When the cement is wanted for use, take one part of the above powder, and 20 parts of clean iron borings, or filings, and mix them intimately by grinding them in a mortar; wet the compound with water, and when brought to a convenient consistence, apply it to the joints with a wooden or blunt iron spatula. —By considering the affinities of these ingredients, those who are at all acquainted with chemistry, will be at no loss to comprehend, that a degree of action and re-action takes place among the ingredients, and between them and the iron surfaces, which at last causes the whole to unite as one mass; in fact, after a time, the mixture and the surfaces of the flanges become a species of pyrites, holding a very large portion of iron, all the parts of which cohere strongly together. Another cement of the same kind is made by mixing together two parts of a mixture of flour of sulphur, and one part of sal ammoniac, and making them into a stiff paste with a little water. When the cement is wanted for use, dissolve a portion of the above paste in urine, or in water rendered slightly acidulous; and to this solution add a quantity of turnings or borings fitted, to get rid of the granular particles. This mixture, spread upon or between the flanges of iron pipes, or put into the interstices of other parts of iron work, will in a little time become as hard as flange.

Mr. Murray's Rule for the Weight of Fly-Wheels to Steam-Engines.—Mr. Buchanan, in his valuable treatise on propelling vehicles, printed at Glasgow in 1816, gives the following rule, as the result of Mr. Murray's long experience in fly-wheel engines.

Rule.—Multiply the number of horse-power of the engine by 2000, and divide it by the square of the intended velocity of the circumference of the fly-wheel in feet per second, the quotient will be the weight of the fly-wheel in hundred weights.

Example.—To find the weight of a fly-wheel proper for an engine of 20 horses' power, supposing the fly-wheel to be 18 feet in diameter, and to make 22 revolutions per second: wheel 18 feet diameter = 56 feet circumference x 22 revolutions per minute = 1232 feet motion per minute ÷ 60 = 20.5 feet motion per second; the motion of the circumference of the fly-wheel. Then 20.5 feet per minute squared = 420.25, and 20 horses' power x 2000 = 40000 + 420.25 = 40420.25 cwt. of the wheel required.

Smoke-Burning Furnaces for Steam-Engines.—The great quantity of smoke which is thrown out by the furnaces of steam-engines, becomes a great annoyance in a town fuch as Manchester or Birmingham, where there are many engines together. To avoid this, as well as from an idea of obtaining a greater effect from the combustion of the smoke, many inventors have been induced to contrive furnaces which shall not produce any smoke. The black smoke which is usually discharged at the top of the chimney, is, in fact, so much good fuel, which only wanted a sufficient heat, and the contact of fresh air, to inflame it under the boiler. It is a fact well known, that the flame which is often seen issuing from the top of the chimneys of foundries, furnaces, &c. has no existence except at the top of the chimney; and that which has ascended, it is only dene, black smoke, containing the azote of the atsmospheric air which has passed through the fire, of hydrogen gas, coal-tar, and carboaceous matter; and this smoke is of such a high temperature, that it only requires oxygen to make it inflame instantaneously: this it obtains from the atmospheric air, into which it descends on issuing from the top of the chimney, and then presents such appearances, as would make a haughty observer adopt the opinion that the flame had ascended, in the state of flame, from the fuel in the furnace, through the whole height of the flue, up to the top of the chimney; but this is by no means the case, and a consideration of this simple fact will convince anyone, that it is not an inconsiderable proportion of the fuel that is thus neglected. Nor is this the only loss sustained; a quantity of heat is required, not merely to render such a portion of the fuel volatile, but to give it a temperature sufficient to produce the spontaneous inflammation at the top of the chimney, of which we have taken notice. This must be furnished at the expense of an extra and unnecessary quantity of fuel.

The first of the smoke-burning furnaces was Mr. Watt's patent of 1785. His method consists in causing the smoke, or flame, of the fresh fuel, while passing from the fire to the flue or chimney, to pass, together with a current of fresh air, through or among fuel which has already ceased to smoke, or which is converted into coke, charcoal, or cinders, and which is intensely hot; by which means the smoke, and groser parts of the flame, by coming in close contact with the intensely hot fuel, and by being mixed with the current of fresh or unburnt air, will be consumed or converted into heat, or into pure flame, free from smoke. This invention is put in practice, first, by stopping up every avenue or passage to the chimney or flues, except such as are left in the interstices of that part of the fuel which is ignited; secondly, by placing the fresh fuel above, or nearer to the external air, than which is burning, and already converted into coke or charcoal; thirdly, by constructing the fire-place in such manner,
STEAM-ENGINE.

manner, that the fresh atmospheric air which animates the fire, and the smoke or flame which rises from the fresh fuel in the first application of the heat, must pass downwards, or laterally, so as to pass through the whole mass of burning fuel, and ifuse from the interstices of the burning fuel at the most remote part, or internal end of the fire-place, to escape into the flues or chimney. In some cafes, after the flame has past through the burning fuel, it is made to pass up a very hot funnel, flue, or oven, before it comes to the bottom of the boiler, by which means the smoke is still more effectually confined.

This invention of Mr. Watt's has been very extensively practiced; but another plan, by Mr. Robertson of Glasgow, has since been found preferable: it is nearly on the same principle as Mr. Watt's. The opening through which the fuel is introduced into the furnace is shaped like a hopper, and is made of cast-iron, built into the brick-work of the furnace. From the mouth, or entrance of the hopper, it inclines downward to the place where the fire rests on the bottom grate.

The coals in the mouth-piece, or hopper, answer the purpose of a fire-door; and the provision must be attended to in the management of this furnace, that the hopper shall be kept full of coal, either wholly or in part with small coals, to prevent as much as possible the air entering by that passage. The coals which are in the lowest end of the hopper are brought to a state of ignition by the heat of the fire upon the bars, before they are forced upon the bars to be burned.

Beneath the lower part of the hopper the furnace is provided with front bars, which serve to admit air among the fuel which lies upon the grate, and offer a ready mode of forcing the ignited fuel, which has just issued from the lower part of the hopper, back upon the fire-grate, where it is completely consumed, and by thus forcing it back, a space is made, into which fresh fuel falls from the lower part of the hopper; but all the smoke which rises from this fresh fuel must pass through the burning fuel, which lies upon the farther part of the grate, and is thus consumed. By this arrangement, the fuel is brought into a state of ignition before it reaches the farther side of the bottom grate, where it is stopped by a rising current of brick-work; therefore, any part of the coals inherited from the mouth-piece, must pass over these burning coals before it can reach the slot of the chimney; but this, though it would cause a large quantity of the smoke to be burnt, would not completely prevent the escape and ascent of smoke up the chimney; for it is not sufficient that the smoke should be exposed to a heat sufficient to ignite it before it escapes; as, unless a quantity of fresh air, able to furnish a sufficiency of oxygen for the combustion of the smoke, can be brought at the same time in contact with it, it will still escape in an undecomposed state.

The principal merit of Mr. Robertson's invention consists in a judicious admission of fresh air, in such a manner that it can reach the smoke without previously passing through the fire, and parting with its oxygen in its passage, and that it shall be in such quantity, as merely to cause the smoke to burn, and not to cool the bottom of the boiler. Beneath the upper side of the mouth-piece, or hopper, which incloses the fresh fuel, and at the distance of about three-fourths of an inch from it, (this space being a little more or less, according to the size of the furnace,) is placed a cast-iron plate, which is above the hopper containing the fuel; and in the space between it and the top of the hopper is an open space for the admission of a thin stream of air, which, rushing down through the opening, comes first in contact with that part of the fire which is giving out the greatest part of the smoke; viz. the fuel that has been last introduced from the lower end of the hopper upon the grate-bars, mixes with the smoke before it passes over the burning fuel upon the interior part of the grate-bars, where it is in a high state of combustion: this enables the smoke to inflame completely. The quantity of air thus admitted to pass over the upper surface of the fuel newly introduced, is a matter of importance to the complete action of the contrivance. The opening for air is regulated by a very simple contrivance. The plate which forms the upper side of the opening for the passage of the air, rests at each end on a flue, or pin, projecting from the cheeks of the mouth-piece, or it is furnished at each end with a pivot, which works in the cheeks. These pins, or pivots, being placed about half-way between the outside and inside of the mouth-piece, or hopper, by elevating or depressing the outer edge of the plate, the opening for the admission of air between the lower end of the hopper and the lower edge of this plate can be diminished or enlarged. When that degree of opening which produces the best effects is obtained, which is easily ascertained by experiment and kept in its place by means of a piece of iron introduced above it, and answering the purpose of a wedge. These furnaces have been adopted by many manufacturers at Leeds, Manchester, and in London, where many works have been indicted as a nuisance for not having adopted the improvement; the magistrates arguing, that though the welfare of the place required that such inconveniences should be submitted to while no possible remedy for them was known, the health and comfort of the inhabitants equally demand, now that evil can be done away, that smoking furnaces should not be permitted in the place. On this account, Mr. Robertson's furnaces have been very much adopted; but we have seldom seen them in such order as to make any diminution in the smoke, which they will do completely, if the regulation of the quantity of air is properly made.

A recent invention by Mr. John Cutler in 1815, is found to burn the smoke most perfectly in common fire-grates, such as are used for warming apartments; and we have seen an experiment of this plan upon a small-engine boiler, which seemed to promise great success in applying it on a larger scale; but such trials have not yet been made, nor the best form of the apparatus settled.

Mr. Cutler's invention consists in applying beneath the place in which the fire is to burn, a chamber or magazine, which is made as close as can be on all sides, except the top, and is of sufficient capacity to contain within it a magazine of fuel, sufficient to supply the combustion for a whole day, or other required space of time. The fire is made upon the top of the mass of fuel which is contained in the magazine, and there are no grate-bars upon which the fire is to lay; but instead, the bars are placed at the side, in a sloping direction, so as to inclose the fire in a grating, which will admit sufficient air sidewise to supply the combustion. The bottom of the magazine is made movable up and down in the chamber; and by means of a rack and pinion, a screw, or some other mechanical power, the whole weight of coal contained in the chamber can be raised up, and a portion will rise up into the grated part, where air is supplied to it, so that it can burn; for the principle of this invention is to make the magazine-chamber beneath the grate as to exclude the air from it, so that the fire cannot burn the fuel contained in it, and to provide that part of the fire-place which is immediately above the top of the chamber with a plentiful supply of air to burn the fuel. By means of the machinery, any quantity
STEAM-ENGINE.

quantity of fuel can be raised up out of the magazine-chamber to supply the deficiency occasioned by the combustion.

The manner in which it burns the smoke, is by obliging it to pass through the burning fuel which lies upon the top of the mass of coal contained in the magazine, because this burning fuel communicates sufficient heat downwards to make the smoke rise from the fuel, and this smoke must pass through the fire above it; but before the fuel comes to be actually burned, the smoke is so far extracted, that the coal is in the state of coke.

The machinery by which the bottom plate of the magazine and the fuel contained in it is raised up, is simply an axle, with chains winding upon it; at least that is the contrivance which Mr. Cutler used in the small roofs for warming apartments; but what method will be found best on a large scale, for its application to steam-engines, remains yet to be determined. We shall give a more minute description of this valuable invention under the article Stove.

The Application of the Steam-Engine to propel Boats or Ships.

—This is one of the most valuable applications of the power of steam, next to that of draining mines; and though proposed at a very early period, has been but lately brought into use.

Captain Savery, in 1702, mentions the application of his engine to a ship, but gives no account of the manner of carrying it into execution; probably he only intended it for pumping out leakage-water.

Mr. Jonathan Hull's patent of 1736, for carrying vessels or ships into or out of any harbour, port, or river, against wind or tide, or in a calm, is the first idea of applying the steam-engine to the purpose of propelling vessels. The engine of Newcomen was made to actuate a wheel placed in a frame projecting from the head of the boat, and the oars or paddles of the wheel were to strike in the water, and advance the boat or vessel containing the engine, which would draw after it the ship or vessel that was to be rowed into or out of the harbour. We have no account of any actual trials made by Mr. Hull; but besides his patent, we have a small pamphlet, printed in 1737, with an engraving.

The account which Mr. Buchanan gives of the introduction of steam-boats in his treatise on propelling vessels, is, that Mr. Miller of Dalfinwood, who made many models and experiments with a view to the improvement of naval architecture, appears to have made the first attempt at working a vessel with steam. The vessel was double, with the paddle-wheels in the middle: the experiment, however, did not succeed to his satisfaction.

About the year 1795, lord Stanhope constructed a vessel, which was tried in Greenland: The paddle were made in the imitation of the feet of a duck, and were placed under the quarters of the vessel, but the mechanism did not answer to his lordship's expectation.

In the year 1801, Mr. Symington tried a vessel propelled by steam on the Forth and Clyde Inland Navigation, but it was laid aside, on account of the injury which it threatened to the banks of the canal, by the surge of water which it made. It does not appear that he tried this vessel on any river.

Mr. Symington's steam-boat is slightly described in the Journals of the Royal Institution for 1803, from which it appears, that the method employed by him for making the connection between the piston and the motion of the wheel was by placing the cylinder nearer in a horizontal position. This is attended with several advantages; the necessity for a beam is avoided, which has ever been a troublesome and expensive part of the common engine. The piston is sup-ported in its position by friction-wheels, and communicates, by means of a rod, with a crank connected with a wheel, which gives a motion to the rowing-wheel somewhat slower than its own; the water-wheel serving at the same time as an addition to the fly. The steam-engine differs but little in its action from that improved by Mr. Watt; there is, however, an apparatus for opening and shutting the cock at pleasure, in order to revolve the motion of the wheels, and put the boat back whenever it may be necessary. The water-wheel is situated near the stern, and in the middle of the breadth of the boat, so that it becomes necessary to have two rudders, connected together by rods, which are moved by a winch near the head of the boat: by this means the person who attends the engine is able to steer also.

Another part of Mr. Symington's invention consisted in the application of steamers at the head of the boat, for the purpose of breaking the ice on canals: these were to be raised in succession by means of levers, the ends of which were depressed by the pins of wheels, turned by an axis communicating with the water-wheel. Mr. Symington stated, in a calculation he made, that a boat doing the work of twelve horses, could be built for eight or nine hundred pounds; and he had ascertained by experiment, that it would travel at the rate of two miles and a half per hour. This is a very slow motion, compared with the present steam-boats, as we shall see.

In 1807, Mr. Fulton of New York introduced steam-boats into America, which were the first that succeeded in a large way, so as to become profitable: they had before this been used in America, and were begun there by Mr. Symington. In 1813, a large boat was set to work on the Clyde, in Scotland; and since that time, great numbers have been made both in Scotland and in different parts of England.

There are several different methods of applying the force of machinery to row boats: the most obvious is by means of oars, similar to those with which a boatman rows; but this action is very difficult to imitate by machinery, and has never been brought into practice. Several ingenious schemes may be found in the Machines Approvées par l'Académie.

The next is by means of paddle-wheels, which are similar to an under-shot water-wheel; and when turned rapidly round by the engine, the floats dip into the water, and row the boat along. This plan was first put in practice by the ingenious Captain Savery, in 1702; but to be turned by men working at a capstan instead of a steam-engine, is now adopted in all the real working steam-boats which have been made. Two wheels are usually placed at the sides of the boat, at about one-third of the length from the head. Attempts have been made to place one wheel in the middle of the boat, but they have not succeeded as well as the others.

Another method is by forcing a stream of water out at the stern of a boat by a large pump, which at the same time draws the water in at the head of the boat. This was suggested by Dr. Franklin, after M. Bernoulli, and was very effectually tried by the late Mr. James Linaker, master millwright of the dock-yard at Portsmouth, but found inferior to the paddle-wheels. It has been also proposed to force out air under the stern of the vessel by a pump, but we do not think it likely to succeed.

A fifth method is by a screw applied at the stern of the vessel, and turned round by the engine, or by a row of paddles.

Lastly, various forms of oars have been applied at the stern of the vessel to move from side to side, and impel the vessel on the same principle, as what seamen call sculling a boat, by an oar at the stern.
STEAM-ENGINE.

As none of these schemes, except the paddle-wheels at the outsidess of the boat, have been brought to any practical utility, we shall not enter into any further particulars, but describe one of the best of these vessels, such as is employed on the Clyde at Glasgow, where steam-boats have been brought to the greatest perfection.

All these vessels are upon one general plan, viz. that of having paddle-wheels, similar to those of steam-water-mills, on each side of the boat, which are put in motion by the steam-engine. In some of these vessels the paddles are placed parallel to the axis of the wheel, in others they are placed obliquely, and in others again they are curved; and it is not yet ascertained which is the best form; for although some boats are found to move with a much greater velocity than others, it is difficult, where so many causes are combined in the operation, to ascertain which one singly produces the advantageous effect. Experiments are yet wanting to ascertain the best number for the paddles on the wheel, and with what velocity they should move. It would doubtless be of advantage to have the means of changing the velocity of the paddle-wheels, according to the circumstances of the current of the water in which the boat moves; because when the boat is moving with the current, the paddle strikes against the water in a contrary direction to its motion, and therefore has the least force to urge the boat forward, at the same time that the boat is moving in the direction of the current, and therefore moves more easily.

On the other hand, suppose the boat moving against the current, the paddles must row the water in the direction of the current, so that supposing they move only with the same velocity, they must have much less force to advance the boat, at the same time that the boat, having to oppose the current, requires a greater force to propel it. One of the steam-boats on the Clyde has eight paddles to each wheel, but it is probable seven would be more efficient; because it is evident, that if too many paddles are used, the water will be so much broken, that it cannot afford that resistance to the motion of the paddle which alone causes the boat to advance. For a small case, suppose so great a number of paddles that they would nearly touch, the wheel would then resemble a solid cylinder, and have no effect to propel the vessel. The velocity with which the paddle strikes the water must be considerable, to obtain a great resistance from the water; but the stroke must not be too frequently repeated, or the weight of the paddle removes will not have time to return to its former place. The fore and aft paddle makes its force known by its stroke, but the paddles of the steam-engine are fitted to the sides, so that all the stroke is necessary to throw the water against the propelling wheel. The paddles are not carried to the bottom of the boat, but to a certain height, as shown in the figure; and the fire-place is an iron tube contained within; I is the fire-door; the smoke, after passing through a small port in the door, gives off through the chimney, C, which is an iron tube, erected perpendicularly in the centre of the vessel, to a considerable height, as shown in the elevation, and is slaved, in the same manner as a mast, by two ropes, or sometimes by iron chains from its top, going fore and aft, with a purchase to each to draw them taut; the fore and rear paddle makes its stroke felt by the paddle wheel, which is made to keep time with the paddle stroke, B, B, and its objects are to carry the steam-box, supplied with steam, and to receive the heated water, G, alternately above and below the piston, so as to give motion to the engine. The steam is made to work on the plan of Mr. Murray’s patent, with the spindle of one through the other. The top of the piston-rod is joined to the middle of a cross-rod, from the ends of which the two iron rods descend, one on each side of the cylinder, and are jointed to the beams, G, G, which are made double, or composed of two levers, joined together in the manner of a frame, so that the cross-iron condensing cistern of the engine is contained between the two, as they work up and down; the beam-centre, or axis of motion, is supported by two bearings, girted up to the bottom of the cistern, so that the beams lie close to each side of the cistern: the cylinder is screwed down into the condensing cistern, and the bearings for the axis of the cross-rod, B, are supported on the other side. The beams, G, G, are united together at the extremity most remote from the cylinder by a cross rod, on the
the middle of which the connecting rod is jointed, which rises upwards to the crank R, on the shaft or axis of the fly-wheel M: this crank-axis is supported in bearings close on each side of the crank, which are framed to the condensing cistern, and also two others at the extremities of the axis, which are placed on the gunwale of the boat, so that the shaft extends completely across the veil, passing through the boiler A, in a tube which extends across it, as shown by dotted lines at a. On each end of the crank-shaft two cog-wheels are fixed, engaging in the teeth of two other wheels, O, O, fixed upon the shafts of the paddle-wheels B, B. These latter-mentioned shafts are each supported in two bearings, one on the outside beam of the gangways or platforms, and the other on the gunwale of the veil: the cog-wheels, O, O, are fixed upon the extreme ends of the shafts within the veil, and they are one-third or one-fourth larger than the wheels on the axis of the crank, so that the paddles do not turn so fast as the fly-wheel of the engine.

It is needless to enter into a description of the action of the steam-engine; the construction of the valves is the same as described in a former part of this article (Plate VII. fig. 5.) and the engine acts the same as Mr. Watt's double-acting engines; but it is necessarily modified, to suit its particular situation, which occasions some defects. The cylinder must be made very short, to come into the height of the boat; and the connecting rod is so short, that the obliquity of its action on the crank is very great. The air-pump, H, is worked by a cross-rod, which moves up and down with the beams, being connected to them by perpendicular rods. The requisite movement is communicated to the valves of the engine by the rod I, one end of which has a circular hoop, that embraces an eccentric wheel, fixed on the axis of the fly-wheel, so that in turning round, it pushes the rod I back and forwards, in the manner of a crank, and thereby alternately opens and shuts the valves at the proper instant to produce the motion.

There is a throttle-valve placed in the steam-pipe at e, for regulating the velocity or stopping the engine, when required.

The arrangement of the apartments in a steam-veilful may be varied according to the purpose for which she is to be employed. In the drawing, we have given the arrangement which appears best adapted for the convenience of passengers, in a veil for quick travelling. (See the plan, fig. 2.) The after or grand cabin, marked 1 in the figure, is generally framed and furnished in an elegant style, for the use of the boat company, who also occupy the deck and gangways about the chimney. The entry to the grand cabin is at the stern of the veilful. The grand cabin is generally situated in the after-part, on account of there being the most room in that part, the engine being always placed considerably nearer the head of the veil than the stern; 3 is a small room for the use of the passengers, and has a door coming out on the gangways. The entry to the engine-house is by steps from the gangway on the opposite side; and the same entry serves for a small room, in which the steward keeps his stores. The coals for working the engine are flowed beneath the floors of the cabins, and the engineer draws them out with a long hook as he wants them. The forward-cabin, 5, is for passengers who pay less than the others; it has a large counter or shelf in the middle, which will contain all the luggages, and serves also as a table for those who fit round it. These passengers have the upper berth in the cabin; but the chimney 1, over the gangways, as at that part are almost entirely occupied by a large water-cask on each side, the cable, stays, falls, or whatever the veilful may require. The rigging of the boat is evident from fig. 1: the carries two large lugger-fails, one fore and the other aft; but these are only intended to be used in fine weather, with a fair and light wind, the masts and cordage being as light as is convenient. A pair of haliards should be provided to the chimney, to hoist occasionally a large light lugger-fail; and if the chiminey is not sufficiently strong, a pair of extra stays may be set up to strengthen it. The chiminey is generally made to lower down, for the convenience of passing bridges, when the veilful navigates a river.

The paddle-wheels of one of the boats on the Clyde, which, Mr. Buchanan says, is considered as a standard, are 8 feet 10 inches diameter, and 4 feet wide, and are calculated, when the engine makes 45 strokes per minute, to move at the circumference, or strike the water at the rate of 13 miles per hour. She is about 80 tons burden, and is 60 feet from stem to stern, and 15 feet 2 inches wide in the beam. The engine is of 14 horses' power, and the goes at an average six miles per hour in still water; therefore, if there is a current, the will go as much faster or slower than six miles per hour as the velocity of the current. The motion of the paddles is rather more than twice that of the boat.

Steam-boats have been built with much more powerful engines, even 20, 25, and 30-horse power; but the increase of the velocity has not been in proportion to the increase of the power of the steam-engines. This will not be surprising, when it is considered that the resistance to which a boat is subject, increases not in an arithmetical proportion, (as 1, 2, 3, 4, 5, &c.) but in proportion to the squares of velocity (as 1, 4, 9, 16, 25.) In other words, to make a fast veifeful move with ten times a given velocity, it requires one hundred times the power; and it is farther to be considered, that one or more powerful engines above mentioned are heavier, and require a greater floating body to support them, which of course increases the resistance. On railways, an increase of velocity requires only an arithmetical increase of power; and to draw a carriage on a railway with ten times a given velocity, would require only ten times the given power.

Steam-boats require a greater power of clearance than any other veifeful of their size, as those hitherto constructed are lees easily transported than veifefals impelled by sails only. The tendency of the wheels acting to the near the centre line of the veifeful, is to propel her straight forward; whereas in turning a sailing veifeful to the wind, she sails her in a curve; and even common oars act far out from the side of the veifeful, that she have much more power to bring her round than the wheels of a steam-boat can possibly have.

A most important point is to have a good steam-engine. All the engines hitherto used in Scotland have been made on Mr. Watt's principle; but those in America have been high-pressure engines, which being more simple, and less expensive, some have been constructed in England. But one of them having exploded in an American boat, the proprietors of some of the English boats have changed their engines for others on Mr. Watt's principle, to avoid similar accidents. We think it quite unjustifiable in any engineer to advise the construction of steam-boats with high-pressure engines, at least for passage-boats, in which so many persons are always assembled together, and so near to the engine, that they would be all destroyed in the event of the boiler bursting.

The engines which work with a bell-crank, or a double beam below the cylinder, and on each side the cistern, instead of a beam working above, are found tostrain the veifefals; those having the beam above, work much more steadily.
STEAM-ENGINE.

steadily. The engines that Meffra, Boulton and Watt have hitherto constructed have had beams; other engines have had cylinders horizontally. Mr. Brunel's engine, of which we have before spoken, has two cylinders acting alternately, so as to require no fly-wheel; but many engines, on the common construction, have been made without fly-wheels, by having the paddle-wheels sufficiently heavy to answer the purpose.

With regard to fuel, it is obviously much more difficult to have every thing kept in proper order in a boat, where the engines are much confined, and the cylinder is made to work with very short strokes, by which the action on the crank is so oblique, and changes its direction so frequently, that the greater part of the power is lost. The quantity of fuel constantly used in steam-boats has been much greater than the usual allowance for Meffra, Boulton, Watt, and Co.'s steam-engines. For one of 14-horse power, they allow 1 cwt. 1 qr. 20 lbs. per hour of good Newcastle coal; but Glasgow coal is much weaker. One of the boats, with an engine of 12-horse power, requires 3 tons 1 cwt. from Glasgow to Greenock (fully 29 miles), and back to Glasgow. One of 15-horse power, and another of 8-horse power, take each the same quantity, viz. from Glasgow to Greenock (26 miles), and back to Glasgow, 1 ton 1 cwt. For farther particulars on steam-boats, see Robertson'sEffay on Propelling Vessels, 5vo. 1816. The Application of Steam-Engines to driving of Carriages.—These are now called locomotive engines, and we may date their introduction with the patent of Meffra. Trevethick and Vivian in 1802, for the high-pressure engines, which were expressly intended for working carriages. It would have been very difficult to have succeeded with any other kind of engine, as the weight of the water necessary to effect condensation must be so great. Mr. Trevethick made a locomotive engine in South Wales in 1804, which was tried upon the rail-roads at Merthyr Tydfil. The engine was the same as that of which we have given an account of its work in speaking of the high-pressure engines, having an eight-inch cylinder, and a four-feet six-inch stroke. It drew after it, upon the rail-road, as many carriages as carried ten tons of bar-iron, for a distance of nine miles; and it performed all that distance without any farther supply of water than that contained in the boiler at setting out, travelling at the rate of five miles per hour.

Since that period they have been tried in many places upon rail-roads, but we do not think they had been really put in practice, to as to work constantly, until 1811, when Mr. Blinkslop, proprietor of the Middleton coal-works, which supply the town of Leeds, adopted them for conveying the coals on his rail-road.

Mr. Trevethick's first engines consisted of a high-pressure engine, with a boiler of caff-iron, of a cylindrical form, five feet long, and four feet three inches diameter, the fire-place being within the boiler. The cylindrical boiler was mounted horizontally upon four wheels, and the cylinder of the engine was placed vertically in the end of the boiler, having two connecting rods descending from the cross-bar of its piston-rod to two cranks, upon an axis extending beneath the boiler and cylinder, and communicating its motion, by means of wheel-work, to the two fore-wheels, upon which the engine runs; and by this means the alternately ascending and descending motions of the piston-rods act to turn round the crank and wheels, and draw the carriage forwards: in this way no fly-wheel was necessary, because the momentum of the carriage to advance itself forward in the road, continued the motion of the wheels and cranks sufficiently to make the carriage pass the line of the centre.

Where these engines were tried, it was found difficult to make the wheels take sufficient hold upon the railway to draw any considerable load after it, unless the weight of the engine and work resting upon the wheels was made very considerable; and then the common iron-rails of the railway were sometimes broken by the pulling of the engine. Mr. Blinkslop, when he adopted the locomotive engine, took up the common rails on one side of the whole length of the road, and replaced them with rails which had large and coarse cogs projecting from the outside. These cogs are called at the same time with the rails, and are hollow beneath, to be as light as is consistent with strength and durability. The pitch of the cogs, or distance from centre to centre, is six inches, so that each rail, of three feet in length, has only six cogs. A wheel, which is fixed on an axis at one side of the carriage, works in the teeth of the rails; and it is turned by wheel-work from the axis of the cranks, the whole machine is caused to advance along the railway. When we saw Mr. Blinkslop's first trial, he employed a small condensing engine, but finding the water to grow to hot that he gained but little by the condensation, he applied a high-pressure engine with a wrought-iron boiler, and two cyliniders in it acting upon separate cranks, so as to produce a constant action to advance the carriage without the necessity of using a fly-wheel.

A similar machine has been tried at Newcastle, but they have attempted to employ the wheels alone, without cogs upon the rails. To relieve the weight upon the rails, and obtain greater re-action to advance the carriage, they applied six wheels for the carriage to run upon; and to make the bearing equal upon all, the two middle wheels were applied to the piston of a small cylinder beneath the carriage, into which steam was admitted, and by its pressure bore up a portion of the weight of the engine; and accommodated itself to any inequalities of the railway.

At present, locomotive engines have been confined to moving upon iron-railways; to make them-engines draw carriages upon public roads, is a refinement not yet attained.

In drawing up this article, we have derived considerable assistance from books, as our numerous references will testify; at the same time we cannot refer to any one work in the English language for a more detailed account of the steam-engine than we have here given. Many detached memoirs on particular points of the principle or construction of the steam-engine, may be found dispersed through the forty-eight volumes of the Philosophical Magazine, and the Philosophical Journal. The first and second volumes of the latter work contain a sketch of the history of the invention, but no particulars which are not given more at large in this article.

The Repertory of Arts, Manufactures, and Agriculture, containing sixteen volumes of the first series, and twenty-eight volumes, now published, of the second series, contains the specifications of a great number of patents for inventions relating to the improvement of steam-engines, of which we have noticed nearly all in this article, which appeared to possess merit, or to have been successfully put in practice.

The article Steam-Engine in the third edition of the Encyclopaedia, which was written by Dr. Robison, is the best and most philosophical view of the subject; but he has not entered at all into details: and as this was composed twenty years ago, the improvements made since that period, in the construction of the machine, have made a total change.

The fullest account of the improved steam-engine is by the celebrated French engineer, M. Prou, who devotes the second volume of his "Nouvelle Architecture Hydraulique," 1796, 9 expressly.
expresly to that subj.. He describes four or five engines, with a great number of large plates, containing every detail of their construction. The work is little more than a description of the plates. These engines are not the best specimens of Mr. Watt's invention; they were all constructed in France by M. Perrier of Paris, who, in 1780, erected a large engine at Chalottet, to pump up the water of the Seine for the supply of the town, and another of smaller dimensions on the opposite side of the river at Gros Caillou. These engines are still at work, and a writer of this article visited them in 1844: they are upon the plan of Mr. Watt's first engines, though, for want of attention to some minute particulars, they do not produce any great effects. M. Perrier had visited England to obtain the requisite instructions for making these engines.

The double-acting engine of Mr. Watt was carried into France by M. Betancourt, whose experiments on the expansive force of steam are referred to in this article. This gentleman came to London in 1788, with a view of collecting models of improved hydraulic machines for the court of Spain, and was admitted to examine the steam-engines made by Meffre. Boulton and Watt at the Albion Mills for grinding corn, which were the first large double-acting engines they had made. M. Betancourt has, in effe&, made a kind of secondary claim to the invention of the double engine, for he informs us, that he knew in part the exterior construction and operation of those machines, but the interior mechanism was so concealed from him, as well as from others who had had the same curiosity before him, that he could only guess at the nature of the construction. He observed, that the chains which were usually applied to the extremities of the beam were suppressed, and that, instead of these, they had applied the parallel motion; that the different parts of the machine were so masked by the distribution of the building, which isolated even the exterior parts into different apartments, as to prevent him from comprehending their correspondence; but, from the result of all his observations, he concluded the machine was of double effect.

On returning to Paris, M. Betancourt made a model of a double cylinder, on a scale of an inch to the foot; and, as he did not know the arrangement of Meffre. Boulton and Watt's valves, he invented those parts himself; and M. Perrier, from this model, constructed a large machine in 1790, at the Hotel Cygnes, in Paris, for grinding corn. By examining the construction of this engine, which is fully described by M. Prony, it will appear that M. Betancourt made good use of his observations, for we find the engine to be the same as Mr. Watt's, in every particular, except in the arrangement of the valves, which part is very defective, as both the steam-pipe and exhausting-pipe must be filled with steam, and emptied at each stroke, in addition to the content of the cylinder, without producing any effect to work the engine. A different construction by M. Betancourt, with two cocks, is also described, but it has the same defect, of which M. Prony was sensible; and in a second machine which he describes, points out the remedy, by varying the arrangement of the valves, so as to bring them very nearly the same as Mr. Watt's, though externally of different appearance. None of these engines have steam-jackets for the cylinders, nor is the expansion principle mentioned by M. Prony. The beautiful contrivance of the regulation by the falling-balls is not described, but all the engines are regulated by a water-cistern and pump, which we have here described. See also Regulator.

It is to be regretted, that none of our experienced engineers have undertaken to write a work on steam-engines, as there is not a single subject in mechanics so interesting and useful.

Almost every introduction to philosophy contains a description of the atmospheric steam-engine, and most of the modern ones a short account of Mr. Watt's improvements; but these are in general very slight and defective; the best is in Brewster's edition of Ferguson's Lectures, which gives a sketch of Mr. Watt's double engine, with the parallel lever and rotary motion; and we believe it was the first description published of that valuable invention, though it had been in general use for twenty-five years before. The engine is clearly described in the British Encyclopedia, 8vo.

Steam-Boiler, in Agriculture, the name of a simple convenient contrivance for preparing different sorts of cattle-food by means of steam, in a small way.

A perfectly convenient and practical contrivance of this kind for farms, where the extent of this sort of food is not required upon a large scale, has been described in the first volume of Communications to the Board of Agriculture: the part in which it is set is of stone or brick, built in a cubical form, about three feet every way; it has the door of a furnace, and an ash-pit: and a shallow iron kettle, about twenty inches in diameter, and seven or eight inches in depth, is placed over the furnace. There is a flat smooth stone covering the whole top part of the building, in the middle of which a round hole is cut out, to admit the iron kettle being fitted closely to it. A cask, the bottom of which is perforated with a number of auger-holes, is placed over the steam-kettle, which is about half filled with water. The cask is then filled with potatoes, and is closely luted or clayed all round the bottom, to prevent the steam escaping between it and the stone: the cover is put on aloof very closely, and there is a short thick plug put slightly in a hole in it, to give air; or this hole may be covered with a piece of lead, fitted closely upon it, and moveable on a leather hinge, that it may of itself give way, to prevent the cask being endangered by the steam. The flue or vent may be built to the wall of any house, or any other convenient place. When the potatoes are steamed or boiled sufficiently, which may be known by taking off the cover, they are either taken out with a shovel, or else the cask is turned over, and emptied into a barrel or tub, and again filled, if necessary. By having it suspended in the middle, on two pins in a frame, it might be made to readily turn upside down, and empty the potatoes or other roots with great convenience.

Though this is a very simple description of steam-boilers, it may be sufficiently to explain the nature of it. But they may be made of various other contrivances, according to the extent required, and one steam-kettle may be made to boil several casks at the same time; or instead of casks, there may be fixed boilers with sliding bottoms, for emptying the potatoes into little wagons, or barrels, wheeled in under. The potatoes might also be taken out of a fixed boiler by means of an iron baleet, made to fit the inside of the boiler; which baleet might be easily taken out with a lever, a small crow, or some other similar contrivance.

And another excellent contrivance of this sort has been made use of by Mr. Stares, which is described in the Annals of Agriculture. But the most complete apparatus for this purpose, where the BUFINa is conducted in a very extensive manner, is that which has been fitted up and described by Mr. Curwen in the fourth volume of Communications to the Board of Agriculture, and which description has been given and recommended to us; in speaking of the use of steaming of cattle-food. It has been suggested, that if steam-boilers be fixed up in a contiguous manner to the kitchens or cellareis of farm-houses, they may be occasionally converted to the use of the families; as this method...
is preferable to the practice of boiling in water for most culinary purposes. See Steaming of Cattle-Food.

Some other very simple and cheap inventions of this kind have also been made and had recourse to in different parts of the country, as will be seen under the head just alluded to.

Steaming of Cattle-Food, the operation or process of preparing different sorts of roots or plants, by means of steam, for the feeding of cattle. It is a practice that may be highly advantageous in such situations and districts as those where both fuel and labour are cheap; but in others it can perhaps seldom be had recourse to with profit. It has been long known that many sorts of roots, and particularly the potatoe, become much more valuable by undergoing this sort of preparation. And it is equally well known, that when thus prepared they have been employed alone as a substitute for hay, and with cut chaff both for hay and corn, in the feeding of horses, as well as other animals. It has, indeed, been observed, that to a farmer who keeps many horses or cattle, or even swine or poultry, the practice of boiling their food in steam is so great a saving and an advantage, that it deserves the most particular attention. It has, however, till lately, been confined to such narrow bounds, that it is known but to very few.

And though potatoes have often been given raw to both horses and cattle, they are found to be infinitely preferable when boiled in steam, as they are rendered thereby much drier, and more nutritious, and better than when even boiled in water; this has been long since flown by the experiments of Mr. Wakefield of Liverpool, who, in order to ascertain it, fed some of his horses on steamed, and some on raw potatoes, and soon found the horses on the steamed potatoes had greatly the advantage in every respect. Thole on the steamed potatoes looked perfectly smooth and sleek, while the others were quite rough. Mr. Ecclestone, near Ormskirk, in Lancashire, also found them useful instead of corn for these animals; and the extensive and accurate trials of J. C. Curwen, esq. have placed the utility and advantage of them in this way beyond all dispute. His statements have been in some measure given in speaking of potatoes. See Potatoes.

It is well known that this, as well as many other sorts of food, may likewise be rendered a great deal more useful and beneficial for feeding and fattening near cattle and sheep by undergoing the preparation by steam. And probably for some other animals.

Mr. Curwen has found, that in their preparation in this way, the waiter of the potatoe is about 3/4th part; and that straw, when given along with them, answers equally well as hay, as the horses keep their condition, and do their work equally well.

The plan of his washing and steaming-house, or apparatus for this purpose, is curious and interesting. It has, in the ground-plan, a well, and a conduit which takes the water from the potatoe washing-machine. The potatoe-washer has a frame, over which a crane moves in a circular manner, which takes the machine out of the tub when the potatoes are wafted, and which empties them into a back, which is raised from the floor the height of one of the steaming-tubs, or will meet another crane, which will place them on the lead-pots, where they are steamed. The two cranes are joined together by a jointed notch, which permits of their being turned, and by which the lead-pot is raised near the place where the tubes stand upon which the steam is let in. There are cocks which let off the condensed water; and a conduit which takes it away. The lead-pots stand upon a framing or platform, which should be ten inches above the floor. There are stone troughs, too, in which the potatoes are bruised for use before giving them to the animals. In the washing-machine, the handle goes twice about for the washer's once. And the crane and jack which wind up the cover is detached from the axle by a jointed notch between the two head-rocks. The water-back is supplied by a spout from a pump, in order to fill the boiler; also, a shorter spout is applied to fill the tub which the washing-machine runs in. It is remarked that a plug is in the bottom of the tub, to let off the dirty water. The boiler consists of two iron pans, screwed together by two flanges; and each pan will hold 40 gallons. The lead-pipe, which leads from the boiler, and conveys the steam to the lead-pots, is one inch and a quarter in diameter. It is noticed that the lead-pots are 12 inches in diameter, and 9 feet in depth. There is a brass cock, which stops the steam when the tubs are taken off; also two other cocks are applied; one to open from the water-back, in order to fill the boiler; and the other to know when the boiler is sufficiently filled with water. There is likewise a steam-valve fixed upon the top of the boiler, of about 4 lbs. to a square inch. The tubs are 2 feet high, and 20 inches wide at the top, and 17 inches at the bottom, and will hold about 11 stone of potatoes.

It is also remarked, that the boiler will steam the four tubs in from 15 to 20 minutes. One or two tubs may be steamed at a time, by plugging up the steam-holes in the lead pots. The tubs are set upon the lead-pots with flannel between, nailed upon the tub-bottom; and each tub-bottom is perforated, to let the steam ascend among the potatoes; and the lids of the tubs are held down by iron ball cleavers, four to each tub. When the potatoes are steamed, the other crane removes the potatoes to the stone trough to be made use of; and also places and replaces the tubs. It is observed, too, that the washer should be about two-thirds filled, and that it will most completely do the potatoes in two minutes. When taken out of the box, it is necessary to either pump or throw a pail of water over them, and to let it drain through them. The fire of the washer must be according to the work required to be done.

Another method has, however, been suggested by Mr. Pietersen of preparing this root, and which he considers as superior in respect to, or so far as the goodness of the food for the use of cattle is concerned, as may be seen under the article Potatoes. This is by means of baking or roasting them in ovens proper for the purpose. The ovens may be constructed in different ways; but that which is here described is three feet six inches by two feet three inches in width, and one foot nine inches in height. It has a cast-iron plate for the bottom, and is provided with flues. The oven, when complete, will contain six digesters.

It may be noticed, that in speaking of the process of baking the potatoes in these ovens, it is observed in the fourth volume of Communications to the Board of Agriculture, that three bushels of potatoes were weighed separately, each bushel weighing 80 pounds before they were put into the digester. The potatoes from the two first digester, taken out of the oven when baked, and weighed together, were 55 pounds; and those from the second two were 54 pounds; and those from the third two, 54 pounds. That the carpenter measured the wood with which they were baked, and he knew that the rated cord of good fuel-wood would bake 90 sets, or 90 times 6 digester, each containing half a bushel of potatoes, at the rate of wood it took to bake the above, which was the second set baked that day. And he adds, that a cast-iron plate five feet long by two feet ten inches, instead of three feet ten inches
inches by two feet ten inches, which will hold eight digester, and by adding a small fire thus,

| Six inches. | Seven inches long, | Six inches. |

on each side the great fire-place, will, in his opinion, accelerate the baking from 15 to 20 minutes in every set, as well as save some fuel.

Also, in a subsequent communication, it is stated that the cord, or, as it is often called, the flack of wood, mentioned in the experiment, is 24 feet long, 3 feet wide, (that is, the wood is first cut into three-feet lengths,) and 1 foot 10 inches high; and is sold for 12s. on the spot in his neighbourhood. Each of the 6 digester holds 6 gallons wine measure, but in potato measure each will only hold half a bushel; so that 1 sack, or 3 bushels, are baked at a time with one part out of 90 of the above cord, or flack of wood. He has never had occasion for more than six bakings in a day; which 6 bakings, that is, 6 sacks, or 18 bushels, at 60 lbs. the bushel, were done within twelve hours, the wood being in a dry state. He believes that eight digester, with the heat properly spread, would be done in somewhat less time, allowing for that of filling and emptying the two additional ones; and this should be sufficiently satisfactory for any person wishing to use the method on a larger scale.

Representations of these different apparatuses for steaming of cattle-food may be seen in the second volume of the "General Dictionary of Agriculture and Husbandry."

There are some other more simple and cheap contrivances in use in different districts for steaming of cattle-food, such as a hoghead cut in halves, the bottom raddled, and mortared half way into a small copper, and coarsely covered with a wooden lid. By this contrivance potatoes are so quickly steamed in Suflex, it is said, that six tubs are done in the course of the day, which is nearly double the number that could be boiled in the water. It is suggested, however, that there should be an easier way of clearing the copper from dirt, which will, in spite of washing, gradually collect at the bottom of it, without the necessity of breaking the mortared joint which connects it and the half-hoghead. Other modes of a similar nature, equally simple and convenient, exist in many other places, which are found to answer perfectly well, where only small quantities of this sort of food are wanted to be prepared at a time.

The steaming of cattle-food is a practice which is yet probably but in its infancy, consequently every discovery of a ready and cheap method of effecting the purpose is particularly deserving of the farmer’s attention, as well as the ascertaining of the improvements which different forts thereby undergo, for the purpose of being applied in the different procédés of feeding and fattening various kinds of animals of the farm fowls.

STEAMING-HO(c)ES, a place properly fitted up for the purpose of preparing roots by steam for the use of cattle. See the preceding article.

STEATITE, in Mineralogy, a mineral particularly distinguished for its unctuous feel, resembling that of soap. That variety which is found in Cornwall differs from common flaxite by the absence of alumine in its composition, and is commonly called soap-flax. See SOAP-STONE.

Steatite is of various shades of white, grey, yellow, and red. It is often semi-massive, and forming incrustations; it is sometimes crystallized; but mineralogists are not agreed respecting the crystals; some considering them as true crystals, others as false ones, formed in the cavities made by pre-existing crystals. The fixated prisms, the rhomb, and fixated pyramid, are considered by Mr. Jameson as sable crystalline; the prisms originating from rock-crystal; the rhomb from brown spar; and the fixated pyramid from calcareous spar.

Steatite is soft, yielding to the nail, but does not adhere to the tongue; the fracture is splintery; it is more or less translucent on the edges, and bears a great resemblance to serpentine; but is much softer than that rock, to which, however, it is nearly allied, being commonly found traversing it in veins.

Steatite also occurs in metasomitic veins, with the ores of copper, lead, zinc, silver, and tin, mingled with albite, mica, and quartz. This mineral sometimes forms beds in primitive mountains. It is infusible by the blowpipe, but changes its colour, and becomes black. According to Klason, the steatite of Bareth contains

with a trace of lime and muriatic acid.

Steatite has been employed in various countries to answer the purposes of soap and fuller’s earth. The white variety is much valued in the manufacture of porcelain.

The inhabitants of New Caledonia are said to eat considerable quantities of steatite. Humboldt states also, that the Otonnacks, a savage race on the banks of the Oronoco, live for nearly three months in the year principally on steatite, which they bake before using, and then soften with water. Mr. Goldbery says, that the negroes on the banks of the Senegal mix their rice with white steatite, and eat it without inconvenience. Very recently, considerable alarm was excited in the county of Cornwall, on the discovery that it had been the practice of a fraudulent miller in that county to mix a considerable quantity of ground steatite with his flour.

Steatite hardens in the fire, and has been successfully employed in imitating engraved gems, by Mr. Vilcot, an artist in the vicinity of Liege. The subjects to be represented are engraved on it with great ease; it is then exposed to a strong heat. It is afterwards polished, and may be coloured by metallic solutions. A variety of steatite found at Argon, in Spain, is used by artists under the name of Spanish chalk; when gently burned, it is sometimes used as the basis of rouge.

Steatite occurs in Cornwall, in Anglesea, at Porpoze, Ixolmkill, and various parts of Scotland; and in Norway, Sweden, Germany, Switzerland, &c.; and, we believe, in all districts where serpentine abounds. Some mineralogists suppose that steatite is formed from the decomposition of felspar and mica; others, that it is nothing more than decomposed serpentine. See SERPENTINE.

STEATOCELE, from σατυς, fat, and ἤσαν, a tumour, a swelling of the frcotum, containing fat.

STEATOMA, a wen, or encysted tumour, composed of a substance like felt.

STECKBORN, in Geography. See STEKBOREN.

STECKM, a town of Flanders; 5 miles S. of Hulit.

STECKEN, a town of Bohemia, in the circle of Czaslau, 4 miles W. of Polna.

STECKENITZ,
STECKENITZ, a river which rises in the territory of Lubeck, and runs into the Elbe at Lauenburg.

STECZICA, a town of Poland, in the palatinate of Sandomierz, on the Wieprez, near its union with the Wistula; 20 miles W. of Radom.

STE, a provincial term applied to a ladder.

STEBERG, in Germany, a town of the duchy of Carniola; 11 miles E.S.E. of Cirkinitz.

STEERG, a sea-port town of Denmark, on the W. coast of the island of Moen; formerly a place of great strength, with a castle, which has been since destroyed; 38 miles S.S.W. of Copenhagen. N. lat. 55° 3'. E. long. 15° 20'.

STEEL, in the Arts, a most valuable metal, conferring on iron combined with carbon. It is chiefly used for edge-tools, and other cutting instrunents, and from its fine polish is used in ornaments of various kinds.

In chemistry it is called a carburet of iron.

Its hardness is greater than that of iron; and its most valuable property is, that it can be made harder than any other metal, by suddenly cooling it when heated to redness; also, if it is heated to a lower temperature than redness, and suddenly cooled, it becomes the most elastic of all the metals. It is of a darker colour when polished, and retains its polish much longer, than being so liable to oxydize.

The specific gravity of steel is greater than that of iron; thus, the spec. gr. of cast-iron is .7270; malleable iron, .7388; steel in its soft state, .7840; hardened steel, .7818.

Steel is manufactured by two processes, one in which the steel is made from pig-iron at once in the forge; this is practiced in Germany, and is called natural steel. Cemented steel is formed by flattening bars of iron with powdered charcoal in a closed vessel, and by keeping the mass at a brisk red heat for a longer or shorter time, depending upon the size of the bars. This process is called conversion. The test of the conversion being complete is its blistered appearance, from which it has been called blistered steel. As the steel in this change does not undergo fusion, all the imperfections in the mechanical texture of the iron will still be found to exist in the steel. A drawing of the furnace employed for this process is given in Plate VII. Iron Manufacture; for the references to which, as well as the mill for rolling steel, see Rolling of Steel. It is from blistered steel that all the different kinds of steel are manufactured. These are principally of the following varieties, viz., cast-steel and sheet-steel.

Cast-steel is blistered. Steel rolled and cast into ingots, which are afterwards drawn into rods by the hammer, or by rolling. By this change the steel becomes much harder, and of course entirely free from those flaws and other defects which exist in the blistered steel: this is what renders cast-steel so much better for polished goods: for when blistered steel is attempted to be polished, the surface is seen to abound with numerous spots, arising from mechanical defects in the bars previous to conversion.

Cast-steel works much harder under the hammer, and will not bear much more than a red heat, without breaking in pieces under it. This, however, is more especially confined to that commonly made; since cast-steel may be made which will bear a white and even a welding heat; but it requires a much greater heat for its fusion, and would in consequence be sold at a higher price.

The refuse of blistered or common steel is generally melted into cast-steel; but this is not of the best quality. This is generally done by mixing the bars of blistered steel, which, for this purpose, are a little more converted than for ordinary purposes, in order to give the steel a little more carbon than if it were used in the state of blistered steel. The bars are broken into small pieces, for the purpose of flowing the greatest quantity in the crucible.

The furnace employed for melting of steel is the bent constructed air-furnace, and is similar in form to those used by brails and iron-founders in the small way, where the crucible is employed. That part of the furnace containing the crucible and the fuel is of a prismatic form, about twelve inches square, and two feet in length from the grate to the top where the cover is placed. About three inches below the cover is a horizontal opening, called the throat of the furnace, which leads directly into the chimney. This opening is about three inches by six, and must never be less than the open part of the grate. In some manufactories, ten or twelve of these furnaces are at work at one time. The mouths of the furnaces are level with the floor of the room where the casting is performed. These are arranged along the two opposite walls, each containing a flack of high chimneys. The ash-pits of these furnaces terminate in a cellar below, which is well supplied with air. The crucibles in which the steel is melted are made on the spot. The material is Stourbridge clay, to which a little coke-dust is added. They are formed in a mould of cast-iron, of the form of the outside of the crucible. The proper quantity of tempered clay is first put into this mould, and then a wooden plug is driven in to form the inside of the crucible. They are then gradually dried, and slightly baked, at a much less heat than is given to the lofted pots. The crucible is generally removed from the baking fire to the furnace, which would be liable to crack if put into the fire cold. The crucible is placed upon a stand about four inches high, which is also placed upon the middle of the grate. The base of this stand is less in diameter than the upper part, in order to intercept the air the least possible. Each crucible is also provided with a flat cover, made very true on the under side, so as to fit. It is a little larger than the top of the crucible, in order to be easily removed with tongs. The cover is generally made of fire-clay a little more fusible than that of the crucibles. This admits of as much vitrification between the cover and the crucible, before the melting of the steel, as serves to keep out the air, which, at this high temperature, would injure the quality of the steel, by first destroying its carbon, and then oxydizing the iron. In order, however, to guard more completely against this evil, some make use of what is termed a flux. This consists of any easily vitrifying substance, such as bottle-glass, in very small quantity. The flux is usually employed to the blast furnace cinder.

The fuel used for melting steel is the coke of bit-coal, very highly baked in kilns used for the purpose. The fracture of these cokes is white and brilliant. They are so hard as to be fonsorous; and their specific gravity is much greater than ordinary cokes. This coke, being broken into pieces about the size of an egg, is made to surround the crucible closely on all sides, and a few inches above the fame. The heat required to melt steel is so intense, that if the fuel were not firm and dense, the fire would not last till the fusion took place. This would require a supply of cold fuel, which would not only endanger the crucible, but occasion great delay. When the steel is thoroughly fused, the crucible is withdrawn with a pair of long tongs, opening with two concave jaws to fit the cylindrical form of the crucible. The tongs are not removed till the metal is poured. Immediately on bringing it out of the fire, previous to which the cover is removed, some foria, or refiners, are placed on the bars of steel. This exposes the steel to the action of the oxygen of the atmosphere. Particles of the metal are now seen to dart out of the crucible in bright corruptions, and these continue all the time the metal is pouring into the mould, causing a grand and interesting appearance. The mould is
of cast iron, giving an octagonal shape to the ingot. These moulds are of various forms. Those used for steel-plate are in the form of parallelograms: and those for making large faws are smaller at each end, in order to roll out into a plate nearly of the form of the faw.

The steel known by the name of shear-steel, has been so called from its application to the cutting part of sheeple or wool shears. It was formerly manufactured at Newcastle-upon-Tyne, and has been called Newcastle steel. From being subject to a similar process to the natural steel made in Germany, it has also been termed German steel.

We have before observed, that the bar-iron of which steel is made, contains many defects in its mechanical texture. In this state, it is liable to the workmen to lose its strength and become softer; as it is depended upon the management of the bar-iron maker. The manufacture of shear-steel consists in removing these defects, and at the same time giving it what is called increased fibre by the operation of hammering.

The first preparation is to lay a number of bars of blistered steel together, and bind them with iron rings at one end, so that the bars which are put in the fire may not be displaced. A portion of these united bars is now to be heated to a full welding heat, keeping the surface well defended by throwing powdered sand upon it from time to time. This fuses the oxides of iron, forming a liquid coating, which defects the surface from the action of the air. If this precaution is not observed, the steel, when heated to the degree of welding, would become what is termed burnt, and its malleability be impaired. In the welding state it is placed under a forge-hammer, working by water or a steam-engine, when the bars become firmly united, and all the loose parts previously existing in the malleable iron are at the same time made found. When a little more than half the length of the bars is treated in this way, the iron rings are removed, and the other end heated and hammered in a similar way. The welded mafs is now drawn down into small bars about an inch and a quarter broad, and three-eighths or half an inch in thickness. In this state it is sold to the consumer, who afterwards has reduced to different sized rods by the tilt-hammer. The steel is rendered so compact in texture by the welding and hammering, as to become susceptible of a much better polish than blistered steel is capable of; at the same time that its tenacity and malleability are much improved. The former improvement highly fits it for table-knives; the latter makes it valuable for springs of various kinds, particularly those of great power.

The processes by which this steel is formed has another advantage besides rendering it found and more malleable. It is found softer and more kind than the blistered steel from which it is formed, and is much more uniform in its quality. This may be explained by the fact, that a quantity of the carbon of the blistered steel is diffused in the form of carbonic acid during the welding and hammering, by which a steel is obtained, having a less than ordinary proportion of carbon, and is consequently liable to break in bending, and at the same time softer and more flexible. Indeed, if the process of welding and hammering were repeated several times, the steel would lose the whole of its carbon, and become pure iron.

Blistered steel should not be used but for the commonest purposes, where great tenacity of polish is not an object. For all nice purposes, where great tenacity and foundness are necessary, shear-steel should be employed; and where a fine polish or great hardness is wanted, cast-steel is indispensable. See IRON and CULINARY.

STEEL, Annealing, or Nailing of, is for the softening it, in order to make it work easier; which is usually done by giving it a blood-red heat in the fire, and then taking it out, and letting it cool of itself. Some have pretended to secrets in annealing, by which they could bring down iron or steel to the temper of lead; this was to be done by often heating the metal in melted lead, and letting it cool again out of the lead. But this method has no other effect than what is obtained from the former, when the cooling is very gradual.

Steel may indeed be made a little softer than in the common way, by covering it with coarse powder of cow-horn, or hoofs: thus inclosing it in a loam, heating the whole in a wood-fire till it be red-hot, and then leaving the fire to go out of itself, and the steel to cool, which it will do slowly from being inclosed. See TEMPERING, and STEEL, forging.

For the expansion of steel by heat, see PYROMETER.

STEEL-Glaifs, a name given by some authors to the metallic spheres used in optics. These, according to Cardan, are made of three parts of brass, one part of tin, and one of silver, with an eighteenth part of antimony; but most either totally leave out the silver, or add only a twenty-fourth part, to fave the expense. There are many other methods, directed by several authors, but most use arsenio and tartar, mixed with the metals. These are afterwards to be polished with emery, rotten-stone, putty, and the like.

STEEL-Ore, is used to signify a particular kind of lead-ore.

STEEL-Powder. See POWDER.

STEEL, Salt of. See SALT of Steel.

STEEL-Waters. See Mineral Waters.

STEEL, Damaeous. See DAMARCOUS.

STEEL, Engraving on. See ENGRAVING.

STEEL, Faggot of. See FAGGOT.

STEEL, in Medicine. See CHALYBEAT, and IRON, in Medicine.

STEEL-Wine. See WINE.

STEEL-Point, in Geography, a cape on the E. coast of Labrador. N. lat. 56° 42'. W. long. 62°.

STEEL-E, Sir Richard, in Biography, a political and miscellaneous writer of considerable note, was born at Dublin, either in 1671 or 1676. His father, who was of English extraction, had been for some time private secretary to the first duke of Ormonde, through whose influence the son was fend, at an early age, to England, and placed at the Charter-House for education. In 1691 he was entered of Merton college, Oxford. Of his acailmatic life little or nothing is known, except that he composed a comedy during his residence, which, by the advice of a fellow-collegian, he suppressed. He left the university without a degree, and feeling a strong inclination for the army, he entered himself as a private in the horse-guards, but his friends soon after procured for him an ensign's commission. Feeling that he might not be able effectually to reifit the temptations incident to his age and situation, he drew up a little treatise for his own admonition, and which is well known even now, entitled "The Christian Hero," this was printed in the year 1701, at which time the author was secretary to lord Cutts, and had, by his means, obtained a company in a regiment of fusiliers. The serio-comedies of the work expos'd him to some ridicule among his companions, and the more so, as it failed in producing the corresponding good effect in regulating his own morals; he therefore, "to enliven his character," as he says of himself, brought out a comedy, entitled the "Funeral, or Grief à-la-mode." This piece proved successful; it had the merit of uniting entertainment with the more direct purpose of moral improvement, than was usual among dramaticats at that time. Either on this or on other accounts he attracted the notice of king William, who meant to have bequeathed
beffowed upon him some mark of the royal favour, but he did not live to effect his intention. He obtained the very humble office of gazette-writer under queen Anne; but he now pursued his career as a writer, and in 1704 brought out his comedy of "The Tender Husband," which was acted with great success. This was followed by "The Lying Lover," which was not well received.

In 1709, Steele began a series of periodical papers, which, more than any of his other exertions, has contributed to establish his fame. The "Tatler," with which it began, was formed upon a plan which included the political information of a common newspaper. Its main object was, however, to improve the morals and manners, by holding up to ridicule fashionable follies and vices of every kind, and inculcating just and liberal sentiments on common topics, with a general regard to the proper decorum of social life. The author was fully qualified for this task by a knowledge of the world, acquired in free converse with it, by natural humour and vivacity, and by a generous and benevolent way of thinking. He had likewise the felicity of being able to engage coadjutors of considerable talents, among whom were Addison and Swift. The Tatler was extensively circulated, and as, in its politics, it sided with the minister, Steele obtained the reward of a place among the commissioners of the stamp-dues, which he retained after the dismissal of the ministers who had granted it. In 1711 this paper was succeeded by the more celebrated "Spectator," in which the plan was matured, the politics of the day were rejected, and the assiduity of Addison and other eminent writers was more constant, though Steele continued his own most active services. This work was brought to a close, and the "Guardian" commenced in 1713, and was terminated in the same year. He afterwards engaged in other periodical works, but being subverient to more political purposes, they have all been long since forgotten.

On taking a decided political character against the government, he resigned his post in the stamp-office, and likewise his pension, which he had hitherto received, as having belonged to the household of the late prince, George of Denmark. He was now returned member of parliament for the borough of Stockbridge. He had not taken his seat long before he was expelled as the author of certain publications to which his name was prefixed, and which the house, in its great wisdom, voted to be seditious and scandalous libels. The most noted of these, entitled "The Crixa," was not written, but was characterized as a character, and political conduct. The charge exhibited in this occasion, that the libels, as they were called, contained many expressions highly reflecting upon her majesty, &c. maliciously inflaming that the Protestant succession in the house of Hanover is in danger under her majesty’s administration. Steele met with very able as well as zealous defenders in Addison, the Walpoles, lords Finch, Lumley, and Hinchinbrooke; but the party in power was determined on the sacrifice, and the charge against him was affirmed by a majority of nearly two to one. After his expulsion he engaged in some literary undertakings; but on the accession of George I. he was taken into favour, and was presented with a small appointment under government.

Having procured a licence to be chief manager of the royal company of comedians, he had interest enough to get this licence exchanged for a patent for life as governor of that company. In the first parliament of the new reign he re-entered the house as member for Boroughbridge, in Yorkshire; and in April 1715, he received the honour of knighthood, on presenting an address; and about the same time, the more substantial reward of 500l. was given him by Sir Robert Walpole, for special service. Thus encouraged, his fertile pen produced a variety of political tracts in favour of that cause which seemed at all times to be near his heart, as well in its depressed as in its triumphant state. Having been appointed, in 1717, one of the commissioners for enquiring into the estates forfeited by the late rebellion in Scotland, he went to that country, and was treated in it with great respect, notwithstanding the unwelcome news of the errand on which he was sent. It was on this occasion that he conceived the project of forming an union between the Scotch and English churches, and had several conferences with the Presbyterian ministers respecting the restoration of episcopacy; but his zeal, it is said, was not directed by judgment. He obtained, and with much justice, the character of a projector, which was both the effect and cause of that perpetual embarrassment under which he laboured, and which was principally owing to a radical want of economy, and a strange inclination to expences. He was twice married, and with each wife he had a good fortune; yet he seems to have been always necessitous. In 1718 he had a project for conveying fish to market alive, for which he obtained a patent, which, instead of mending his circumstances, only involved him full deeper in difficulties. His biographers observe, that "it was to be wished that his diffidence had occasioned no other failures than that of money; but there is reason to suppose that they sometimes interfered with the dictates of conscience." Whiston says, that once having met with Steele after a vote in parliament contrary to his former declarations, with which he slightly upbraided him, the knight replied, "Mr. Whiston, you can walk on foot, but I cannot." Steele’s spirit was not, however, formed for implicit submission, and for his opposition to the peerage bill in 1719, he was deprived of his theatrical patent. He appealed to the public, and was restored in the following year. He pleaded the cause of the nation by a pamphlet against the Southsea scheme. In 1722 he brought forward his comedy of "The Conscious Lovers," which was received with great applause. He dedicated it to the king, and was remunerated with 500l.; but his embarrassments pressed upon him; and in addition to his other misfortunes, he engaged in an unsuccessful law-suit. Broken in fortune and constitution, he retired to an estate in Wales, where he died in 1729.

He appears to have been much beloved for the benevolence and warmth of his heart; in understanding, he has been characterized as a shrewd and sagacious man; his productions are lively, but they display neither great force nor accuracy. His style and his train of thinking are equally lax and incorrect. He was a lover of virtue, and frequently painted it in pleasing and attractive colours. His reputation as a writer seems to have been much indebted to the partnerships which he formed; and his name is scarcely entitled to a place among those which throw peculiar lustre upon the period of English literature. Biog. Brit.

Sir Richard Steele, without much taste or science in the art, was a musical critic and projector. His divorce on Nicolini, in the Tatler, No. 115, would have done his taste and judgment honour, if he had not afterwards treated opera in general, when they clashed with his interest in the playhouse, with the utmost contempt. He joined with Clayton, Haym, and Dieupart, in a concert at York-buildings, against the opera; and afterwards employed Hughes to alter Dryden’s Ode on St. Cecilia’s Day for music, to let which he employed Clayton but the plan failed. And he had the room in York-buildings afterwards fitted up a considerable expense; and a rotunda erected for himself to read lectures in, on the drama and other subjects. We have heard, or
or read somewhere (we hope not in Joe Miller), that when
the room was finished, he defined the carpenter to mount
the rostrum and speak a few words, loud, that he might judge
what effect the voice would have at different distances; but
the carpenter pleading his inability to say any thing worth
for Richard’s hearing, excused himself as long as possible;
yet sir Richard persisting in his wish to hear a few words
uttered with a loud voice upon any subject the carpenter
might choose, the carpenter, at length, addressing himself to sir
Richard from the rostrum, cries out, with considerable energy,
seasonable elocution, and a loud voice,—“Sir Richard! you have
done me the honour to employ me as your carpenter several
years, without ever asking for your bill; now if you will but
have the goodness to discharge the debt, I should be much
obliged to your honour.”—“Enough, enough,” cries sir
Richard, “the found is not very agreeable; but I believe
it will do.”
Sir Richard Steele was certainly a man of wit and hu-
mour, and in some of his whimsical writings there were good
intentions; but he seems to have been (says Dr. Burney)
unprincipled politician, an occasional Christian, and a pre-
tending, self-interested and ignorant musical critic.
STEELER, in Ship-Building, a name given to the fore-
mast or aftermost plank, in a strake which drops short of the
flem and stern-post, and of which the end or butt nearest
the rabbet is wrought very narrow, and well forward or aft.
Its use is to take out the faying-edge occasioned by a full
bow, or bulbous, circular buttress.
STEELING, in Carley, the laying on a piece of steel
upon a larger mass of iron, to make that part which is to
receive the edge harder than the rest. The body of the axe
may very well be of iron, as it never comes into use to
cut with, and perhaps is stronger, and less liable to break,
than if of steel; but it must have a quantity of steel at that
part where the edge is to be made.
STEELYARD, or STILYARD, in Mechanics, a kind of
balance, called also "fuseta Romana" or the Roman balance; by
means of which the gravities of different bodies are found
by the use of one single weight.
STEELYARD, Construction of the. It consists of an iron beam
A B (Plate XXXVIII. Mechanics, fig. 6.), in which a point
is affixed at pleasure, as C, and on this, a perpendicular
raised, C D. On the shorter arm, A C, is hung a scale or
balance to receive the bodies weighed; the weight I is shifted
this and that way on the beam, till it be a counterbalance
to one, two, three, four, &c. pounds placed in the scale; and
the points are noted in which I weighs as one, two,
three, four, &c. pounds. From this construction of the steel-
yard, the manner of using it is apparent. But the instru-
ment, being very liable to deceit, is therefore not to be
countenanced in commerce.
STEELYARD, Spring, is a kind of portable balance, serving
to weigh any matter, from about one to forty pounds.
It is composed of a brass tube, into which goes a rod, and
about that is wound a spring of tempered steel in a spiral
form. On this rod are the divisions of pounds and parts of
pounds, which are made by successively hanging on to an
hook fastened to the other end, one, two, three, four, &c.
pounds.
Now the spring being fastened by a screw to the bottom of
the rod; the greater weight is hung on the hook, the more
will the spring be contracted, and, consequently, a greater
part of the rod will come out of the tube; the proportions
of which greater weights are indicated by the figures ap-
ppearing against the extremity of the tube.
STEELYARD, Company of the. See STILYARD.
STEELYARD, Chinese. The people of China carry this
fuseta about them to weigh their gems, and other things
of value. The beam, or yard, is a small rod of wood or
ivory, about a foot in length; upon this are three rules of
measure, made of a fine silver-flapped work; they all begin
from the end of the beam, whence the first is extended eight
inches, the second fix and a half, the third eight and a
half. The first is the European measure, the other two
fuseta. At the other end of the yard hangs a round scale, and at three several distances from this
end are fastened so many slender strings, as different points
of suspension. The first distance makes eight-fifths of an
inch, the second is double to the first, and the third four
inches and four-fifths. When they weigh any thing, they
hold up the yard by some of these strings, and hang a sealed
weight, of about one ounce and one-fourth troy weight, upon
the respective divisions of the rule, as the thing requires.
Grew’s Museum, p. 369.
STEELYARD-Song. In the Philosophical Transactions
(No. 462, sect. 5.) we have an account of the steel-yard
spring, proposed as a mechanical method for affixing children
labouring under deformities, owing to the contraction of the
muscles on one side of the body. The crooked person
is supported with cords under his arm, and these are placed
at equal distances from the centre of the beam. It is sup-
posed that the gravity of the body will affect the contra-
icted side, so as to put the muscles upon the stretch; and hence
by degrees the defect may be remedied.
STEEN, JAN, in Biography, one of the brightest orna-
maments of the Flemish School of painting, was born at Ley-
den in 1619. His father was a brewer in that city, who
perceiving an inclination in his son for painting, placed him
as a pupil with N. Knusser, an historical painter at Utrecht.
That he might not be entirely dependent upon his talents
as an artist, his father established him in a brewhouse at
Delft; but this kindness, which might have secured him
comfort, only afforded him the means of sensual indulgence,
by which he was prone, and which, in a short time, led to the
ruin of the concern; and his father finding him irreclaimably
bent on dissipation, at length abandoned him. He after-
wards became a keeper of a tavern; but this was a more
ruinous occupation than the former, and soon brought on
the calamities his conduct merited; as he was said to be a
more active consumer of his own flores than any of his
customers.
Amidst the interruptions of indulgence and of businees,
he continued constantly to prate the art he had acquired;
prentening generally the scenes and subjects in which he
passed his time and were most congenial to him. The fel-
city, frolic, and fun of low life in the alehouse or other
places of public resort, he treated with the clearest expre-
sion and character; and executed them with a pure tone of
colour, and a freedom of touch peculiarly his own. Some-
times, however, he feared somewhat higher, and entering
the domestic circles of his friends, perpetuated with the great-
est felicity the diversities of character and amusements which
pretended themselves to his observant and intuitive eye. In
no man’s pictures is an observer more amused with variety than
in Jan Steen’s; or more entertained by wit and humour,
unless he be in those of our own Hogarth. His drawing
and composition are in general very good, and his colour ad-
mirable, particularly in parts; but oftentimes his manage-
ment of chiaro-scuro is deficient, and his pictures want air.
While he lived, his works were not in much estimation; per-
haps his vulgar and disorderly habits prevented them from
being known; but since his death, and particularly since
for Joshua Reynolds evinced an estimation of them, they have
risen in value, and are now sold, when of fine quality, at very

R 2

great
great prices, and sought with avidity. He died in 1689, at the age of fifty-three.

STEEN, in Geography, a town of Norway, in the province of Agder, 15 miles N. of Christiania.

STEENBERGEN, a town of Brabant, formerly a place of considerable importance, on the sea-side, with a convenient harbour, but now, in consequence of the recedes of the sea, a league from it; and by this circumstance, as well as the calamities of war, reduced so as to have scarcely the appearance of a town; 25 miles N. of Antwerp. N. lat. 51° 37'. E. long. 4° 11'.—Also, a mountain of Africa, near the Cape of Good Hope.

STEENHOUSE, a town of Scotland, in the island of Pomerania; 7 miles W. of Kirkwall.

STEENKERKE, or Steenkerque, a village of France, in the department of the Somme, where a bloody battle was fought by the allies commanded by William III. king of England, with the French under the duke of Luxemburg, July the 24th., 1692, in which the latter were victorious; 13 miles N. of Mons.

STEENKIRK, Steenburch, or Steenkirk, a town of Flanders; 8 miles W. of Dijmude.

STEENPLaat, a town on the W. coast of the island of Gibio. N. lat. 1° 20'. E. long. 127° 21'.

STEENWORDE, a town of France, in the department of the North, and chief place of a canton, in the district of Hazebrouck; 4 miles E. of Cassel. The town contains 347, and the canton 23,650 inhabitants, on a territory of 150 kilometers, in 9 communes.

STEENWYCK, Henry, in Biography, was born at Steenwyck in 1550. He was a scholar of John de Vries, a painter of perspectival and architectural scenes. Steenwyck surpassed his master in the fame subject, viz. interiors of churches and Gothic buildings, which he painted with great neatness and cleanliness. His colouring is rich and brilliant, but he injured his effects by painting the lights too much in lines, unblended and too sharpened, which destroys the appearance of solidity. He died in 1603, and left a son, Henry Steenwyck, born in 1589 at Antwerp, who excelled him in the same line and manner. He usually painted on a larger scale than his father. Vandyck, with whom he lived in intimacy, recommended him to Charles I., who invited him to England, where he resided several years, and died in London. The pictures of both these painters were embellished with figures by friendly artists, as old Franck, Teniers, Breughel, Van Thulden, &c.

STEENWYCK, in Geography, a town of Holland, in the department of Overijssel, situated on the river Aa, in the country of Zallant, and on the confines of Friesland. It has three churches; 55 miles S.W. of Emden. N. lat. 52° 48'. E. long. 6°.

STEEP, in Agriculture, any kind of liquid or other preparation that is used for steeping any sorts of grain or seeds in, which are destined to be sown for raising crops, in order to prevent disease taking place in them. That which is most highly esteemed by the farmer in common, is a very strong solution of common salt in water, such as will keep up a heavy egg upon its surface. Strong stale chamber-ley, in which common salt has been dissolved, is also much used by some farmers in different situations. And there are other sorts of preparations which have been long tried with this view both for feed-grain and small feeds, not without some effect in preventing the danger from disease, as well as from the attacks and ravages of different sorts of insects in the infant state of vegetation and growth in the different kinds of plants as crops.

Several different sorts of preparations, contrived expressly for the purpose of being applied in this way, are given under our articles Pickle, Steeping of Seed-Grain and Seeds, and Turnip-Flies.

STEEP, in Rural Economy, a term sometimes employed to signify the prepared maw-lkin, bag, or stomach of a calf which is killed when suckling. Those in which the calf is perfectly healthy when killed, has been wholly supported with the milk of the cow, and in which there is found a white currly matter to be present, are the best for the purpose, when well prepared by proper salting and steeping in pickle. See Dairying and Kinnen.

STEERP, in Geography, a small island in the Mergui Archipelago. N. lat. 10° 43'.

STEEP Rocks, a ledge of perpendicular shelly rocks, forming, with some interruptions, the W. bank of Hudson's river, for 12 or 13 miles from the Tappan fea, to within 11 miles of the city of New York. Some of these rocks are from 150 to 200 feet high.

STEEP Point, a cape on the S. coast of the island of Java. S. lat. 7° 41'. E. long. 107° 4'.

STEEPHOLM, a small island in the Bristol Channel, about midway between the coasts of England and Wales. N. lat. 51° 10'. W. long. 3° 7'.

STEEPING of Seed-Grain and Seeds, in Agriculture, the practice of preparing wheat, barley, and other sorts of seeds, before putting them into the ground, by means of steeping, in order to prevent disease. It is observed by Mr. A. Young, who has made a great number of interesting experiments in this way, that the effects of steeping, brining, and timing seed-heat, are innumerable, and all equally intended against the smut. From his experiments it seemed that steeping from twelve to twenty-four hours in a ley of wood ashes, in lime-water, and in a solution of arsenic, gave clean crops from extremely smusty feed, but that a short time in these mixtures had a much less effect.

In the northern districts, the practice of steeping is almost in general use with steep of the chamber-ley and salt kinds with lime, and the following are the practices in two of the principal grain districts in the southern parts of the kingdom. It is stated in the Agricultural Survey of Norfolk, that Mr. Robinson, of Watton, for many years has had no other smut on his farm, than what has been caused by accidently fowling a headland, and finishing a corner of a field with dry feed; but if steeped, the prevention is infallible. His method is, to steep it in a brine made with common salt, of strength to bear an egg, for twelve hours, and then to dry with lime. Mr. Dover, of Hockham, had great plenty of pheasants, but lost them all by using arsenic in steeping his wheat-feed. Mr. Salter, of Winborough, however, dresses with salt and lime, without steeping, and never has the smut; it is only to be concluded, that he has always found clean feed. And Mr. M. Hill flake's the lime with salt, dissolved in a small quantity of water; dips the wheat in a steep in plain water only; lays it on the floor, and incorporates it with salt and lime, and then dries it with lime. Mr. Overman finally his feed well in pump-water, then lays it in a heap to drain, and adds half a pound of salt to every bushel, rolls it well together, and dries with lime; this he finds sufficient against the smut. Whence the writer concludes that his feed is always free from that distemper, or affixed he would find the process to fail, for he does not leave it any time limed.

The salt is dissolved in a very small quantity of water; with this salt and water the lime is flaked, and with this fa...
line preparation in its hottest state the wheat becomes can-
died, having previously been moistened for the purpose of
pure water.

Alto in Hertfordshire, Mr. Byde brines his wheat; he
swims it, but takes it out directly and limes it. And about
Theobalds they make a brine with salt, which will swim a
new-laid egg. They leave the feed from two to four hours
long in this brine, and tair and skim it; they lime it over
night, and then sow it next morning, but if it be kept a
week it will receive no injury; they are however not free
from fumit, and have occasionally much over the whole
country, even from Watford. A steeping of one hour is
trusted to at King's Waltham. Sometimes, when the barley is
be added or
thrown on the feed after brining, it kills the wheat. Mr.
Leach has bought fumity wheat to sow for curiosity, and
even the worst which he could find; he steeped it six hours
in a very strong brine, made to swim a large egg; he dried
it with hot lime and fowled it directly, and had no fumit.
He has tried this several times, always with success. He steeped
clean wheat but three hours. But Mr. Sedgwick steeped his
feed in brine above six hours, then dries it with lime and
fows it directly, and he never has any fumit; he omitted it
three or four years, and suffered severely by such omission.

In the Appendix to the Inquiry concerning the Nature and
Causes of the Blight, &c. some useful practical observations
have been infected from Mr. Blackie, the bailiff of the earl
of Chesterfield, on the farm at Bradby-Hall, in Derbyshire.
It is there stated that it has been found by experience, and
is pretty generally known, that fumity feed-grain of the
wheat kind will produce fumity crops; but it is believed,
that it is not generally understood, that the most fumity
feed, by being properly cleaned, will produce clean crops:
such, however, is the fact; it is said; and it has been found
that the purest feed will, by being properly cleaned, or inoculated,
as it is called, with the dfeased, produce fumity wheat-
crops. It is for the naturalist, it is supposed, to affign
a cause why the disease should be infectious; but it is sufficient
for the practical farmer to know that the fact is indisputably
established, and that it is in every one's power to satisfy himself
on the point.

It is noticed farther, that many farmers have felt themselves
disappointed in not having their wheat-crops clear of
fumit, after having been at the trouble and expense of
changing the feed, and even washing and steeping or brining
that feed, not being aware of the infectious nature of
the disease against which they were guarding; and that the
very means they were taking to clean the feed, were also perhaps
the means of inoculating, impregnating, or infecting
it with the fumity matter. For after the operation of steeping
or pickling is performed, the feed is generally spread
out on the barn-floor to drain, and probably on the very
fame floor where fumity wheat had previously been threshed
out; or perhaps the feed is put up into sacks in which had been
fumity wheat but a short time before. The inoculation
or infection is then, it is said, complete; the feed is
fowled; the produce will inevitably and invariably prove
fumitted; and the farmer naturally feels himself disappointed,
after all his attention, trouble, and expenditure. It would
also, it is said, be prudent in every farmer to see to the
washing and steeping or pickling the feed himself, for if he
trust that operation to servants, he will generally find himself
disappointed.

It has been known that some farmers sow the same wheat
for a succession of years, and with very little preparation or
cleaning of the feed, yet have no fumit in their crops; and
so they may with safety continue to do, so long as they keep
clear of the infection, by not borrowing or lending sacks,
by change of barn, or implements, or of other things em-
ployed about it. It is suggested, that the infection is also
sometimes probably carried from the barn-door, when the
dung is taken green to the fields, without being properly
turned and fermented. It is likely too, it is said, that
there are various other ways by which the infection is com-
municated, but which the careful farmer will guard against,
when he becomes more sensible of the contagious nature of
the disease.

In the result of two experimental trials, which were
made in the years 1807 and 1808, on the same farm, under
the patronage and inspection of the noble owner, there is
much certainty and satisfaction afforded on this important
and interesting subject.

In the first trial, it is said that in the autumn of the pre-
ceding year, his lordship bought a peck of very fumity dis-
 eased wheat from a neighbouring farmer, who had that year
great losses in his crop from fumit. A piece of land was then
set apart for the trial; one half of the wheat was sown in the
state in which it was bought, and the result proved, it is said,
as might be expected, two-thirds of the produce being fumit.
The other half peck was washed as clean as possible, chang-
ing the water three times, and then put into a brine or steep
some time enough to carry a new-laid egg, in which it remained
two hours, being stirred up twice in the course of that time;
when taken out it was dried over with quick-lime, and
fowled on the other half piece of land; the result, it is said,
proved entirely satisfactory, as it produced a full crop of
fine wheat, without a single ear of fumit.

In the second trial, in the preceding autumn also, his
lordship, by way of change in the feed-grain, had the whole
of his feed-wheat from Dunstable: it was fine, it is said,
and perfectly free from fumit. Six ears of the fumity kind
were fawed from the crop of the preceding year's trial;
they were put into a small bag, and rubbed therein; the
fumity grain was then carefully shook out of the bag, so
that there only remained the black duft: a quart of Dun-
stable wheat was then taken, and although perfectly clean
at the time, was washed in three waters, and then put into
the fumity bag for the purpose of inoculation, or being im-
regnated with the infection; it was shook in the bag, in
which it remained two days, and was afterwards sown. The
result is stated to have been highly satisfactory in proving
the effect of inoculation, as a very great proportion of the
produce was entirely fumit; while out of twenty acres sown
with the same feed-grain not inoculated or infected by the
fumity matter, not one fumity ear was found, although care-
fully examined expressly for that purpose.

These trials are said to be known, and to have been seen
by many farmers and other persons in the neighbourhood.
And that the inoculated wheat, on being cut and carefully
threshed out, was kept for the purpose of being flown to
any person who might think it worth while to examine it.

It is further noted, that since the advance in the price
of salt, the expense of good brine for steeping or pickling
feed-wheat has become a consideration to farmers, and that
in consequence, various substitutes have been adopted, fre-
quently not efficacious.

It is thought too, that it would be very advisable, in ad-
dition to all other precautions, that the feed should be well
washed, and all the refuse scummed off from the surface of
the liquid made use of for that purpose.

All above observations and results are strongly enforced,
and flown to be correct by the following statement. In the
autumn of 1805, after having finished the wheat-feeding on
the above farm, a neighbouring farmer was advised to feed
for the steep or pickle which was left. He has suffered
much
much in former years from the smut, and previous to his fencing for the pickle, had that year four half of his wheat field drained or flaked in his usual way; the remainder of the seed was well washed, was steeped or pickled, and proper precautions taken in the manner directed above; the result was quite satisfactory, as the crop from the first fown seed proved full of smut; whereas there was not one smutty ear to be found among of the latter fown seed.

On the nature and cause of the disease there are so many notions and opinions, that, it is said, one farmer fits down contented with his crop of flaked wheat, under the idea that it has been caused by something pernicious in the atmosphere; another thinks that it is owing to the nature of the soil, which he concludes to have always grown smutty wheat; and a third, who is better informed on the matter, conceives that it proceeds from the feed, which, though brought from a distant district for the sake of change, and appearing to be pure feed, yet was the means of commenting the smut, contends that it is of no use to change the feed, as he is still liable to get smutty wheat; various other causes of the disease are also maintained by others, which need not be here noticed.

It may be reasonably concluded, that it has surpassed the writer much, that sensible practical farmers and agriculturists should still remain so greatly prejudiced, even against their own interests, as not to endeavour to eradicate or remove this pernicious disease, when it is certainly within their power so to do. The means by which it is thought possible to accomplish so desirable an object, are, it is said, first to impress on the minds of all such persons, that the disease originates with the feed; secondly, that it is in a high degree infectious; and, thirdly, that the same preventive and cure are to be effected by proper care and attention to the established practices of well washing, and bruising, steeping, or pickling the feed.

In short, there has been such a variety of contradictory opinions and conclusions entertained in relation to the use and efficacy or advantage of steeping and preparing feed-grain, that nothing could hitherto scarce be attempted or established upon any thing like a satisfactory or scientific basis; but the result of the whole of what has been stated from the above experiments and trials would seem to direct and lead to greater correctness and certainty in the principles and practice which are to be pursued, as it shows, that the disease to be guarded against by them is of a very infectious kind, even when in the smallest and most minute portions of the seed-grain, and probably that the infection lies in the black powdery matter which adheres to the grain; consequently that every sort of washing, steeping, and perhaps rubbing, may be of some benefit, but especially the two first, when performed with sufficient care, attention, and caution in every way, and for a proper length of time. When, in spite of such care and precaution, some ears of a crop may become diseased, it must be the consequence of some minute particles of this black powdery material still adhering, in defiance of every effort for their removal, to the feed-grain.

The accidental occurrence of the disease in such cases, may, however, as has been seen, sometimes originate from incaution and the imperfect execution of the means which are made use of for the purpose, in the barns or other familiar places, as well as from slight portions of the powder substance being incalculably carried or conveyed into the fields in a variety of different ways, as by the facks with the grain, the hoppers, the feed-lips, and numerous other modes.

In regard to the use of steeping feeds of the turnip and other small field kinds, it has been noticed by a late writer on agricultural chemistry, that these are different preparations and menstrua of the chemical kind which render the process of sprouting or germination much more rapid than usual, when the seeds have been steeped in them. As in these cases the feed-leaves are quickly protruded and produced, and more speedily perform their functions, it was proposed as a subject of experiment to examine whether such menstrua and preparations might not be useful in raising the turnip in a more speedy manner to that state in which it would be secure against the attacks of insects, especially the fly, which is so destructive to it; the result, however, it is said, proved that the practice was inadmissible; as seeds so treated, though they germinated much quicker, did not produce healthy plants, and often died soon after sprouting.

In the month of September 1807, radish-feeds were steeped for twelve hours in a solution of chlorine, and similar feeds in very dilute nitric acid, in very dilute sulphuric acid, in weak solution of oxy sulphate of iron, and some in common water. The feeds steeped in solutions of chlorine and oxy sulphate of iron, threw out the germ in two days; those in nitric acid in three days, in sulphuric acid in five days, and those in common water in four days. But, it is said, in the case of premature germination, though the plume was very vigorous for a short time, yet it became at the end of a fortnight weak and sickly; and at that period less vigorous in its growth than the sprouts which had been naturally developed, so that there can be scarcely, it is thought, any useful application of these experimental trials. Too rapid growth and premature decay seem invariably, it is supposed, connected with organized structures; and that it is only by following the new operations of natural cauuses, that we are capable of making improvements. See Tunntre.

However, if the result of these trials should be confirmed by further ones, and more full and complete experience, although steeping feeds of these kinds in these sorts of preparations may not be capable of being usefully had recourse to in the above intention, it may often be beneficial for promoting the healthy sprouting and early growth of these and many other sorts of small seeds in very dry times and hot parching seasons, as well as, in common water, for dwarfing them of various sorts of extraneous matters and light in imperfect seeds. Many of the preceding observations may be applied with advantage by the gardener, in steeping peas and beans, &c. as well as the nuts, kernels, and frames of many different sorts of plants and fruits.

STEEPLE, an appendage generally raised on the western end of a church to hold the bells. Steeples are denominated from their form, either spires or towers. The first are such as ascend continually, diminishing either conically or pyramidal.

The latter are more parallelepips, and are covered at top, platform like.

In each kind, there is usually a fort of windows, or apertures, to let out the sound; and so contrived, at the same time, as to drive it down.

Mafius, in his treatise of bells, treats likewise of steeples. The most remarkable in the world is that at Pisa, which leans all to one side, and appears even now ready to fall; yet is in no danger. This odd disposition, he observes, is not owing to a shock of an earthquake, as is generally imagined; but was contrived for at first by the architect; as is evident from the ceilings, windows, doors, &c. which are all in the level.

STEER, Hog-starr. See HoO and Ox.

STEERAGE, in a Ship, that part of the ship shaft where
where the tiller traverses between decks. In merchant-ships, it is the space between the companion-ladder and the captain's cabin. In large ships of war, it is used as a hall, through which it is necessary to pass to or from the great cabin. In merchant-ships, it is generally the habitation of the inferior officers and ship's crew.

**STEEERING** is also used to express the act of directing a ship's way from one place to another, by means of the helm and rudder, or of applying the efforts of the helm to regulate her course when the advances.

He is held the best steerman, who uses the least motion in putting the helm over to and against, and who keeps the ship left from making yaws; that is, from running in and out.

For this purpose the helmsman should diligently watch the motion of the head by the wind, and, seeing the wind is fair or large, give the proper indications by the helm or rudder. He should note the effect the helm has on the ship's movement, and use the least amount necessary to bring the ship up to the desired course.

The steering wheel, in **Ship-building**, is the wheel on the quarter-deck, to which the tiller is connected by a sufficient number of turns round its barrel, by turning of which the helm is moved from one side to the other with the greatest ease.

**STEERING**, in **Rural Economy**, a term applied to young growing oxen, in contradistinction to **OXEN**.

**STEEVENS, GEORGE**, in **Biography**, the most successful of all the editors and commentators of Shakespeare, born at Poplar in the year 1725 or 1726, was the son of an East India captain, afterwards a director of the company. The subject of this article received the elements of his education at King's College, Cambridge, and having acquired a large portion of classical literature, with a general taste for learned pursuits, he devoted his time and fortune to the study and collection of books.

On the first establishment of the **Essex militia** he accepted a commission, but he spent the concluding years of his life in almost total seclusion from the world, seldom mingling with society, but was found either in the shops of booksellers, in the Shakespear gallery, or in the morning conversations of Sir Joseph Banks.

Although not an original writer, he deserves a place among the chief literary characters of the age, considering the works which he illustrated, and the learning, sagacity, taste, and general knowledge which he constantly exhibited in his writings. With a great versatility of talents, he was eminent both by his pen and pencil; but his chief excellence lay in his critical knowledge of an author's text; and the best specimen which he gave of his great talents is his edition of the works of Shakespeare, in which he is said by competent judges to have left all competitors far behind him.

He had studied the age of Shakespeare, and employed a very large portion of his life in becoming acquainted with the writings, manners, and laws of that period, as well as the provincial peculiarities, whether of language or customs, which prevailed in different parts of the kingdom, but more particularly in those in which Shakespeare lived the early years of his life. He was continually increasing this store of knowledge by the acquisition of the obsolete publications of a former age, to obtain which he spared no expense. His critical sagacity and observation were constantly employed in calling forth the hidden meanings of the dramatic bard. In preparing his last edition for the press, he gave a very singular example of diligence and perseverance. To this work he exclusively devoted a period of full eighteen months, during which he left his house at Hampstead every morning at one o'clock, and coming to London, without any regard to the weather, or the season of the year, he found a proof-sheet of Shakespeare ready for his perusal and correction. Thus, while the printers slept he was awake, by which means he completed in about the time already mentioned his splendid edition of the works of Shakespeare, in 15 vols. 8vo.

Mr. Steevens died in the year 1800, at the age of about 65 years. He bequeathed his valuable copy of Shakespeare, illustrated with 300 prints, to Lord Spencer; his Hogarth, which was perfect, with the exception of two prints, he bequeathed to Mr. Windham; and his corrected copy of Shakespeare, with 200 guineas, he left to Mr. Read, at whose chambers he always corrected the proofs of his work in the silence of night.

Mr. Steevens was a man of great wit, and indulged his propensity freely, not only in conversation, but in various other modes in which he threw ridicule upon some of his antiquarian friends, whom he was fond of leading into errors. "His satire was severe and not without malignity, and his character seems to have been far from amiable, though he is said to have been bountiful, on many occasions, to perfons in distress." He was indefatigable in every thing which he undertook, but subject to caprice in his habits and attachments.
the elevation of a ship's cathead or bowsprit above the stem, or the angle which either makes with the horizon.

STEVING, in *Merchant Ships*, is used for the flowing of cotton or wool, by means of sclers, to force it closer together.

STEFANO, called *Il Fiorentino*, in *Biography*, is the only one of Giotto's scholars who aimed at something beyond the mere imitation of his master, whom, according to Valari, he surpassed. He was born at Florence in 1301, and was the grandson of Giotto, by a daughter called Caterina. He was the first who attempted foreshortening; and if he failed of complete success, he certainly corrected perspective, and gave more varied turns, more character, and greater vivacity to heads. His most accredited works in the church of Afa Celi at Rome, Sta. Spirito at Florence, and elsewhere, are no more. No authentic record of his remains, unless we except a Madonna in the Campo Santo at Pisa, undoubtedly in a greater style than the works of his master, but retouched. He died in 1350, aged 49. Fueller.

STEFANO, TOMASO, according to Baldinucci, was the son and disciple of the foregoing artist, and born at Florence in 1324. He acquired the name of Il Giottino, from the great reemphasis of his works to those of Giotto. A Pia, which still remains of him at S. Remigio at Florence, and some frescoes at Assisi, bear indistinguishable marks of that style. He died at Florence, at the age of 52.

STEFANI, AGOSTINO, a disciple of the elder Bernabei, was born in 1615. Though Walther and most of the Germans, who wish to rank him among their countrymen, say that Leipzib was the place of his birth; yet Handel and the Italians make him a native of Castello Franco, in the Venetian state. He was a chorister at St. Mark's during his youth, where his voice was so much admired by a German nobleman, that, obtaining his dismission, he took him to Munich in Bavaria, and had him educated, not only in music under the celebrated Ercole Bernabei, but in literature and theology sufficient for priest's orders; in consequence of which, after ordination, he was distinguished by the title of abate, or abbot, which he retained till late in life, when he was elected bishop of Spiga. In 1674, at the age of 19, he published his "Psalms," in eight parts. He likewise published "Sonate a 4 Stro-menti," but his chamber duets are the most celebrated of his works, and, indeed, of that species of writing. In his little tract, "Della certezza Del principij della Musica," he has treated the subject of musical imitation and expression, according to P. Martini, like a philosopher, and agreeable to mathematical principles. This work, written in Latin, which we have never seen, was held in such high estimation in Germany, that it was translated into the language of that country, and reprinted eight several times. Walther and Marpurg have given the following list of Italian musical dramas or operas, which the admirable Stefani set for the court of Hanover, where he resided many years as maestro di capella: "Alejandro," "Orlando," "Enrico," "Alcide," "Alcibiade," "Atalanta," and "Il Triunfo del Faro," which were afterwards translated into German, and performed to his music, between the years 1655 and 1660, at Hamburg. About the year 1724 he quitted the court of Hanover, when he is said to have resigned his office as maestro di capella in favour of Handel. He was elected honorary president of the Academy of Ancient Music in London. In 1725 he went into Italy, to see his native country and relations, but returned the next year to Hanover. However, soon after, having some business to transact at Frankfort, he was there seized with an indis-}

position, of which in a few days he died, at near fourscore years of age. There are perhaps no compositions more correct, or fugues in which the subjects are more pleasing, or answers and imitations more artful, than are to be found in the duets of Stefani, which, in a collection made for queen Caroline, and now in the possession of his majesty, amount to near one hundred. The greatest fingers of Italy during the last age used to exercise themselves in these duets, as folleuggi. Mrs. Anne, the widow of Dr. Arne, and scholar of Gemignani, who sung in fewer of Handel's latter operas, has frequently assured us, that she had often heard Scuclino, the Strada, and other eminent opera singers, sing them during their morning studies. They were then in the best melody of the times; but, at present, there are very few passages which opera singers would be likely to meet with in parts of the operas of the present day.

STEFT, in *Geography*, a town in Germany, in the principality of Ansbach; 3 miles S.S.W. of Maynernheim.

STEG, in *Rural Economy*, a provincial term sometimes applied to a gander. Stegs which are of some age are always better than such as are too young, in the management of geese and their young flocks.

STEGETANIA, in *Botany*, so named by Mr. R. Brown, from *styga*, closely covered, is a genus of ferns, separated by that learned botanist from *Blechnum* and *Pteris*, in his Prodr. Nov. Holl. v. 1. 152. Its character is made to consist in the linear assemblages of capules, *Sori*, covering the frond, or the contracted fructifying portions of it, entirely, the involucrum being marginal, opening at the inner edge, and uninterrupted. The habit of the genus, of which eight New Holland species are defined in the work above cited, is said to be like *Blechnum*, while the character is not always distinguishable from that of *Pteris*. It is hinted that *Blechnum boreale*, Fl. Brit. 1135, and *Pteris crispis*, ibid. 1137, may perhaps belong to *Stegania*. A genuine example of this genus is, however, *Onoclea nuda*, Labill. Nov. Holl. v. 2. 96. t. 246. *Blechnum procumbens*, ibid. t. 247. *Stegania procumbens*, Br. n. 8, seems, by the figure, to be a real *Blechnum*, the infestation of the involucrum being not strictly marginal, scarcely more so indeed than in *B. boreale*, of whose genus we cannot entertain a doubt. In this state of things we hesitate to admit *Stegania*, left all its species, if examined at a proper period of growth, should prove to have an involucrum not originating from the margin, however near that part it may be inferted.

STEGANOGRAPHY, *στηγανογραφία*, formed from *στηγανό*, secret, and *γραφία*, to write, the art of secret writing, or of writing in cyphers; known only to the persons corresponding. See CIPHER and DECHERERING.

STEGEBORG, in *Geography*, a town in Sweden, in East Gotland; 8 miles N. of Calmar.

STEGEN, a town of Norway, in the diocese of Drontheim; 100 miles N. of Drontheim.—Alfo, a town of the duchy of Holstein; 15 miles S.E. of Braemsted.—Alfo, a small island in the North sea, near the coast of Lapland. N. lat. 67° 30'.—Alfo, a town of Prussia, in the province of Natangen; 14 miles S. of Braunsburg.

STEGNOSIS, *στεγνώσις*, an obstruction of any natural discharge, especially that by the pores.

STEGNOTICS, *στεγνώτικα*, formed from *στεγνό*, close, *con spirao*, I close, in *Medicine*, remedies proper to close and stop up the orifices of the vessels, or emunctories, when relaxed, stretched, lacerated, &c.

Such are pomegranate leaves, red roses, plantain leaves, tormentil roots, &c. Stegnotics are proper in the hemorrhoids, and other fluxes of blood.

STEGOSIA,
STE

STEGOSIA, in Botany, so called by Loureiro, Fl. Cochinch. 51. from creos, a roof, is a genus of grallae established by that author, which proves not distinct from Rottbollia. (See that article.) The original specimen of Loureiro's only species, sent by him to Sir Joseph Banks, was found by Mr. Brown to be R. casperata, Linn. Suppl. 114. It is used in Cochinchina for thatch.

STEN, in Geography, a town and fortress of Bades, on the east side of the Rhine; 4 miles S. of Worms. — Alfo, a town of the duchy of Baden; 3 miles E. of Carlribe. — Alfo, a town of the duchy of Carinthia, with a castle, on the Drave; 2 miles S. of Chagensfurth. — Alfo, a town of Saxony, in the lordship of Schonburg; 7 miles S.E. of Zwicau.

STEIN, or Kamnetz, a town of the duchy of Carniola, on the Feilir; 10 miles N. of Laybach. N. lat. 46° 22'. E. long. 38° 20'.

Stein am Rein, a town of Switzerland, in the canton of Zurich, situated on the north side of the Rhine, at the west extremity of the lake Zell, with a bridge over the river. This town was surrounded with walls, in the year 966, by Burcard, the second duke of Swabia, who endowed it with several privileges; and in the year 1005, the convent, founded by his consort at Hohenweil, was removed to Stein, and continued in this place, under the government of an abbot, till the time of the reformation. In 1437, the town devolved upon the family of Hohenklingen, and in 1435, both the seat of that name, which is still standing above the town, and the town itself, was sold to the Klingen family; and in 1457, the burghers redeemed themselves, and soon after entered into an alliance with Zurich and Schaffhausen. In 1484, retaining their liberties and privileges, they put themselves under the protection of Zurich, as they continue to this day. At the period of the reformation, Stein, in conjunction with most of its contiguous titulars, embracing Protestantism, the convent was suppressed; and in 1524, Zurich appointed a bailiff to superintend and collect its revenues. The high and low jurisdiction is lodged in the town, the magistracy of which is composed of burgomasters, and a council, who are all natives, and of its own nomination; excepting the judge and his conseiller, who are appointed by the city of Zurich, though even these must be burgesses of Stein. The fore-mentioned seat of Hohenklingen is converted into a watch-tower, and the caffellian refides in it. On the other side of the Rhine, in a place called "Burgh," opposite to the town, is a church, seated on an eminence, and belonging to Stein. Some are of opinion that this is the site of the castle of a Celtic town, called "Gauonduriam," which is supposed to have extended to the village of Eschenz; 10 miles E. of Schaffhausen. N. lat. 47° 39'. E. long. 8° 50'.

Stein, a town of Germany, in the margraviate of Anspach, on the Redneck; 28 miles E.N.E. of Anspach.

See Stein.

STEINA, a town of Bavaria, in the bishopric of Bamberg; 6 miles W. of Burg Eberach.

STEINACH, a town of the duchy of Steiria; 11 miles W. of Rottenmann. — Alfo, a town of Lechens, which runs into the lake of Constance, 2 miles W. of Rofbach. — Alfo, a town of Bavaria, in the bishopric of Bamberg; 2 miles N.E. of Burg Eberach.

STEINACH, or Stadt Steinach, a town of Bavaria, in the bishopric of Bamberg; 30 miles N.E. of Bamberg. N. lat. 50° 11'. E. long. 11° 37'.

STEINACH, a town of the duchy of Wurzburg; 5 miles N. of Munderhaut.

STEINACH, Ustra, a town of Germany, in the principality of Coburg; 5 miles E. of Bayreuth.

VOL. XXXIV.

STEINACH, a river of Wurtemberg, which rises S. of Neifen, and runs into the Neckar, near Nurtingen. — Alfo, a river which runs into the Maine, 1 mile S. of Zeulen, in the bishopric of Bamberg.

STEINACH, Markt, a town of the duchy of Wurzburg; 3 miles E.N.E. of Schweinfurt.

STEINACH, a town of Ania, on the Little Erfall; 10 miles S. of Ips.

STEINAM ANGER, or Szombathely, a town of Hungary, built on the ruins of an ancient Roman town, called "Sabaria;" 48 miles S. of Vienna. N. lat. 47° 50'. E. long. 16° 58'.

STEINAU, a town of Sileia, and capital of a circle, in the principality of Wohlan, on a small river near the west side of the Oder; containing two churches, and some manufactures of cloth. It has had the misfortune of being sacked and burned in several successive wars; 80 miles W.N.W. of Wohlan. N. lat. 51° 32'. E. long. 16° 24'.

STEINAU, or Szczawa, a town of Silesia, in the principality of Oppeln; 22 miles S.S.W. of Oppeln. N. lat. 50° 18'. E. long. 27° 18'.

STEINAU, a town of Germany, in the county of Hassau-Munzenburg; 16 miles S.W. of Fulda. — Alfo, a town of Germany, in the duchy of Bremen; 24 miles N.E. of Carlburg. — Alfo, a river of Sileia, which runs into the Nyele, opposite to Löwin.

STEINBECH, a town of Germany, in the lordship of Schwarzenberg; 3 miles E. of Schainfeld. — Alfo, a town of Germany, in the county of Henneberg; 5 miles E. of Smalkalden. — Alfo, a town of Austria; 6 miles S. of Steyr. — Alfo, a town of Germany, in the principality of Naflau-Dillenburg; 6 miles N.N.W. of Dillenburg. — Alfo, a town of the duchy of Baden; 5 miles W.S.W. of Gerzschach.

STEINBECH, Langen, a town of the duchy of Baden; 3 miles N.W. of Baden.

STEINBECK, a town of Prussia, in the canton of Stettin; 24 miles S. of Brandenburg.

STEINBERG, a town of Bavaria, in the bishopric of Bamberg; 3 miles N. of Cronach. — Alfo, a town of Weitphalia, in the county of Lippe; 10 miles E.N.E. of Lemgow. — Alfo, a mountain of Welfphalia, in the principality of Calenberg, near Minden. — Alfo, a town of Saxony, in the circle of Erzgebirg; 14 miles S.S.E. of Freyberg. — Alfo, a town of Germany, in the county of Hennep; 3 miles E. of Rombild.

STEINBERGEN. See Steenberg.

STEINBIZA, in Ichthyology, a name given by Hildegard, and some other writers, to that small species of carp, called by others carasius aculeatus, and tenia cornuta. It is the carp with a forked spine under each eye, described by Artedi.

STEINEA, in Geography, a town of Switzerland, belonging to the canton of Zurich, in the Thurgrau; 4 miles N.E. of St. Gall.

STEINFURT, or Burg Steinfurt, a town of Germany, and capital of a county, to which it gives name, on the Rhine; 17 miles N.W. of Munster. N. lat. 54° 15'. E. long. 7° 15'.

STEINFURT, a town of the duchy of Wurzburg; 3 miles W.S.W. of Hasfurt. — Alfo, a county and principality of Germany, surrounded by the bishopric of Munster, about 35 miles in length, and from five to eight in breadth; raised to be a principality of the empire in the year 1495. Part of the territories belonged to the bishop of Munster, and part to the count of Benthem. To a Roman month it contributed 7 florins 32 krueckers, and it was taxed to the imperial chamber 30 rixdollars 44 krueckers.

STEINFURT, or Dernsteinfurt, a town of Germany, in the
the bishopric of Munster; 11 miles S. of Munster. N. lat. 51° 28'. E. long. 8° 31'.

STEINHARD, a town of Germany, in the principality of Anspach; 5 miles S.S.E. of Waffertudingen.

STEINHAUS, a town of the duchy of Sturia; 4 miles N.E. of Muertenzenberg.

STEINHAUSEN, a town of Switzerland, in the canton of Zug, at the north end of the lake of Zug; 2 miles N.W. of Zug.

STEINHEID, a town of Germany, in the principality of Coburg; 9 miles N.N.E. of Coburg.

STEINHEIM, or Ober Steinheim, a town of Germany, in the circle of the Lower Rhine, on the Main; 2 miles S. of Hanau.

STEINHEIM, a town of Westphalia, in the bishopric of Paderborn; 14 miles N.N.E. of Paderborn. N. lat. 51° 47'. E. long. 9° 54'.

STEINHEIM am Mähr, a town of Wurttemberg; 10 miles N. of Stuttgart.

STEINHOF, a town of the Helvetian republic, in the canton of Berne; 16 miles N. of Berne.

STEINHOF, a town of Germany, in the county of Schauenburg, on the south side of the Steinhuder Meer; 13 miles N.W. of Hanover.

STEINHUDER MEER, a lake of Germany, in the county of Schauenburg, six miles long and two broad; 12 miles N.W. of Hanover.

STEINHUN, STONEHEN, in Ornithology, a name given by the Germans to a bird of the lagopus kind, more commonly known by the name of otoa, and in some places by that of colomys.

It seems not to differ from the lagopus in any thing but colour, and that bird being known to change its colour in the summer months, it is probably no other species.

STEINHURST, in Geography, a town of the duchy of Holstein, with a castle; 25 miles E.N.E. of Hamburg.

STEINING, a term used for the lining of stone or bricks to a wall, shaft, or tunnel pit.

STEINISNAK, in Geography, a town of Croatia; 10 miles E.S.E. of Carilid.

STEINKIRCHEN, a town of the duchy of Bremen; 10 miles S.E. of Strande.

STEINORT, a town of Prussia, in Norderney; 52 miles S.E. of Königberg.

STEINPLEISZ, a town of Saxony, in the circle of Erzgebirg; 5 miles W.S.W. of Zwickau.

STEINDORF, a town of Saxony, in the circle of Neustadt; 3 miles S. of Weyda.

STEINSTADT, a town of the duchy of Baden. In October, 1706, the French were defeated here by the Austrians; 16 miles S. of Friburg.

STEISBEL, a mountain of Hungary; 4 miles N. of Kemnis.

STEITZ, a town of Germany, in the principality of Anhalt Zerbst; 6 miles S. of Zerbst.

STEKAN, in Commerce, a liquid measure in Holland. Rhine and Mofel wine, and also spirits distilled from corn, are sold by the am, which contains 4 ankers, 8 rekans, 21 viertels, 64 flours, 128 mingles, 256 pints, or 1024 mussels; and which holds 8956 Dutch, 7705 French, or 9351 English cubic inches, or about 404 English wine gallons. Lined and rape-feed oil is sold in saums of 7½ rekans, or 130 mingles, weighing about 186 lbs. wovindouro.

Train-oil is sold in quarters of 18 or 21 rekans; also in vats of 13 rekans, or 253 mingles. The mingel of 2 pints, or 8 muelles of rain-water, weighs about 2 lbs. 4½ oz. Amsterdam weight: 10 mingels = 6 English wine-gallons, and 27 mingels = 7 English beer-gallons. A vat of oil of olives contains 717 mingels, and weighs 1750 lbs. avoirdupois: 19.83 rekans of Amsterdam = 100 English gallons, and each rekan = 1165 cubic inches.

STEKBOREN, in Geography, a town of Switzerland, in the Thurgau, on the south side of the lake of Zell; 7 miles W. of Constance.

STEKEN. See STEKKEN.

STEKENITZ. See STEKENEK.

STELL, in Ancient Geography, the name of a town in the island of Crete, near Pareaus. Steph. Byz.

STELL, Erota, in Antiquity, a kind of punishment, being a pillar whereon a criminal was exposed, and on which was engraved an account of his crime.

The persons thus exposed to the laughter and reproaches of the people, were called stelis. Potter, Arch. Graec. lib. i. cap. 25. tom. i. p. 130.

STELECHIA, a word used by some authors to express the vena porte.

STELECHITES, in the Materia Medica, a name given by Dioscorides, and some other of the Greek writers, to a peculiarly fine kind of florax. It was the same with the florax calaminus, only that its calamine or catalamine was of a larger, and the name catalamine to the smaller or slenderer pieces. Pliny, Strabo, and many others, join in telling us, that the wood of the florax-tree, on account of its softness and sweet taste, was the most subject to be eaten by worms of that of any tree in the world.

When the worms attacked the body of the tree, the dust they made by their erosis formed a hillock or heap round the tree, or at its foot, and the extravasated balsam running about this dust, made a mafs that was called the cymatium florax at that time, and was the same with the common florax now in use.

STELLERICHEE Stelis Facis, in Natural History, a very uncouth name given by Aldrovandus, and some others, to the entrochi. He gave them this name from the resemblance of some of the longest pieces to fragments of the trunks of trees, the arms parting out from the sides of these main branches, the rudiments of which are very frequent in many of the entrochi, paling for the remains of bougles, and the hollow in the middle, for the cavity where the pith of the plant was. The addition of stelis facis was only from the observing that the top and bottom were radiate to or frigated, from the central hole to the circumference, in the manner of antimony. These are truly no vegetable remains, but parts of the arms of that strange fish called stella arborifera. See Star-Fish.

STELERCHIS, a stirrup, or an instrument used in the baths to rub off the sweat from the skin.

STELENDA, in Ancient Geography, a country of Asia, in Syria, near the delents of Palmyra. Pliny.

STELHAVEN, in Geography, a town of Holland; 3 miles S.W. of Gertrudenburg.

Gen. Ch. reformed. Cal. Perishath of three equal, ovate, keeled, somewhat concave leaves, cohering at the base. Car. Petals two, distinct, much smaller than the calyx, oblong, concave, vaulted over the columns. Nectary a lip without any spur, of the same, and nearly the shape, of the petals, somewhat emarginate, inflexed at the edge. Stem. Anther a vertical moveable deciduous lid, of two cells; masses of pollen globular, at length waxy, solitary. Pjst. German inferior,
STELIS.

inferior, ovate; style very short, dilated, hollowed, with three teeth, at the summit; stigmas in front, near the anther, convex. Peric. Capsule oval, with three angles and three furrows, one cell and three valves; the uppermost furrow keeled.

Section 1. Inflorescence terminal.

1. S. ophiodon. Adder's-tongue Stelis. Swartz Ind. Oec. 1551. Willd. n. 1. Ait. n. 1. (Epidendrum ophioglossiodes; Linn. Sp. Pl. 1553. Jacq. Amer. 225. t. 133. f. 21; extr. Smaller's synonymy. E. trigonorrhizum; Swartz Prodr. 125.)—Stem with a solitary, oblong-lanceolate leaf, about the length of the spike. Cloised flowers three-flowered.—This grows on the stems and branches of trees, in the mountainous woods of Jamaica, and other islands of the West Indies, flowering in July and August. The pinnate root consists of numerous long, simple, zigzag, whitish fibres. Stems several, two or three inches high, simple, clothed with compresse, oblique, tubular, membranous sheaths, and bearing at the top one coriaceous, ribbed, blunth, nearly elliptical leaf, two or three inches long, on a short twisted footstalk. Spike generally solitary, axillary, stalked, erect, slender, simple, rather taller than the leaf, bearing numerous, alternate, small, ovate, acute bracteas. Flowers very minute, nearly or quite ellow, flat at the base, when closed perfectly triangular. Calyx pale green. Petals light red. Lip dark purple. Anther purple.

2. S. micrantha. Small-flowered Stelis. Swartz Ind. Oec. 1553. Willd. n. 2. Ait. n. 2. Sm. Exot. Bot. t. 28. 31. t. 75. (Epidendrum micranthum; Swartz Prodr. 125.)—Stem with a solitary, lanceolate leaf, shorter than the spike. Cloised flowers fix-flowered.—Found on trees, and at the sides of rocks, on the lofty mountains of Jamaica. Swartz. The marquis of Blandford received it from thence in 1805, and it flowered in his lordship's flower in November 1806. This has the habit of the preceding, but is rather larger, with a longer, stronger, narrower, leaf. The flowers are numerous, revolved in their position, but we know not whether this character is proper to the whole genus. When closed, they form a roundish fix-flowered figure. Calyx green. Petals and lip, as well as the column and anther, of a dark brownish-purple.

3. S. acutifolia. Sharp-flowered Stelis. Willd. n. 3.—

4. S. lanceolata. Lanceolate Stelis. Willd. n. 4.—

5. S. polyrhachis. Many-spiked Stelis. Willd. n. 5.—

6. S. obliqua. Long-leaved Stelis. Willd. n. 6.—

8. S. revoluta. Revolute Stelis. Willd. n. 8.—

9. S. cordata. Heart-shaped Stelis. Willd. n. 9.—

10. S. racemosa. Yellow Racemose Stelis.—Leaf lanceolate, emarginate, on a short footstalk. Clusters radical, nearly sessile, deflexed.—Found by Dr. F. Buchanan, on trees in Upper Nepal. The root is thread-shaped, creeping, fixating itself at intervals by means of tufts of numerous fibres, from the crown proceeds a green ovate bulb, an inch long, bearing an erect leaf, measuring, with its short footstalk, four or five inches. Clusters solitary from the bases of some of the bulbs, each four inches long, pendulous, on a short footstalk, enveloped in membranous sheaths. Flowers about ten, rather ditant, revolved, each on a very short partial footstalk, accompanied by a lanceolate membranous bracteas equal to the germin, or longer. Calyx-leaves yellowish-green, about half an inch long, equal, lanceolate, erect; one of them gibbous at the base. Petals very short, obtuse, of the same hue. Lip short, ovate, thick, entire, revolute.

11. S. hirta. Hairy-flowered Stelis.—Leaf ... Spike radical, cylindrical, on a long footstalk, drooping. Calyx hairy. Gathered by Dr. Buchanan, on mossy rocks in Upper Nepal, flowering in January. The inhabitants call it Sunipia, whence Dr. Buchanan named all the species of this section Sunipia, as composing a new genus. The difference of their habits from the original Stelises countenances this measure, but we are not distinctly enough acquainted with the precise structure of their flowers, to deduce a character from thence. The species before us has a creeping root, with crowded owate bulbs. Of its leaves nothing is known. The flower-stalks are solitary, from the base of each bulb, erect, a span high, with a few scattered sheaths; and each bears a dense drooping spike, nearly its own length, of very numerous, viscid, highly fragrant, crowded flowers, of the size and shape of the last, but remarkable for their calyx being all over finely hairy on both sides.

12. S. odoratissima. Capitate Fragrant Stelis.—Leaves elliptical, obtuse, sessile. Flowers capitate. Native of mossy rocks, in Upper Nepal. Buchanan. The root creeps, bearing diffusor oblong bulbs, on each of which stands a feathery leaf, nearly two inches in length, and somewhat emarginate. Flower-flasks erect, from the base of each bulb, and as tall as the leaf, each bearing a round drooping head of several white highly fragrant flowers, the points of the calyx yellow.

13. S. biflora. Two-flowered Stelis.—Leaves ovate, obtuse, on long footstalks. Bulbs nearly globose. Stalks about two-flowered.—On the mossy rocks of Upper Nepal. Buchanan. The branching creeping roots bear scattered globular bulbs, not an inch in diameter. The footstalk of each leaf is an inch and a half long, erect. Leaf two inches, or more. Flower-flasks a little remote from each bulb, hardly as long as the leaf, bearing usually two yellow flowers, larger than any of the foregoing; their petals an inch long, gradually swelling upwards. Petals pointed, much smaller than the ovate calyx-leaves. Lip ovate, revolute, entire, stalked, as long as the calyx.

We find among Dr. Buchanan's drawings and descriptions several more species, referred to his genus Sunipia, whose habit agrees exactly with our four last described. The parts of the flower however appear more unequal, or irregular, than properly belongs to Stelis, as is somewhat the case with our biflora. We leave them therefore, having no
specimens, to the future illustration, as we hope, of their ingenious and accurate discoverer.

STELITÆ, Στήλης, in Antiquity. See STELE.

STELLA, Jacques, in Biography, an eminent French painter, was born at Lyons in 1596. He was the son of an artist of that name, originally of Flanders, but who had settled at Lyons on his return from Italy. His father taught him the rudiments of design, but he was deprived of his instructor when only nine years old. He had however already imbibed sufficient taste to proceed by himself, without the help of another master. In his twentieth year he travelled to Italy, intending to proceed to Rome to finish his studies; but was stayed in his progress at Florence, by Cosimo de Medici, to assist in the decorations preparing for the marriage of his son Ferdinand. The grand duke retained him in his service, and gave him a pension, with apartments, and he remained there seven years. At the end of that time he continued his intended journey, and at Rome he studied with unremitting attention the works of Raphael, in company with Nicolo Poussin, with whom he lived in intimacy and friendship.

He had received repeated invitations from the court of Spain, and set out from Italy with an intention of going there, but was again interrupted in his journeys by the solicitations of cardinal Richelieu, who recommended him to Louis XIV., and procured him a pension of a thousand livres, together with the employment of flaman painter, and an apartment in the Louvre; and, besides all these advantages, the order of St. Michael was conferred upon him, as a particular mark of the king’s favour.

Stella had considerable genius, but wanted a pure taste; his knowledge of Raphael and the Italian schools had not given that bleffed odour to his works. His invention was ready, and his execution agreeable; the attitudes of his figures, however, exhibit the study and the lamp; and nature is less frequently the guide of their expressions than art. His colouring is completely artificial; and yet with these defects, there is an agreeable air in their effect; the parts are well balanced, and life and activity reign in them. He was most successful in his smaller productions. He died at Paris in 1647, aged 51.

STELLA, Francis, was the younger brother of Jacques, and born in 1601. Though he lived very much with his brother, he never arrived at much eminence. There are many of his pictures in the churches in Paris.

STELLA, Giuseppe Maria, an Italian ecclesiastic, author of a treatise entitled Alli Grandi, per imparare con ogni facilità l’It. Fermo I°; or short rules for young students to learn with the utmost facility canto fermo, divided into two parts. In Roma, 1665, 4to.

This is an elaborate treatise on the subject, probably intended for the instruction of young persons intended for holy orders in the Romish church. The notes are taught by the Guidonian hand. The clefs and hexachords are explained in a clear manner, and the service of the whole year is given in Gregorian notes, on four lines only.

STELLA, the name of a bandage in Surgery, resembling a bandage, the numerous offerings which it makes. It is employed after arteriotomy in the temple.

STELLA. See PSEUDOSTELLA.

STELLA CRiminis, in Natural History, a name given by Linkius to a genus of star-fish, the characters of which are these: that they have more than five rays, and from these have several other lateral processes, which are covered with a fine down or hair.

STELLA, in the Materia Medica, the name of a floss which has been very differently interpreted by different writers. Some have supposed it the ateria of Pliny, and some the common corallloid alkorites; but Meufele explains it to be the lapis lazuli.

STELLA, in Natural History. See STAR-FISH.

STELLA, Aropeciunt. See BASKET-FISH, and STAR-FISH.

STELLA Occidens, a word used by some of the chemical writers to express fial ammoniac.

STELLA Schelendrenica, a name given by Linkius to a kind of star-fish with an undivided body, and five rays, resembling the bodies of the scolopendra, as those of the more usual kind, called fella lumbrieralia, do the bodies of common earth-worms.

STELLA Vermiformis, a name given by Linkius, and other authors, to a common kind of star-fish, which has five rays parting from the body, each somewhat resembling the body of a large worm.

STELLA, in Geography, a river of Friuli, which runs into the gulf of Venice, 4 miles S.S.E. of Prienissa.—Alfo, a small island of Italy, in the lake of Garda; 14 miles N.W. of Verona.—Alfo, a mountain of Naples, in Principato Citra, on the coast, near Cape Licoja.—Alfo, a town of Italy; 12 miles N. of Friuli.—Alfo, a mountain of the Grifons; 15 miles S.W. of Tufa.

STELLA, La, a town of Naples, in Principato Citra; 27 miles S.W. of Cassigiano.

STELLAR. See INTER-STERLAR.

STELLARIA.

decisive mark, under its numerous varieties, it may be known at once from every plant of its natural order, except S. cerafoioides; but particularly from Cerastium aquaticum. Leaves opposite, ovate, entire, smooth, on fringed flalks. Flowers white, inconspicuous, on foliar, axillary, or terminal flalks, which are hairy on one side.

"It is a good vegetable boiled like Spinach. Small birds eat the whole herb, as do young poultry."

3. S. dichotoma. Forked Stitchwort. Linn. Sp. Pl. 603. Sm. Pl. Ic. t. 145—Leaves ovate, sessile. Stem forked. Flowers foliar. Stalks when bearing fruit reflexed. —Native of Siberia, whence it was sent by Gmelin to Linnaeus. It flowers in July. Root annual. Stem round, downy, much branched, and spreading on all sides, remarkably forked, leafy, many-flowered. Leaves two at each division of the stem, opposite, acute, sessile, downy. Flowers foliar, on round, downy flalks, which are upright at first, but bent back, as if broken, when the fruit is ripened.

4. S. radicans. Radiated Stitchwort. Linn. Sp. Pl. 603. Wildl. n. 3. (Alline faxatilis, angulato et oblongo falcis folio, flore albo, tenuissimi lacinante; Amm. Ruth. 64. t. 10.)—Leaves lanceolate, with small ferratures. Petals deeply five-cleft. —Native of Siberia, in swampy ground. Root slender, yellowish, jointed. Stems at the radical joints, about a span high, slender, upright. Leaves opposite, pale green, hairy, veined, like those of a willow. Flowers terminal, solitary, white, on slender flalks, with much-divided or jagged petals, in which respect it differs from all the other species.

"This herb has so much of a grassy appearance, that old botanists have named it the white-flowering grass."

7. S. graminea. Leaffer Stitchwort. Linn. Sp. Pl. 604. Engl. Bot. t. 803.—Leaves linear-lanceolate, entire. Panicule terminal, spreading. Calyx three-nerved, about equal to the petals. —Common among furze-bushes, heath, and low broom, on a gravelly or sandy soil, principally observable in the early summer months. Root perennial, creeping. Stems and flower-flalks perfectly smooth. Leaves entire, scarcely ever rough at the margin. Flowers in a divaricate panicule, extremely elegant, white, bepansing furze-bushes and other shrubs, which so conceal the herbage as to make the flowers seem suspended in the air. The calyx-leaves are remarkable for having three, acute, green ribs. The whole habit of this greatly resembles that of the last species, but its size is smaller, and the colour a grafs-green, not glaucous.

8. S. glauca. Glaucous Marsh Stitchwort. Sm. Pl. Brit. 475. Engl. Bot. t. 825. (S. paludis; Wildl. n. 7.)—Leaves linear-lanceolate, entire, glaucous. Flower-flalks erect. Calyx three-nerved, shorter than the petals. —Found occasionally in a moitl, gravelly soil, on meadows or in ditches, in many parts of Great Britain, flowering from June to August. Very nearly allied to the preceding species in form, but perfectly distinct. Its glaucous colour, perfect smoothness of the edges of the leaves as well as of the stem, and larger flowers, the petals being twice as long as the calyx; to which may be added that the flower-flalks are more universally lateral and foliar, much less collected into a panicule, and the three nerves of the calyx less sharply prominent; all these circumstances help to distinguish it from the former. In colour, size, and general habit, it rather approaches the S. bolsoidea, but that is beautifully distinguished by the total want of nerves in its calyx, and the rough edges of its leaves and flalks."

9. S. vulgaris. Bog Stitchwort. Sm. Pl. Brit. 476. Engl. Bot. t. 1074. Curt. Lond. facs. 6. t. 28. (S. Alwe; Wildl. n. 9.)—Leaves elliptic-lanceolate, entire, with a callous tip. Flowers irregularly panicked, lateral. Petals shorter than the calyx. —Frequent in rivulets, and clear brooks or ditches by road-sides, flowering plentifully in June. Root annual, fibrous, small. Stems numerous, feebly, branched, square, smooth, leafy. Leaves much veined, pale, glaucous, a little undulated at the margins, with a callous tip. Flowers very small, yellowish, on axillary and terminal flalks, generally three in number, two of which are three-cleft and three-flowered, the remaining one single-flowered, all furnished with membranaceous, lanceolate bracteas. This species, like S. cerafoioides, is remarkable for varying in the number of its stamens, from three to five.

10. S. cacipera. Many-flaked Stitchwort. Wildl. n. 17. Engl. Bot. t. 1259.—Stem shorter than the flower-flalks. Leaves linear-lanceolate, rough-edged. Calyx three-nerved, the length of the petals. —Native of Scotland, where it was discovered by Mr. G. Don in 1794. Root perennial. Stems very short, (Wilkewow incorrectly says, none,) tufted, thickly clothed with numerous, opposite, acute leaves, smooth except at the edges, turning red in decay, each having a fingle rib, very thick at the base, tapering and vanishing towards the point. Flowers terminal, white, on long, moity single flalks.

three or four inches long. Leaves opposite, sessile. Flowers axillary and terminal, two or three together, on capillary, long-stalked stalks.

16. S. biflora. Two-flowered Stitchwort. Linn. Sp. Pl. 604. "Swartz in Stockh. Tran. 1788. t. 4. f. 1."—Sagina ramis erecitis bifloris; Fl. Lapp. ed. Sm. 126.—Leaves awl-shaped. Branches divided. Petals emarginate. Calyx fringed.—Native of the Lapland Alps, and of North America. The habit of this species greatly resembles that of either a Sagina or Arenaria. Stems scarcely three inches long, thread-shaped, almost naked. Leaves radical, tufted. Flower-stalks two together, at the divisions of the stem, each bearing a delicate, white, very small flower, with slightly emarginate petals; the figure in Fl. Dan. t. 13. appears to be incorrectly quoted by authors for the present species.

17. S. groenlandica. Greenland Stitchwort. Wildl. n. 15. Retz. Prod. Fl. Scand. 192.—Stems decumbent, generally two-flowered. Leaves linear, slightly fringed at the base. Petals emarginate. Fruit globose.—Native of Greenland. This delicate little herb is scarcely more than an inch in height, with very slender stems. Leaves a little flabby, and fringed at the margin with long hairs. Flowers white, large in proportion to the plant, with scarcely emarginate petals.

18. S. Arenaria. Sandwort Stitchwort. Linn. Sp. Pl. 604. Wildl. n. 16.—Leaves spatulate. Stem erect, bifid. Branches alternate. Petals emarginate.—Native of Spain. Root annual, fibrous. Stem erect, round, a span high, downy and rather glabrous, with spreading hairs. Branches alternate, nearly as long as the stem. Leaves sessile, smooth above, hairy at the margin, and beneath. Flowers white, large, one at the division of the branches, the rest alternately from their axils.

19. S. pilosa. Woolly Stitchwort. Michaux Borel. Amer. v. 1. 273. Pursh v. 1. 217.—Leaves sessile, ovate, fringed. Flower-stalks erect. Petals longer than the calyx.—Native of shady woods on a rich soil from Pennsylvania to Carolina, flowering in May. All that we know of this species is from the above quoted authors, the former of whom observes that the whole herb is remarkable for being clothed with a downy woolenline. The flowers are large and white. Calyx leaves oval.

Stellaria is also a name used by some authors for the common chickweed. See CARYOPHYLLACEAE.

Stellaria is also a name given by many authors to the various species of arthrotes, or star-fish. See STAR-STONE.

STELLATA, in Geography, a town of Italy, in the department of the Lower Po; 12 miles N.W. of Ferrara.

STELLATE PLANTS, such as have their leaves growing on the stalks, at certain distances, in the form of a star with rays; or such flowers as are star-like, or full of eyes resembling stars.

Mr. Ray makes the stellate plants, so called from the disposition of their leaves, the tenth genus of English plants; of which kind are croft-wort, mollugo, wild madder, aseprula or woodruff, gallium, or ladies bed-straw, sparine or cleavers, and rubia tinctorum or dyers' madder.

STELLENBOSCH, in Geography, a small town of South Africa, near the Cape of Good Hopes. It consists of three long, straight streets, running parallel to each other, and several cross streets intercepting these at right angles. The houses are all spacious, and substantially built, though only thatched with straw. Each street resembles an avenue, since, on both sides before the houses, are large shady oaks, which are almost as old as the place itself, which was built at the beginning of the former century, though it was wholly burnt down in 1710. In December, 1803, a similar accident happened, when the number of houses left standing was about 60. The church was built in 1728, and though not equal in size to the churches of Roodezand and Paarl, it is no way inferior to them in point of architecture. The number of inhabitants at Stellenbosch, including slaves and Hottentots, is estimated at 1000. Every person in this town carries on, with his trade, some portion of agriculture and horticulture; and as there are none who can be called actually poor, who labour for hire, they are obliged to have slaves, who do not pay the expense of keeping them.

Strangers, who in their long voyages make any stay at the Cape, never fail to visit Stellenbosch; and people of property at the Cape Town also, in the fine season of the year, often make parties of pleasure to this fertile spot. Hence houses are fitted up here for the accommodation and entertainment of strangers.

STELLENBOSCH. See DRAKENSTEIN.

STELLENBOSCH, Drostdy of, one of the divisions of the Stellenbosch district, is a very handsome village, consisting of about seventy habitations, to most of which are attached offices, out-houses, and gardens, so that it occupies a very considerable space of ground. It is laid out into several large or open spaces, and particularly at the back, which have here attained a greater growth than in any other part of the colony. This village, which is the residence of the drostdy, is delightfully situated at the feet of lofty mountains, on the banks of the Eerste, or First river, at the distance of twenty-six miles from Cape Town. In it is a small neat church, which is annexed a parsonage-house, with a good garden, and very extensive vineyard. The clergyman has a salary from government of 150£ a-year, with this house, garden, and vineyard, free of all rent and taxes, in lieu of other emoluments received by the clergy of Cape Town. A popular clergyman is loaded with presents from day to day. Game of all kinds, fat lambs, fruit, wine, and other good things, are pouring in upon him occasionally. His outgoings are chiefly confined to the expense of clothing his family, and a little tea and sugar. The drostdy has a salary and emoluments that seldom fall short of 150£ a-year; an excellent house, in a pleasant situation; and an extensive garden, orchard, and vineyard. The grounds in or near the village are mostly such as they call eigendoms, or freeholds, though they are held by a small recognizance to government; but they are totally different from loan-farms, which are the usual kind of tenure in the colony. There are eight other small divisions, besides this drostdy, which surround it, and lie between it and Fallof bay. They consist chiefly of freehold ewes, and produce wine, brandy, fruit, fresh butter, poultry, and a variety of articles for the Cape market, and for the supply of ships whilst they continue
continue in Simon’s-bay. They yield also a small quantity of corn. Barrow’s Africa, vol. ii.

St. S. Paffriss has eight Ramens, S. Chamaejasme ten. Linnens and other authors inaccurately define the calyx as a corolla. Ed. Ch. Calyx mostly four-cleft. Corolla none. Stam. very short. Nut foliary, beaked.

1. S. Paffriss. Flax-leaved Stelleria. Linn. Sp. Pl. 512. Jacc. 1c. Rar. v. 1. t. 68.—Leaves linear. Flowers axillary, sessile, with a four-cleft calyx.—Native of dry, sandy fields, in Germany, Switzerland, France, and Italy, flowering in July and August. In general appearance, this herb resembles Thyrsus alpinus. It is acrid, bitter, and purgative. ""Red, angular, spindle-shaped, nearly simple, yellow on the outside, white within. Stem upright, about fix inches in height, much branched from the very bottom. Leaves alternate, sessile, acute, entire, smooth, spreading, reflexed, shaped like a sparrow’s tongue, whence Linnens adopted its old generic name as a specific one. The stem and branches are terminated by long, loose, interrupted, leafy spikes. Flowers sessile, three, four, or five together, at the axils of the leaves, imbedded in wool at the base, greenish, with yellow tips.

St. Chamaejasme. Siberian Stelleria. Linn. Sp. Pl. 515. Gmel. Sib. v. 3. 37. (Chamaejasme radice Mandragora; Amman. Ruth. 16. 2.)—Leaves lanceolate. Flowers terminal, clustered, naked, with a five-cleft calyx.—Native of Siberia, on the banks of rivers; flowering in June. Root externally brown, internally white, having a sweetish taste, and in its mode of growth greatly resembling the Mandrake root, divided generally into two parts, each furnished with numerous radicles. Siumi numeros, slender, weak, reddish below, pale green at the summit. Leaves alternate, short, acute at each end, nerved. Flowers white and purple, five-cleft.

STELLI0, in Zoology, the name by which authors call the swift or spotted lizard. The spots which distinguish this kind are not, however, reticulated, as might be supposed from the name, but round: some small, and scattered irregularly all over the body; and others larger, and disposed in thirteen zones or semicircles. The spots are much more distinct and clear on the back than on the belly. It is common in Syria, and some other places. See EFT and Lizard.

The flax, named by the Greeks coccodrilo, is the most common species of lizard in all the islands of the Archipelago, in Crete, in the Morea, on the coast of Naxos, in Egypt, and in Syria. Olivier describes it as having the body mixed with green, yellowish, and brown; the head and the back covered with scales, simple or tubercled, and pointed. The scales of the feet are more turned up, and more pointed, than those of the back. The tail is verticillated, and covered with prickly scales. This lizard acquires ten or twelve inches in length. It lives on insects, and does no mischief. It seeks the sun in summer; in winter it keeps in holes, and there pusses that feaion in a kind of torpor.

STELLI0 Adelfa, an affected term used by some chemical writers for cinnamon.

STELLIONATE, Stellionatus, in the Civil Law, a kind of crime committed by a fraudulent bargain, where one of the parties sells a thing for what it is not. 

When fairs, the word comes from latine, a very subtle kind of lizard. We find mention of it in the Code, leg. 1. tit. 54, as, if I sell an eftate for my own, which belongs to another; or convey a thing as free and clear, which is already engaged to another; or put off copper for gold, &c.

The Romans frequently used stellinatus to express all kinds of crimes that had no proper names.

STELLITES, in Natural History, a name given by some writers on fossils to a kind of white stone found on mount Libanus, and in some other parts of Syria, containing the lineaments of the fish-scalps. The same names frequently contain the lineaments of other fishes.

STELLOW, in Geography, a town of the duchy of Holstein; 9 miles N.N.E. of Elmenhorn.

STELLOCHITES, a name given to oceocolla.

STEM, in Botany, that part of a plant arising out of the root, and which sustains the leaves, flowers, and fruits.

In trees, the stem is called the trunk, or stock; in Latin saxalis, and truncum.

In herbs, it is ordinarily called the stalk; by the Latins caulis; and stipeus, when flattened like a column.

In the several kinds of corn, and plants of that kind, it is more properly called culmus.

The stem of the plant, according to Dr. Grew, is no more than the cuticle, or skin, which at first covers the two lobes, and the plume of the seed, and which is further dilated as the plant grows.

The stems of shrubs and trees are, for the most part, a great deal larger, and more woody, firm, and solid, than those of the herbs. See Stalk.

They are of the stems of forest and some other sorts of trees, which principally form and constitute, as well as afford, the timber which is employed for different rural uses; and which may be made to serve different purposes and intentions, by the different modes of training and managing them. See Timber.

In gardening, the stems of fruit-trees and fruit-shrubs are trained and managed in a great many different ways and manners, so as to suit different uses and intentions in this sort of culture and practice. They have also lately, for serving particular purposes and designs, been found capable of being so trained, where the trees are to be planted on the contrary sides of the walls to those on which they are to run and be wrought, as to be introduced through holes, made in a slanting upward direction from the bottom parts of them, to the sides of about five inches in diameter, and the name of number of inches in height from the surface of the borders, with great success and benefit. See Standard-Tree and Wall-Tree.

The stems of many low plants and trees are likewise sometimes trained with different kinds of ornamental heads, and other parts, for a great variety of different uses and purposes, as pleasure-ground planting. See Planting.
The term "item" is also occasionally, in some dicotyledons, made use of to signify the handle of any sort of tool of the folk kind.

**Stems of Ships.** A circular piece of timber, into which her two sides are united at the fore-end; the lower end of it is scarfed to the keel, and the bowprit rests upon its upper end.

The item is formed of one or two pieces, according to the faze of the vessel; and as it terminates the ship forward, the ends of the wales and planks of the sides and bottom are let into a groove or channel, in the middle of its surface, from the top to the bottom; which operation is usually called rabbotting.

The outside of the item is usually marked with a scale, or division of feet, according to its perpendicular height from the keel; the intention of which is to ascertain the draught of water at the fore-part, when the ship is in preparation for a sea-voyage, &c.

The item, at its lower end, is of equal breadth and thickness with the keel, but it grows proportionately broader and thicker towards its upper extremity. Falconer. See SHIP-BUILDING.

**Stems, Fauxs, that fixed before the right one.** When a ship's item is too flat, so that she cannot keep a wind well, they put a false item above, which makes her ride more way, and bear a better sail.

**STEMMATTA, in the History of Insects,** are three smooth hemispheric dots, placed generally on the top of the head; as in most of the hymenoptera, and other classses. The name was first introduced by Linneaus. See ENTOMOLOGY.

**Gen. Ch. Cal. Perianth inferior, of one leaf, five-cleft, erose, equal, permanent. Cor. of one petal, irregular. Tube the length of the calyx. Limb two-lipped, almost upright; upper lip ovate, undivided; lower lip divided into three, rounded, equal segments. Stem. Filaments four, nearly equal, as long as the tube, all cloven; anthers eight, one placed on each division of the filament. Pfl. Germen superior, rather obtuse; style simple, the length of the filaments; stigma somewhat blunt. Peric. Capsule oblong, ovate, of two cells and two valves of a contrary partition. Seeds numerous, globose. Recaptae nearly cylindrical.

**Eff. Ch. Calyx five-cleft. Corolla two-lipped. Filaments cloven, each furnished with two anthers. Capsules two-celled.**

1. **S. maritima.** Sea Stemodia. Linn. Sp. Pl. 881. Swartz Obs. 242. (Scordium maritimum, fruticosum procumbens; Siamen Hift. Jam. v. 1. t. 110. f. 2.) —Leaves opposite, half clasping the stem. Flowers few, solitary. —Native of the southern parts of Jamaica, on the sea-shore. Root, probably biennial, long, round, fibrous. Stem from one to three feet high, hairy, erect, or occasionally scarce, much branched. Leaves small, few, ovate-elliptical, obtusa, serrate, thickish, hairy, with smaller ones at the sides of the larger. Flowers few, axillary, among the terminal leaves. Small, white or blue.

The whole herb has a plesant aromatic smell, with a bitterish taste.

2. **S. durantaefila.** Marsh Stemodia. Wild. n. 2. Swartz Obs. 240. (Capraria durantaefila; Linn. Sp. Pl. 876. Veronica caule hexanguli, folia faturee terius, serrata; Sleume Hill. Jam. v. 1. t. 134. f. 2.) —Leaves three in a whorl, combined. Flowers two or three together, nearly sessile. —Native of Jamaica, in marshes on the shore, in clay. Stem herbaceous, a foot high, erect, branched, leafy, angular at the base, roundish upwards, hairy, clummy. Leaves sessile, toothed or rather serrated, spreading, nervcd, downy. Flowers on such short stalks as to be all but sessile, small, of a blue colour.

3. **S. villosa.** Vidic Stemodia. Mart. Mill. Dict. n. 3. Roxb. Coromandel. v. 2. 153. t. 165. —Leaves opposite, clasping the stem. Flowers on stalks, solitary. —Native of Coromandel, in rice-fields after the crop has been cut. The Telingas call it Buda-forum. —Stem herbaceous, two feet high, generally inclining to one side, branched from the base, square, hairy. Leaves linear, serrated, clummy like the whole herb. Flowers axillary, small, violet-coloured. The plant has a pleasant aromatic smell.

Vahl mentions a variety of **S. camphorata**, with narrower leaves, which, he says, may probably be **Dedarias orientalis**.

6. **S. aquatica.** Water Stemodia. Wild. n. 5. —Leaves three together; those immersed doubly pinnae, pinnae; those above water undivided, lanceolate, sessile. Spikes axillary. A native aquatic of the East Indies, found near Tranquebar. —Stem from six inches to two feet in height. Flowers few; doubly pinnate; three-nerved, smooth, deeply serrated from the middle to the tip. Flowers alternate, sessile, in terminal spikes. —S. parviflora. Small-flowered Stemodia. Ait. n. 1. ("Eruis verticillatus; Mill. Dict. ed. 8."") —Stem prostrate, much branched, downy. Leaves three together, on stalks, ovate, crenate. —Native of South America, flowering in July and August. First cultivated by Mr. Philip Miller in 1759. We know nothing further of this species than what is here extracted from the Hortus Kewensis.

**STEMOCHA,** was so denominated by Loureiro, from **stemma, a stem,** because of the remarkable form and connection of those organs in its flower; which latter circumstance led him to refer the genus to the class Monandria. His genus, however, proved by the description, and indeed by the synonym of Rumphius, to be no other than our's and Mr. Dryander's *Roxburghia*; see that article. We had not made this discovery when the said article was written. What would those who fickle for the mere right of priority of names, in spite of authority, sense, utility, or taste, do in this case? Stemona is by far the oldest name, liable to little or no exception, and given by an able and learned botanist. Yet surely every one would retain Roxburghia, for the sake of its author's authority. We cannot but contest for the occasional exercise of some discreditable power, when obviously for the good of science; however averse we may always be to alterations of established and received names, though perhaps for the better.
STEMPHYLITE, a name given to the ancients to express the stalks of grapes, or the remains of the pressings of wine. The same word is also used by some to express the remaining mass of the olives, after the oil is pressed out.

STEMPHYLLITES, a name given by the ancients to a root of wine pressed hard from the hulks.

STEMPLES, in Mining, crofts bars of wood in the shafts, which are sunk to mines.

In many places the way is to sink a perpendicular hole, or shaft, and hew sides of which they strengthen, from top to bottom with wood-work, to prevent the earth from falling in: the transverse pieces of wood, used for this purpose, they call stemples, and by means of these the miners in some places defend, without using any rope, catching hold of them with their hands and feet.

STEMSON, in Ship-Building, a piece of compacts timber, wrought on the outside of the apron, the lower end of which scars into the keel. Its upper end is continued high enough to tenon into the under side of the middle or upper deck hook, in the thickness of the stem. In five short, spreading, lanceolate, blattish segments, bearded underneath at the extremity, as well as half way along the dish from the base. Nectary a cup-shaped undivided gland surrounding the base of the germen. Stem, Filaments five, inserted into the tube, and enclosed within it, thick and fleshy, broader than the anthers, which are linear, in the mouth of the tube. Pjft. Germen superior, roundish, of five cells; fyle capillary, the length of the tube; stigma simple, obtuse. Peric. Drupa nearly dry, globose. Seed. Nut of three or more cells, with a thick, not very hard, shell, not bursting, with a pendulous kernel in each cell.

Eff. Ch. Outer calyx of many imbricated leaves. Corolla tubular; its tube swelling, twice as long as the calyx, naked within; limb much shorter, spreading, bearded half way. Filaments included in the tube, fleshy, broader than their anthers. Drupa almost dry, of three to five cells.

1. S. pinifolia. Pine-leaved Stenantha. Br. n. 1. — Native of the neighbourhood of Port Jackson, New South Wales, from whence we have a specimen gathered by Dr. White, but this shrub has not yet found its way into the gardens of England. It is the only known species of its genus. The stem is woody, erect, spreading, branched, scarred; the younger branches hairy, clothed with innumerable, crowded, awl-shaped, pungent, revolute, roughish, fleshy leaves, about an inch long. Flowers axillary, erect, fleshy, about the base of each branch, very beautiful, with a rich scarlet tube an inch long, and a yellowish-green limb, making a singular, but most agreeable, contrariety. Drupa the size of a small pea, invested with the brown chaffy calyx.

STÉNAY, in Geography, a town of France, in the department of the Meuse, and chief place of a canton, in the district of Moultmèdy; 21 miles N.N.W. of Verdun. The place contains 3599, and the canton 14,434 inhabitants, Vol. XXXIV.

STE, on a territory of 170 kilometres, in 18 communes. N. lat. 49° 30'. E. long. 5° 16'.

STENBOCK, MAGNUS, in Biography, a distinguished Swedish general, son of Gustavus Otto Stenbock, a general under Charles XI. and XI., was born at Stockholm in 1664. He was educated at Upsal, and in 1683 he set out on his travels, and having entered into the Dutch army, he served several campaigns with the allied forces in the Netherlands, and on the Rhine, under the princes of Wal- dec and Baden. He distinguished himself so much by his bravery and good conduct, that he was, in 1697, appointed to be colonel of a German regiment, then in the garrison at Wismar, where he employed his leisure time in composing a work on the art of war, entitled "The Swedish Military School," which, however, he did not find leiture or inclination to publish. He accompanied Charles XII. in almost all his expeditions, and contributed by his skill and exertions to the victory obtained at Narva. In the Polish campaign, till 1706, he sometimes accompanied the king and the main army, and sometimes was entrained with the command of detached bodies employed chiefly in levying contributions; a service for which he was unusually well qualified; he was also employed in constructing bridges over such rivers as the Swedish army had to pass, on its incursions into Poland, and on its return from that country. In the year 1706 he attended the king to Saxony, where he was appointed governor of Scania. When he arrived there, he found every thing in the utmost confusion; the most shameless abuses had been committed; and in order to put an end to them, and deter others from similar practices, he put the laws into most severe execution; but a war breaking out put a stop to his plan of reform. When intelligence of the Swedes being defeated at Parnawa by Frederic IV. of Denmark, he made preparations for the invasion of Scania. Stenbock was appointed to oppose him; he put himself at the head of 8000 old troops and 12,000 new levies, and went in pursuit of the Danske, who were committing incredible ravages in the country. There was no time to clothe the newly raised troops in military array; of whom the greater part was drenched in frocks, and had piloths tied to their girdles with cords. They attacked the enemy; and what was wanting in order and discipline, was amply compensated for by the untrained raw troops completely defeated the regular army of the king of Denmark. The Danses quitted Sweden with great precipitation, having first killed their horses, and destitute by fire their baggage and magazines. They left behind them about 4000 wounded soldiers, of whom the greater part died, as well by the infection from the dead horses, as by the want of food, of which they had been deprived by their own countrymen. After Scania had been freed from the ravages of the enemy, Stenbock's first care was to strengthen the fortifications of Christiansbad, being a place of great importance, for the defence of that part of Sweden. The activity which he displayed on this occasion, induced Charles, the year following, to entrust him with the direction of another enterprise, the successful and speedy execution of which great importance was attached. This was to repair, as speedily as possible, with several regiments to join the troops in that province and to proceed afterwards, under the command of Stanislaus, to meet his Sweedish majesty, on his proposed return from Turkey. In this measure he was thwarted by the senate, and he experienced many difficulties which he did not anticipate; of these, one was the want of money. He, however, went to Stockholm, and exerted himself to successfully, that he collected, in the course of a month,
more than $300,000 rix-dollars, and fitted out some vessels for his intended expedition. In the course of his voyage he fell in with the Danish fleet, by which he was attacked, and more than thirty of the Swedish ships were lost. In consequence of this unfortunate event, Stenbock drew up a paper in vindication of his own conduct. After this he took Roftock; and having received a considerable reinforcement of troops, gained a memorable victory, in 1712, over the Danish and Saxon forces: he then proceeded to the army in Holstein, and having burnt Altona, was, in the month of May, 1713, hemmed in at Tooningen, by the combined Danish, Saxon, and Russian army, in such a manner, that he was obliged to sign a capitulation. Being now a prisoner, he was conveyed by order of his Danish majesty to Copenhagen, and so closely confined, that he was separated from all his attendants, except two domestic servants, who obtained leave to wait upon him, and was in other respects subject to great restraint and severity. At length, exhausted by miles, privation, and disease, he drew up, in the beginning of the year 1716, an account of his sufferings, to serve, to use his own words, as a confession to his disfriended relatives, and, at the same time, to preserve his name and reputation to posterity. This work was printed in 1773, in Lübom's "Anecdotes of celebrated and distinguished Swedes." He died in 1717, and was interred, with military honours, in the garrison church of Copenhagen. After the conclusion of peace, his body was conveyed to Sweden, and deposited in the cathedral of Uppsala. Stenbock was a man of large and varied attainments, always held in high estimation by Charles XII. In his political sentiments he adopted the system of his father-in-law, the celebrated Oxenstierna. He spoke his sentiments with freedom, and gave such advice as he thought most conducive to the good of his country. In speaking of the Polish war, in one of his letters, dated June 20th, 1702, he says, "according to every appearance, unless Providence interfere in a very remarkable way, war will be declared against the republic. How we shall get out of it God only knows. For my part, I would run no risk, but in a war really unjust, I would have no share in the deposition of Augustus, for whom he had a sincere effence. He incurred considerable blame for the severity which he exercised at Altona, and the ministers and generals of Poland and Denmark wrote to him complaining of his cruelty on that occasion; but Stenbock, who confided this measure, however harsh, as a just retaliation for the conduct of the Saxons and Danes at Stade, which they had bombarded and burnt to ashes, replied, "that he proceeded to such an extremity, in order to teach the enemies of his sovereign, in future, not to wage war like barbarians, and to cauie the law of nations to be respected." Gen. Biog.

STENBRUGGE, in Geography, a town of Norway; in the province of Aggerhus; 8 miles N. of Tonberg.

STENBY, a town of Sweden, in Esat Gotland; 11 miles E. of Nordkiopning.

STENCH. See STINK.

STENCILLING. See PAPER-Hangings.

STENCKBACH, in Geography, a river of Saxony, which rises 4 miles S. of Landberg, and runs into the Fulme, 2 miles N. of Zobitz.

STENDAL, a town of Westphalia, and late capital of the Old Mark, containing four churches, with considerable manufactures, introduced by the French refugees; 18 miles W.N.W. of Brandenburg. N. lat. 52° 56'. E. long. 13°.

STENDALICHEN, a town of Brandenburg, in the Ucker Mark; 10 miles N.E. of New Angermunde.

STENDORP, a town of the duchy of Holstein; 6 miles E.N.E. of Eutyn.

STENE, a town of Norway, in the province of Drammen; 48 miles E. of Drammen.

STENFORT, a town of Hinder Pomerania; 8 miles S. of New Stettin.

STENHEL, a town of Sweden, in Wetf Bothnia; 32 miles N.W. of Lulea.

STENO, NICHOLAS, in Biography, a distinguished physician, and subsequently bishop of Tittipolis, and vicar-apostolic of the northern countries, was born in Copenhagen in 1638. His father was a Lutheran, and goldsmith to Christian IV., king of Denmark. Having had the advantage of studying medicine and anatomy under the celebrated Bartholin, whose friendship he obtained by his ingenuity and industry, he was well prepared to profit by his travels through various parts of Holland, Germany, France, and Italy, in visiting the best schools, of which he gained several years. He was made a professor in 1660, and resided during the three succeeding years at Leyden, where he pursued his studies with the utmost diligence. He arrived at Paris in 1664, and at the end of two years more went to Vienna, traveled part of Hungary, and entered Italy by the Tyrol. He visited the principal cities of this fine country, and passed some time especially at Rome and Florence, in the latter of which cities his reputation reached the court of Ferdinand II., grand duke of Tuscany, who appointed him his physician about the year 1667, with a liberal salary. He was afterwards honored with the eeeen and confidence of Cosimo III., who made him as preceptor to his son. His attachment to the Protestant religion had been shaken by the eloquence of Bossuet while he was at Paris, and in 1669 he abjured that faith, and adopted the Roman Catholic persuasion. Frederick III., king of Denmark, invited him, near the close of his reign, to return to Copenhagen; but he refused the invitation, because he could not obtain permission to exercise the religion which he had adopted; but Christian V. repeating the invitation without any such restraint, about the year 1671, Steno returned to Copenhagen, and was appointed professor of anatomy. He found his change of sentiments and circumstances, however, productive of less agreeable results than he had anticipated, and he again quitted Denmark, and refused the education of the young prince of the house of Cosimo, at Florence. Some time after his return, he entertained a wish to enter the ecclesiastical state, and he embraced that profession in 1677. He was speedily nominated, by pope Innocent XI., to the bishopric in Ifaura, which we have already mentioned; and was afterwards appointed vicar-apostolic to all the states of the north, in which capacity he became a zealous preacher in Hanover, Munster, Hamburg, and various parts of Germany, and died in the course of his missionary labours, at Schwerin, in the duchy of Mecklenburgh, in 1686, in the 49th year of his age.

The works of Steno which are extant, relate principally to medical subjects. He was a zealous cultivator of anatomy, and the author of some discoveries relative to the minute circulation of the eye, the nape, and organs of voice, and to the lymphatics; as in the papers which he communicated to the Academy of Copenhagen, and his other works, will testify. The titles of the latter are: "Observationes de Oris, Oculorum, et Nariurn Vasibus," 1662; this was enlarged and reprinted in 1664, with the new title "De Muculis et Glándulis Observationum Specimen," "Elementorum Myologie Specimen, seu Muculi Descriptio Geometrica," 1667. "De solidio intra solidum naturaliter

Steno's Duó, a name given, from its discoverer, to the superior vaginal duct.

Several anatomists, particularly Heister and Palñyn, have disputed whether Steno's duct is pervious in recent foetuses, as well as in the skeleton. Dr. Kulm affirms, he has demonstrated it to several to be pervious in deer, bears, wild goats, hares, calves, and in the human subjects, and mentions the manner of tracing it. See Med. Edinb. Abridg. vol. ii. p. 431.

Gen. Ch. Cal. none. Cor. Petals four, distint, linear, equal, all turned to one side; their funnits ovate, concave, bearing the stamens. Neatly a gland, half embracing the tusk of the vessel. Stigma Filaments four, very fine, inserted into the hollow tip of each petal; anthers roundish, funk in the same cavity. Pith. German superior, flaked, oval, style terminal, cylindrical, deciduous; stigma oblique, dilated, orbicular, peltate, flatish. Peric. Follicle linear, flaked, coriaceous, recurved. Seeds numerous, imbricated, winged at the base.

1. S. Forsteri. Oval-leaved Stenocarpus. Br. Tr. of Linn. Soc. n. 1. (Embothrium umbellatum; Linn. Suppl. 128. Lamarr Dict. v. 2. 355. Illust. n. 1285. t. 55. f. 1.) Willd. Sp. Pl. v. 1. 158. E. umbelliferum; Fori. Gen. t. 8. f. a. f. — Leaves elliptic-oblong, obtuse, without prominent ribs.—Gathered by Forster in New Caledonia. The stem is shrubby, with alternate, round, smooth, leafy, dotted branches. Leaves alternate, on short thick stalks, coriaceous, smooth, entire, an inch or half and long; tapering at the base; obscurely triple-ribbed in a dry state. Flowers about half an inch long, red, about five or seven together, in axillary, flanked, smooth umbels, subtended by three or four small, membranous, ovate bracteae. Follicle near two inches long, like a small legume, with hollows for the seeds.

2. S. foetidus. Willow-leaved Stenocarpus. Br. ibid. n. 2. Prodr. n. 1. — "Leaves elongated, lanceolate; three-ribbed at the base."—Found by Mr. Brown, on the eastern coast of New Holland; on the rocky banks of rivers near Port Jackson. The flowers are of a yellowish-white. Umbels flaked. Whole shrub very smooth.

A genus of New Holland shrubs, either nearly smooth, or clothed with very fine greyish down. Leaves alternate, without veins; mostly undivided. Flowers few, solitary, single-flowered, without bracteae. Flowers either purple or yellow. Nut of the drupa often with only two cells, the others proving abortive.

"Bonita, though very nearly related to Stenochilus, differs in having the upper lip of its corolla emarginate, the lower three-lobed; a two-lobed stigma; and the nut of two divided cells, each with four seeds, according to the younger Gartner, in his v. 3. 168. t. 212."

1. S. glaber. Smooth Stenochilus. Br. n. 1. — "Leaves lanceolate or elliptical, undivided, smooth, scarcely longer than the flower; sometimes toothed at the extremity. Young branches downy. Stem diffuse."—Gathered by Mr. Brown, on the south coast of New Holland. This gentleman mentions another species, nearly akin to the present, except being hoary with down, which was gathered on the western coast of New Holland; but he leaves the description of it to his friend Lefchenault.

2. S. longifolius. Long-leaved Stenochilus. Br. n. 2. — "Leaves linear, somewhat lanceolate, elongated, undivided; hooked at the point; smooth when full-grown. Young branches downy. Stem erect."—Found also on the south coast of New Holland, by Mr. Brown. The flowers were past, but the habit, as well as fruits, answered to the preceding. The leaves are from three to five inches long.

STENOGRAPHY, SHORT-HAND, from roots; and γεωτρία. Passing over the Egyptian mode of writing by hieroglyphics, we may observe, that "The History of Hebrew Abbreviations, as a Key to understand the Rabbinical Authors," by the learned Buxtorf, appears to have unfolded one of the earliest notions mankind had of a method of short-writing. Some of these abbreviations are merely the incipit letters of several words joined together as one, and marked at the top with points; others are the final or terminational letters of words; and others, again, are contracted words, wherein two or three letters are made to denote an entire word.

The Jews, we are told, were particularly partial to these methods of abbreviation; to which they added a few arbitrary characters, to express certain proper names, such as God, Jehovah, and the like awful and sacred terms.

By degrees the Greeks acquired this mode of writing, and it was very successfully practised among them. Indeed, the Greek abbreviations and contractions have very much the character of genuine stenography.

It was at Nicolai that this method of writing was first introduced to the Greeks by Xenophon himself, who wrote by certain arbitrary notes, in the nature of characters. This opinion is confirmed by Laertius, who particularly notices two distinct methods of stenographic writing: namely, one by simple contractions; and the other by arbitrary marks or symbols.

The Romans practised this art at a very early period. Some writers have even ascribed to the poet Ennius the merit of having first invented a method of writing, by which the orators were enabled to follow the most rapid of their orators. This, however, is extremely hypothetical. It is added, that Ennius's method was much improved upon by Tyro, Cicero's freed-man; and still more by the learned Seneca.

Ennius, it appears, began at first to write with one thousand one hundred marks of his own contrivance, to which he might add, as circumstances and necessity de-

T

manded,
STENOGRAPHY.

manded. In what the subsequent improvements consisted we have no account; probably only in the invention of new symbols or characters, and not in any attempt to write in a short manner, by the combination of new and more simple letters.

It is evident the Romans held this art in great estimation; for Suetonius, speaking of Caligula, expresses his surprise, that an emperor, who, notwithstanding his numerous vices, was not deficient in capacity and parts, should remain ignorant of the art of stenographic writing. Titus Vespasian, however, in almost every respect a very different character from Caligula, is mentioned as being remarkably attached to short-hand, and himself practised it with great facility, and often made it not only his business but his amusement. He seemed to have great pleasure in calling his amanuenses together, and witnessing which of them wrote the fuller. He not only admired himself with stenography, but with imitating the hand-writing of others; and, by constant practice, acquired such a command of hand, and such a facility in imitation, that he was wont humorously to observe concerning himself, that he should have made an excellent mimic or counterfeit.

Various were the schemes, as at present, which were formerly used to write after public speakers; but they were probably all of them exceedingly arbitrary, and, for the most part, unintelligible to any but those who practised them; and, on that account, were soon forgotten and destroyed. The art was consequently much neglected, as is evident from two books of short-hand, mentioned by Triedemius. The first was a Short-Hand Dictionarius, which he bought of an abbot, a doctor of law, for a few pence, to the great satisfaction of the community to which he belonged, who had defined the short-hand marks to be erased, for the sake of the parchment on which they were written. The other was a short-hand copy of the Book of Psalms, which he met with in another monastery, where the monks had inscribed upon it, by way of title, “A Pfalter in the Armenian Language.”

Several copies, however, of a Dictionarius and Pfalter, in Roman short-hand, are mentioned as extant in different libraries; but they are in general the same method, as may be conjectured from those who mention them, and also from the appearance of an old short-hand Pfalter in the library of St. Germain, at Paris, carefully preferred as a stenographical curiosity. The late Mr. Byrom had a few pages of this transcript of his inscription and use.

Plutarch, in his Life of Cato, informs us, that the celebrated speech of that patriot, relating to the Catalinian conspiracy, was taken and preferred in short-hand; and there are numerous epigrams of Autolius, Martini, and Manlius, descriptive and commendatory of this art. But we must pass over all other ancient allusions and conjectures, observing, that, probably, the oldest method of short-writing at present extant or known is a Latin MS., entitled “Ar Scrybendi Caracteres,” or “The Art of Writing in Characters.” The author of this is not known, but it was printed about the year 1422.

We may just, however, remark on this head, that the ancient Irish alphabets, called Boholeath, a specimen of which may be seen in Ledwich’s Antiquities, and also in Dr. Fry’s Penographia, have much the appearance of some of our modern short-hand. Two of their alphabets were called Irith ogums: Celtic words implying letters written in cypher, and, indirectly, an occult science. They were first stenographic, then peganographic, then magical, and, lastly, alphabetic.

The Japanese alphabets (for they have three, two of which are in general use among the natives, the other only at court, and among the great) appear to have a stenographical character; most of them combining two, and others three, letters.

The two alphabets attributed to King Solomon, but upon what authority is not stated, by Thebeus Ambrosius, in his Appendices des diverses Lettres et des différentes Langues,” and cited by Delair, p. 139, have much the same cast in their formation; but the one, of which a beautifully engraved specimen may be seen in the Encyc. Franc. pl. xxv., partakes most of the nature of short-hand of any other yet mentioned. The Japanese has, in fact, but 328 sounds, which are all monosyllables, applicable to 80,000 characters, of which the whole language is composed.

Lambinon, in his “Recherches upon Printing,” observes, that modern stenography, which, like the telegraph, dates in France from the foundation of the republic, has neither the inconvenience, nor the obscurity, nor the danger of the ancient. The old characters varied under the hand of the copiers, and the sense changed according to the genius of the interpreters; so that their contractions are become so many enigmas, because we can refer to no other copies to ascertain the true reading, and because the authors are no longer in existence. “But,” continues this writer, “by the present system of stenography, the writers follow the words of the public orators, take down their speeches, the debates of the tribunal, or the lectures of the professors of the Lyceum, and produce a literal translation at last, in the usual characters and in print.” It is to be feared that this description of Gallic stenography is a little too highly colored; no system of French writing, that has hitherto come under our notice, having any such perfect facility of copying as is here stated; but, certainly, our neighbours across the Channel can both speak and write with wonderful rapidity.

The attempt of the late learned and ingenious bishop Wilkins to form a real character and philosophical language should not be overlooked. This pared-down, perhaps, more than all others, of short-hand, properly so called; but was not intended for much for expedition and brevity in writing, as for an universal communication or correspondence of ideas. Of its fitness for such a purpose, it is not the object of this article to discuss. We know a gentleman at this time, of great opulence and well-known character in the metropolis, who is of opinion, that he can express all ideas common to mankind in general by only three letters, which may be known all over the civilized world, and we believe it is his intention to make an experiment of the practicability of his scheme.

The art of short-hand was first attempted in this country by Dr. Timothy Bright, who published his “Charactère” in the year 1588. The “Writing School-Master” of Mr. Peter Bale, appeared two years after Dr. Bright’s work. Bale’s book is divided into three parts, the first of which is entitled “Brachypography,” and contains rules to write as fast as a man can speak with propriety and distinctness. In 1618 appeared Willis’s “Stenography, or Short-Hand Writing by spelling Charactères.” This method consists of ten alphabets, denominated words of fort; seven of which are composed of the initial letters of words; the rest, principally by the omission of unnecessary letters, and by symbolical figures.

Henry Dix’s “Brachypography” was an attempt to improve upon Willis’s; but all improvements of the art, till the invention of Byrom, were little better than the original—arbitrary and mysterious.
It is not requisite to detail the history of this art more minutely; nor to mention the numerous systems or methods, all tending to perfection, though each professing to excel its predecessors. We will, therefore, proceed to key before the reader such a system of stenography, which, if generally known and practised, would infallibly supersede the necessity of any other; and yet, it must be confessed, that the art of short-hand is far from having attained that perfection of which it may be capable.

The next system, as to beauty and practical utility, to the one about to be here developed, is doubtless that of Dr. Major's invention, who, however, candidly admits that, in the construction of his own work, he has proceeded upon Mr. Byrom's "general principles," which he owns, "must for ever form the basis of every future rational system."

Mr. Byrom's method of short-hand, as improved by Mr. Molineux, being now generally esteemed the best and most practical system extant, we shall give a brief yet comprehensive analysis of the whole, premising, that the rules which the inventor had prescribed to himself, in the execution of his plan, were,

1st. That all the simple sounds of the language should be denoted by the shortest and simplest marks in nature.

2dly. That those marks which were the shortest, and most easily formed, should be allied to the letters which are of most frequent occurrence.

3dly. That the letters which are most frequently combined in pronunciation, should be denoted by such marks as are most easily joined by the pen.

4thly. That all the marks of which any word may be composed, should generally be written without taking off the pen; and that the writing should not rise above or sink below the parallel lines, between which it should be uniformly comprised.

5thly, and lastly, That all the rules of abbreviation should be founded upon the properties of the language, and exemplified by the characters of the short-hand alphabet only, without the introduction of any arbitrary marks, either for abbreviation or any other purpose.

To unite so many different perfections in one scheme, and to make a regular and scientific system of the whole, was an undertaking of no common labour and difficulty. Mr. Byrom, the inventor, was well qualified for such an arduous undertaking, by a very extensive knowledge of the nature of language in general, and a thorough acquaintance with the properties and peculiarities of his own in particular; and it was by an indefatigable perseverance in making, through the course of many years, continual trials, alterations, and amendments, that he at last succeeded, to the satisfaction of himself and a few learned and judicious friends, to whom he first communicated the particulars of his invention. To remove any doubt which the public might entertain of its merit, these gentlemen, his scholars, drew up and signed a recommendatory description of his method of short-hand, which testimonial was prefixed, by way of preface, to the original publication.

Mr. Byrom's method of short-hand is there stated to be the best, consisting of all the words and phrases of the English language by a character which is perfectly regular and beautiful, and at the same time the shortest possible. Perfect beauty and regularity indeed, so far from being inconsistent with the greatest possible brevity, are in fact the only means of attaining it; and by a strict adherence to these principles, Mr. Byrom has completely succeeded in the invention and establishment of his system. In fine, his method of short-hand writing is no fanciful theory; but, on the contrary, is founded upon rational and philosophical principles: it pro-

poses nothing impracticable; it is not a mere jumble of awkward marks thrown together without order, and consequently unintelligible to the writer himself after the lapse of a few months or years.

For beauty, legibility, and the greatest possible uniformity in the writing, it stands unrivalled. It was a principal object with the inventor to expunge every thing arbitrary, both from the short-hand characters and the rules of abbreviation; and in this truly essential point he has succeeded so happily, that his system seems to claim pre-eminence over every other.

It may be useful to refer such of our readers as may wish to attain a complete knowledge of Mr. Byrom's system, to "An Introduction to Byrom's Universal English Short-Hand," by Mr. Molineux, of Macclesfield, explaining the theory of the art in a very clear and periphrastic manner, and to a supplementary work, entitled "The Short-Hand Instructor, or Stenographical Copy-Book," which exhibits the practice, adorned with its peculiar characteristics of ease and beauty. These two elegant little works form together a complete system of stenography, and have the merit of familiarising Mr. Byrom's excellent method for the general use of schools, and for the particular guidance of those who, without the assistance of a living instructor, may be desirous of a literary attainment, which is at once useful and ornamental.

The letter C, having always the sound either of k or s, is here represented by those letters respectively; z and ϭ, and also f and Ϫ, having a near affinity to each other in sound, are denoted by one and the same mark. The short-hand alphabet consists of the following consonants; viz. b, d, f, or ϭ, (the latter being easily distinguished, when necessary, by a thicker stroke,) g, h, j, k, l, m, n, p, q, r, s, or ϱ (distinguishing the latter, when necessary, by a thicker stroke,) t, w, x, y, ch, ß, and th. The vowels, viz. a, õ, Ϫ, or y, ρ, and u, though often omitted in short-hand, are easily represented in a dot or dots in five different positions, when preceding or following a single consonant, or when any of them are to be interposed between two consonants. When a dot stands alone, the vowel which is meant to be represented by it is easily ascertained, by observing what part of the space it occupies between the short-hand parallels; thus, a is meant if it be found at the top, u, if it be at the bottom, i, in the middle, &c.

11th. When any consonant stands by itself, it expresses some common word or particle, as denoted in the third column of the engraved table or alphabet.

12th. When a single consonant mark is prefixed, or placed close before any other characters, it denotes some common preposition, or leading part of a word. These prepositions are respectively given in the fourth column of the alphabet.

13th. When a consonant mark is subjoined, or placed close at the end of other marks, it signifies an appropriate termination or ending. These terminations are given in the fifth or last column of the short-hand alphabet.

From the easy and regular affixation of a threefold power or preposition to each consonant, a threefold advantage naturally follows. First, by allotting to each mark, standing by itself, a word or particle of which it is the start or some constituent part, we obtain a number of common words, some or other of them perpetually occurring, expressed by a single character, which otherwise would stand for nothing.

Secondly, The prepositional part of a word being designated by its leading consonants, placed near, but not joined to the following part of it, secures alike the beauty and
STENOGRAPHY.

and brevity of the characters, which in many cases could not otherwise be maintained.

Thirdly, A similar advantage is gained by representing the terminational part of a word by an appropriate confluence of characters, not by a word, but postposed at the end of the word. Characters, when, by the mutual help of each other, they describe long and complex words in a neat and concise manner, and are easily distinguished from all others.

Two marks, it will be seen, are allotted to the consonant B, and they are each used, when standing alone, to denote two different words, the first is, and the second but. The principal reason, however, for assigning two marks to the same consonant, is to secure a more easy combination of the marks in writing, the first being used, for instance, before a defending character, as bo or bi, and the latter before one which acends, as br or bl. The first character is generally written upwards, but the second is always made downwards.

Ufed as a preposition, the first denotes ke; and the second, used as a termination, represents -ible or -ible.

One of the most common terminations in our language is denoted by the letter D, which the learner will observe stands for the word and when written separately, for ds as a preposition, and for ed as a termination. This letter is never written upwards, and the same rule will invariably apply to all those characters, whether curved or straight, that are strictly perpendicular; the oblique letters may be written either upwards or downwards.

Neither prepositions nor terminations are invariably detached from the roots of their respective words. It is difficult to lay down any precise rule for this; certainly in cases wherein the preposition or termination can conveniently be joined, it would be a needless waste of time to lift the pen. Much, however, depends upon the degree of force or importance which the termination may add to the correct pronunciation of the word, in writing the phrase, a learned man, be is learned in the law, &c.; it is not chaste to say a learn’d man, learn’d in the law. On this account it will admit of a question, whether it would not be more correct to detach the termination ed in short-hand, notwithstanding it will so conveniently join in this word. And here let the learner observe, once and for all, that he should acquire such a method of writing short-hand as will create the least possible ambiguity, or difficulty in reading it; and this can only be done by adhering as much as possible to the rules of a correct orthography and pronunciation.

The letters F and V are always written downwards. In cases where dispatch is not required, the letter v may be denoted by writing the character a little thicker. And this distinction is not only convenient, but perfectly rational: there is a kind of affinity betwixt the sound of the letter v, and the thickened of the line by which it is expressed; the letter f has, to use such a term, a thinner sound, and may fitly be denoted by a thinner character; the sound of f and v, however, is so nearly the same, that the same shaped character is very properly used for both letters. These remarks will apply to the letters r and s; in which is the same similarity of sound, shaded by the same respective strength in the pronunciation.

This character, as a word, stands for of; prefixed to other characters, it represents the preposition for; and, as a termination, -ify.

The letter Q is represented on the Short-hand plate by a character which is to denote both the hard and the soft sound of that letter. In the latter capacity, it is occasionally used instead of f. Standing by itself, it is a note, when written at the top of the line, the word again, and at the bottom, against. It has no prepositional or terminational character.

H is denoted by two characters, but the first only is to be considered as the proper representation of that letter. It is written downwards from the twirl. The other character might very well have been dispensed with, but being retained in the alphabet, may fill be used fling to denote the word bad; and notwithstanding the twirl is at the bottom, it is better to write it downwards. The first character stands for the word base.

When it is requisite to write the words bat, bit, bot, but, or any others beginning with b, and ending with t, with one or more vowels in the middle, the vowels may be indicated by placing the vowel in its appropriate position with reference to the line, but out of its usual order in other respects, vis., immediately before the consonant, and not lengthening the last letter, or t, below the line. By writing the letter r, in the words bitter and bitherto, only half its usual size, the t in the former part of the word denotes tb.

The letter J having been accidentally omitted in the plate, it is supplied here by the following characters ʒ, ʒ, standing, when written separately, for the words judge, and just; but the first only is the proper mark for the letter, the second character standing in a similar situation to the last character for b; being in a manner unnecessary, when ufed, however, it must be written downwards. There are some infinates in which the letter g may be used for j.

The next letter, K, is a very important one; for it represents the c hard, and of course is the initial letter of all those words beginning with that letter, and in all other places where it is required: it is also the first letter in words beginning with k. The soft sound of the letter c is expressed by the letter s; and sometimes the b and g are used prumiscuously for each other, whenever greater facility, convenience, and beauty of joining, may by such means be obtained. This character being, moreover, an horizontal one, may be placed at the top, middle, or bottom of the short-hand space or line. When written at the top of the space, it stands for cas; and at the bottom, for could or couldst. As a preposition, it represents, at the top, middle, or bottom, com-, con-, and contra-: in the middle of the space, it denotes the terminations -ical or -ical.

Cn and cn occurring very frequently at the beginning of words, the corresponding characters may be shortened, by cutting off the horizontal part of the letter b or c, and commencing the next letter, m or m, immediately after the formation of the twirl. This will, however, apply only to the commencement of words.

L is represented by three characters, of which it may be observed generally, that in all of them the twirl is formed to the right hand. When written fling, the first character denotes the word all, the second always, and the third altogether.

M, and indeed the horizontal characters generally, are of frequent and important use in short-hand. This letter, when written at the top of the space, represents the word am, and at the bottom among, or amongs. As a preposition, at top it is magni- in the middle mid- and at the bottom omni-. Used as a termination, it is ment; and it is customary, in this case, to write it at the top of the line.

N, the letter m reversed, is also of frequent use. As a different word, it stands am for at the top, nm in the middle, and under at the bottom. Prepositionally, it is anti- or anti-, inter- or in- and at the bottom, under- or un-. As a termination, it stands for -eat at the top, and -et at the bottom; but when used in the latter case, it is customary
STENOGRAPHY.

omary, to add a short s, or horizontal straight line, to it. Both this and the letter m, when used as a preposition or termination, should be made somewhat less than the usual alphabetical size. The same observation will apply to the letters b, d, r, t, w, &c.

P is the same letter in a perpendicular position, and is, in fact, the d reversed. As a word, it stands for upon; and as a preposition, for per-, pre-, or pre-. It may also occasionally be used for pe-

Q is the 1 reversed. In the middle, and at the end of words, it is frequently used instead of that letter. Used flangly, it is the word quaestion.

R is the oblique character used for f, with its inclination to the right, and may be written either upwards or downwards, according to the nature of the marks which may happen to precede or follow. When not joined to other characters, it is always supposed to be written downwards; and in that case the vowels are, of course, reckoned from the top downwards. As a word, it stands for for; and as a preposition, for re-; and as a termination, for -ery and -ing. The plural of which may be denoted by a small s added to it. It is seldom necessary to use the detached preposition re- in short-hand, except when the consonant which follows that preposition does not admit of being conveniently joined to the letter r.

S, or Z, expressed by a straight horizontal line, as being made a little thicker if necessary, is a letter of infinite service in our language, and in short-hand particularly. It is, as before observed, the soft. At the top, when used independently, it stands for as, in the middle for is, and at the bottom for us. By the same rule of position, it stands for the prepositions satir-, circum-, super-, and sub-. And, again, as a termination, according to the order of the vowels, for...-

T is a perpendicular line or stroke. As a word, it stands for the; as a preposition, for trans; and as a termination, for -ty. It should uniformly be written downwards.

When two s’s form a word, or part of a word, a little break must be made, to signify that such is the case. This may be done without lifting the pen; but only very lightly, moving it on the paper to the right, before the last letter is committed.

This letter, in short-hand, is often used to denote th, which is done by making the adjoining consonant, either preceding or following the t, only half its usual size: thr, thb, &c. are very conveniently so signified. In all other cases, a letter of half the size denotes that the adjoining character is to be resolved into two letters or parts; as, when in the words terror, proper, &c. the first letter is made small, and the other, the r, is its usual length: this, however, should be referred to as seldom as possible.

V is the oblique letter f, made a little thicker when needful.

W has two characters, of which the first is the proper one for the letter, as in the case of j and b. This character stands for will, the other for would and wouldst, and is written downwards: as a preposition, it is with; and as a termination, -ward and -wardly. With respect to the use of the letter s, in union with w, see the observations on b respecting that point.

X has also two characters, but the first only is used as the letter. The one stands for except, and the other for extra. As a preposition, it is ex- and extra-. The letters k and g will often express the sound of this letter.

Y is used only at the beginning of words, and for the word yet. At the end and in the middle of words, the vowel i is always used.

Z is the same as s, made thicker, when needful.

Ch are denoted by a character resembling the short hand g reversed, and stands for the word which. When founded hard, like k, as in words from the Greek, it is not used, but this letter used instead of it.

Sh have two characters, but the first is the proper representative of these combined letters. This character stands for the word shall, and the other for should and shouldst.

As a termination, it is used for -ship.

As a very frequent combination of consonants, are denoted by two characters, either of which may be considered as the legitimate representative of the united letters; but Mr. Molineux prefers the latter, which is used for the word that; the first in the formation of words only.

Et cetera. This common abbreviation is denoted by a t, and a small s or e soft, drawn from the e’s place.

Thus have we gone through the alphabet, as exhibited on the plate; and the reader, by comparing the one with the other, may readily acquire a pretty competent knowledge of the leading principles of this system of short-hand writing. So far appears to be every thing that is absolutely necessary to lay down by way of instruction to learners wishing only to acquire so much knowledge of stenography as will enable them to use it for the convenience of epistolary correspondence, for the purposes of literature and study, in the writing of common-places, making extracts, private memoranda, &c.

But as there is a higher and more desirable object to be attained by the practice of this art, viz. that of taking down the speeches of public orators, trials, &c. it is essential, to effect this object, that a still more concise method of writing should be acquired; and this may be accomplished by attention to the simple rules given in the following short extracts, abridged from Mr. Molineux’s excellent treatise.

Of Abbreviations.—An alphabet, formed upon the most just and natural plan, by which, with the help of a few general rules, all the words of the language to which it is adapted, may be easily, neatly, and speedily written, will not alone be sufficient to satisfy the expectations of an inquisitive reader; who must be sensible, that however complete the alphabet may be, yet many compendious applications of it may be obtained by an inquiry into the nature of our language, and the abbreviations of which it admits. He will not be satisfied with being only taught how to express all the letters of a word by the shortest and easiest strokes, but will also require further instructions how to describe intelligibly words and sentences, by as few of those strokes as possible. To investigate from a few things given, many which are omitted, will be found not only the capacity of the learner’s faculty, but if the few be properly given, the sense of the passage, and a due attention to the idiom of our language, will render the discovery of the omissions more certain, and also less difficult, than the unexperienced would be apt to imagine. Without some rules of abbreviation, one end of short-hand, that of following a speaker, would fearfully be attainable.

It may be proper, however, to advise the learner not to embarrass himself with short-hand abbreviations, till, by a competent
competent practice of writing according to the rules already laid down, he is become so well acquainted with the characters, as to be able to write and read them with nearly as much ease as common long-hand. He will then meet with little more difficulty in reading words contracted, than he formerly did in those written more at length, provided that the rules of abbreviation be duly attended to. A summary of the principal rules and most practical methods of abbreviation is here given, and it is left to the skill and discretion of the writer, by observing their nature, and proceeding upon the same principles, to make such farther advances and improvements as his occasions may require.

A brief Summary of the principal Rules of Abbreviation.

Rule 1.—To join the auxiliary verbs, the particle not, and the pronouns together; as can be, have been, may be, cannot be, he must be, ought not to be, &c.

Rule 2.—To join the marks in an unusual manner, in order to shew that each particular mark denotes a word, and not a single letter; as in the, it is, as it is, since it is, it was, it was not to be, &c.

Rule 3.—Derivative substantives may be very conveniently represented, by placing a point at the end of the words from which they are derived. Derivative adjectives and adverbs may be represented also by points, distinguishable by their situation, both from the substantive and the vowel points; which may be done by placing them in a line, which, if produced, would pass through the substantive point, and would also be peculiar to the last substantive mark; one placed before the substantive point, signifying the adjective, one after it, the adverb; as, forgetful, forgetfulness, forgetfully; reasonable, reasonably, reasonableness; sufficient, sufficiently, sufficiently.

No great accuracy is necessary with respect to the adjective and adverb points, provided they be placed so as to be clearly distinguished from the vowel and substantive points.

Rule 4.—Such words as, either by their particular relation to the subject, or frequent occurrence, are easily discoverable, however concisely written, may be denoted by the first letter, if they begin a substantive, or by the first vowel and consonant, with the adjective, substantive, or adverb point annexed; as, life and mortality are brought to light by the gospel; the resurrection of the dead, and a future state of rewards and punishments, are plainly and positively taught in the gospel. The adjectives which usually accompany such substantives may also be denoted by their first consonant, joined to the substantive; as, with humble submission to your lip.

Most writers of short-hand accusm themselves to mark such words as most frequently occur in their own particular professions, by the initial letters only, with the substantive, adjective, or adverb points, which, through custom, easily suggest those words to them at first sight. But it must not be understood, that those marks imply those words exclusively, and no other. They may stand for any other beginning with the same letters, which the sense of the passages necessarily requires.

Rule 5.—A dot placed at the point of concurrence of two consonant marks, denotes two substantives, of which those marks are the first consonants; and also that the latter is governed of, or connected to, the former by some preposition, which is omitted; as, the love of money is the root of all evil; seek ye first the kingdom of God, and his righteousness, &c.; the effects of gravity are visible in every part of that system to which we belong, but the cause of gravity still remains undiscovered.

And if an adjective precedes either of the substantives, they may all three be represented by their first consonants joined together, with the dot always placed at the end of the first substantive; as, the great goodness of God is manifested in all his dealings with his creatures; his majesty the king of Great Britain.

Rule 6.—The substantive point, placed before a single consonant mark, denotes that the substantive is to be repeated, with some intervening preposition; as, day after day; from time to time.

Rule 7.—The substantive, adjective, or adverb point, placed before two or more consonant marks joined together, denotes two or more substantives, adjectives, or adverbs, of which those marks are the first consonants, and also that they are connected by a conjunction; as, the precepts both of natural and revealed religion forbid us to do our neighbours any injury; what doth the Lord thy God require of thee, but to live soberly, righteously, and godly in this present world.

Rule 8.—Many long words, especially those in which the marks for the consonants will not join neatly, may be denoted by their first syllable, with as many points annexed as there are syllables wanting; as, multitude, correspondence. And when great dispatch is required, the points may be omitted, especially if the words do not begin with prepositions; as, specification, difficulty, negligence.

Rule 9.—Words beginning with prepositions may be denoted by their respective prepositions, together with the next consonant and vowel, and sometimes with the next consonant only, adding, if necessary, the substantive, adjective, or adverb point; as, deliberate, transtimation, recommendation, confounding, &c.

The participles may be abbreviated after the same manner, by adding, instead of the points, the terminations ing or ed to the latter consonant mark; as, considering, considered.

Words beginning with double or treble prepositions, may be written after the same manner, joining the prepositions together; as, representation, misrepresentation, incomprehensibility. If two substantives begin the next syllable, the writing of them both will help to discover the remainder of the word; as, misunderstanding, transtination.

Rule 10.—Words ending in any of the terminations which in the alphabet are denoted by consonant marks, may be expressed by their first consonant and vowel, together with the proper mark for its termination; as, arbitrary, opportunity, curiosity, lawfulness.

Rule 11.—Such words as are easily discoverable by the particular prepositions which they require, may be denoted by their first consonant only; as, this belongs to me; he made some good observations upon it; we must guard against such passions as we are most liable to.

As few English words end with the syllable are, the preposition to may be joined to the preceding word, which is signified by its first consonant only; as, this belongs to me, liable to, satisfactory to.

Other prepositions which are denoted in the alphabet by a single consonant, may, in like manner, be joined to the preceding word; as, he made some very good observations upon it.

Rule 12.—Prepositions generally require after them either a noun or pronoun. The pronouns being few in number, and some of them used as substantives, or adjectives, for nouns, must occur very frequently, and by that means soon become familiar to the learner; pronouns, therefore, may be joined to the prepositions, without danger of creating any difficulty to the reader; as, to me, to you.

Rule 13.—The preceding word, the preposition, and pronoun, may be joined all together; as, belongs to me, extends to us, agreed with me, depend upon me, observations upon this.

The words same, any, none, which, such, best, &c. followed
lowed by a preposition and pronomes, may be denoted by
their first consonants, and may be joined to the preposition
and pronomes; as, some of them, any of us.
Rule 14.—The adverbs preceding the verbs, and the sub-
stantives following the pronominal adjectives, may be joined
to the verbs and adjectives respectively, denoting both the
adverbs and substantives by their first consonants, or at most
by their first consonants and vowels; as, "you may safely de-
part upon my account."

Rule 15.—Many common phrases, formed by a substan-
tive preceded by the prepositions with, without, in, &c., and
followed by to, of, &c., may be very conveniently abbrevi-
ated; as, with regard, with or, in order to, to, in con-
sequence, comparison, or consideration of.

Rule 16.—Common adverbial phrases are, in like manner,
often denoted by their initial consonants joined together; as,
at the same tome, at present, in this manner, in like manner,
in a great measure, in the same manner, in the mean time, in
general, in particular.

And when the proportion of equality is expressed, with
some one word intervening, they may be all joined together;
as, as much as, as well as, as soon as.

Rule 17.—The conjunctions which may be made, when it
is or it was, are followed by an adjective, and to or that, are
very numerous; as, it is impossible, it was unnecessary, it
is contrary to, it is according to.
STENOMARGA, in Natural History, a name used by
some authors for a light marly earth, more usually called
epicurus minerals, and late luna by the later writers, and terra,
or creta Selenehcyca, by Dioecides and Galen.

STENOSA, in Geography, an island in the Grecian Ar-
chipelago, about 10 miles in circumference, inhabited only
by a few goats and their keepers. N. lat. 37° 5'. E. long.
25° 55'.

STENSKAR, two or three small islands on the W.
sie of the gulf of Bothnia. N. lat. 65° 12'. E. long.
21° 40'.

STENSITZ, a town of Poland, in the palatinate of
Sandomirz; 30 miles E. of Radom.

STENTATO, an Italian musical term, given by Brof-
ward, which no longer occurs in musical works at present.
It seems to have been superceded by Sforzando.

STENTEROPHONIC TUBE, a speaking trumpet, so
called from Stentor, the vociferous Stentor, celebrated by
Homcr (Ilad, lib. v.) as the most illustrious throat-per-
former, or herald of antiquity:

"Stentor the strong, endued with brazen lungs,
Whose throat surpass'd the note of fifty tongues."

Pope observes on this passage, that "there was a necessity
for cryers whose voices were stronger than ordinary, in those
ancient times, before the use of trumpets was known in their
armies. And that they were in esteem afterwards, may be
seen from Herodotus, where he takes notice that-Darius
had in his train an Egyptian, whose voice was louder and
stronger than that of any other man of his age."

The speaking-trumpet, under the title of the Stentero-
phonie tube, was long ascribed in England to sir Samuel
Moreland; but Kircher has formally laid claim to it in his
"Mufurgia," however, the Stentorophie horn or tube of
Alexander the Great claims primogeniture, as well as su-
perior magnitude; for it is said that he could give orders to
his army at the distance of 100 stadia, which is above twelve
English miles. See Trumpet.

STENWICK, in Geography, a town of Norway, in the
province of Drontheim; 24 miles S.W. of Drontheim.

STENYCLARUS, in Ancient Geography, a town of Lo-
Vol. XXXIV.

conia, upon the river Pamyus, N. of the gulf of Messenia;
where Crephonte, one of the chiefs of the Heraclidae,
established his residence, and which he made his capital, so
that it was called a royal city, or βασιλικὸς.—Allo, a plain of
Messenia, W. of the river of Paunfania, known on account
of a battle very disastrous to the Lacedaemonians, in the year
684 B.C. Paunfania places this plain on the road from Meg-
ara, in pass of Arcadia to Ithome.

STENZYLE, in Geography, a town of Poland, in Vol-
bynia; 15 miles N.E. of Luckow.

STE. See Pack, Stair, &c.

Steps, in Ship-Building. Steps for masts, into which their
heels are fixed, are large pieces of timber. The main and
fore-step are fixed across the keel, and that for the
mizen-mast upon the lower-deck beams. The hole, or mort-
tice into which the heel of the mast steps, should have suf-
cient wood on each side, to accord in strength with the
tenon left at the heel of the mast, and the whole cut rather
less than the tenon, as an allowance for shrinking. The step
for the capstan is a solid lump of oak, let down between
the beams, in which the spindle at the heel of the capstan
traverse in an iron cup. Steps for the ship's fide are pieces
of oak quartering, with tenonings, nailed on the fides at
the gangway, about nine inches aunder from the wales upwa-
dards, for the convenience of getting up the fides.

Step, or Tongue, in Rope-Making, for the tar-kettle, is
made of three-inch oak-plank, five feet long and thirteen
inches broad, which tapers to nine inches at the bottom,
and is put into the kettle through a mortise in the bridge.
Within four inches of the lower end of the step is a round
hole five inches diameter, for the yam to pass through. The
step is suspended and regulated by a tackle.

Step and Leap, in the Manege, one of the seven airs or
artificial motions of a horse, consisting, as it were, of three
airs: viz. the pace or step, which is terra-a-terra; the
jumping before, which is a curuet; and the whole finished with
a fault or leap, which is a capriole.

This manege is infinitely less painful to a horse than the
capriole; for when you dress a horse to the capriole, he will
of himself take to this air for his ease and relief; and in time
those horses which have been drest to the caprioles, will
execute only balotades and croupades, unless particular care
is taken to make them yerk out.

It is this, likewise, which, next to running a brisk coure,
enliven's and animates a horse most: to reduce a horse to the
jufness of this air; you must begin by emboldening and
making him lose all fear of correction, teaching him to keep
his head steady, and in a proper place, lightening his fore-
parts by putting him to make pefades, and teaching him to
know the aid of the switch, the fame as in the lefton of the
capriole, and by giving him a firm and good appu, and
full in the hand; though it is certain that the step contrib-
utes to give him this appu, inasmuch as that it puts him in
the hand; besides, that it gives him strength and agility
to leap, just as we ourselves leap with a quicker spring
while running, thus if we were to stand quite still and leap;
therefore, most old horses generally fall into this air.

When your horse is sufficiently knowing in these several
particulars, teach him to rife, and hold him in the air; then
let him make three or four pefades, and afterwards let him
walk four or five steps low and equal. If he forces the
hand, or retains himself too much, he should be made to
trout these four or five steps rather than walk: after this,
make him rife again, and continue this lefson for some
days.

When he is so far advanced as to comprehend and un-
stand this sufficiently, begin by putting him to make a
U
pefade;
pèfades; demand then a leap, and finith by letting him make
two pèfades together.

There are two things to be observed, which are very
efficient in this lefson: one, that when he is to make the
leap, he should not risé so high before as when he makes
pèfades only, so that he may yerk out with greater ease and
liberty; the other caution is always to make your last pè-
faide longer and higher than the other, in order to prevent
your horse from making any irregular motions, by shuffling
about his legs, if he should be angry and impatient, as well
as to keep him in a more exact obedience, and to make him
light in the hand, if he is naturally heavy and loaded in his
fore-parts, or apt to lean too much upon the hand.

Again, reduce the third or fourth pèfade into a leap, as
you did the first, then make two pèfades following; and
after this, let him walk quietly four or five steps, that he
may make again the same number of pèfades, and in the
same order. In proportion as the horse begins to under-
stand, and is able to execute these lefsons, you should aug-
ment likewisè the leaps one by one, without hurrying or
changing their order, making always between two leaps a
single pèfade, but lower than thefe in the first lefson, and
then two more again after the last leap, and sufficiently
high.

By degrees the horse will grow active and light in his
hinder parts; you must raise him then higher before, and
support him longer in the air, in order to make him form
the leaps perfect, by means of prudent and judicious rules,
often practised and repeated.

If a horse forces the hand, or preties forward more than
you would have him, either from heaviness of make, or from
having too much fire in his temper; in this case, you should
oblige him to make the pèfades in the same place, without
stirring from it; and instead of letting him advance four or
five steps, you should make him go backward as many.

This correction will cure him of the habit of prelling for-
dward, and forcing the hand. Upon this occasion, likewisè,
you should use a hand-spur to prick his croup, instead of a
switch.

To make this air just and perfect, it is necessary that the
action of the leap be finished as in the caprioles, except
that it ought to be more extended; and that the pèfade, which
is made between the two leaps, should be changed into a
time of a quick and short gallop; that is, the two hinder
feet ought to follow together in a quick time, and briskly;
the fore-feet, as in curvets in the meazir; but in this the
horse should advance more, not be so much together, nor
rise so high.

The perfection of this time of the gallop depends upon
the justness of the horseman's motions. They ought to be
infinitely more exact in this lefson than in the caprioles,
or any other airs which are performed straight forward.

In reality, if the horseman is too flow, and does not catch
the exact time which parts the two leaps, the leap which
follows will be without any spring or vigour, because the
animal so restrained and held back can never extend himself,
or put forth all his strength. If he does not support and
raise his shoulders sufficiently high, the croupe will then be
lower than it ought to be, and this disproportion will force
the horse to tosé up his nose, or make some other bad mo-
tion with his head, as he is coming to the ground in his
lep; or else it will happen from this, that the succeeding
time will be so precipitate, that the next leap will be falle
and imperfect, as the horse will not be sufficiently united,
but will be too heavy, and lean upon the hand. If he is not
together, the leaps will be too much extended, and conse-
quentially weak and loose; because the horse will not be able
to collect his strength, in order to make it equal to the
first.

Learn then, in a few words, what should be the horse-
man's feat, and what actions he should use in this lefson:
He should never force, alter, or lose the true appui,
either in raising, supporting, holding in, or driving forward
his horse.

His hand should be not only firm and steady, but it is
indispensably necessary that his seat be exactly straight and
just; for since the arm is an appendix of the body, it is cer-
tain that the motions of the horse shake or disorder the body
of the rider: the bride-hand must inevitably be shock, and
consequently the true appui destroyed.

In this attitude then approach the calves of your legs,
support and hold your horse up with your hand; and when
the fore-part is at its due height, aid with the switch upon
the croupe.

If your horse rises before, keep your body straight and
firm; if he lifts or tosés up his croupe, or yers out, fling
your shoulders back, without turning your head to one side
or the other, continuing the action of the hand that holds
the switch.

Remember that all the motions of your body be so neat
and fine, as to be imperceptible: as to what action is the
most graceful for the switch-hand, that over the shoulder
is thought the belt; but then this shoulder must not be more
back than the other; and care must be taken that the motion
be quick and neat, and that the horse do not see it so plainly
as to be alarmed at it.

It is said, that when the horse makes his leps too long
and extended, you should then aid with the hand-spur, and
for this reason, because the hand-spur will make the
horse raise his croupe without advancing, as the effect of
the switch will be to raise the croupe, and drive the horse for-
ward at the same time; it should, therefore, be used to such
horses as retain themselves.

Remember that you should never be extreme with your
horse, and work him beyond his strength and ability: indeed
one should never ask of a horse above half of what he can
do; for if you work him, he will grow languid and tired;
and his strength and wind fail him, you will be compelled to
give your aids rough and openly; and when that happens,
neither the rider nor the horse can appear with brilliancy
and grace. Berenger's Horsemanship, vol. iii. ch. 21.

STEPAN, in Geography, a town of Poland, in Vol-
hynia; 15 miles N.E. of Luckow.

STEFENITZ, a river of Mecklenburg, which joins
the Trave, at its entrance into the Baltic.—Alto, a river
of Saxony, which runs into the Elbe, near Wittenberg.—

hemia, in the circle of Chrudim; 16 miles N.E. of
Chrudim.

STEPHANIA, in Botany, so named by Loureiro,
from στέφας, any thing encircling the summit of some-
ing else; whence comes στέφας, a crown; and hence the above
appellation alludes to the anther, "which surrounds the head
of the filament, like a crown of gold."—Loureir. Coehinch.
Sarmentaceae, Linn. Alphanagi, Jull.

Gen. Ch. Male, Cal. Perianth of six rather acute,
spreading leaves; the three alternate ones smaller. Cor.
Petales
name given by this author to Aublet's *Palicourea*. (See that article.) The genus itself is, however, abolished, Dr. Swartz having reduced it to *Pachytopia*. Fl. Ind. Occ. v. 1. 433, in which he is followed by Wildenow, Sp. Pl. v. 1. 971. These authors call Aublet's plant *Pachytopia Palicourea*. It is a native of Guiana and the West Indies. *Stephanium* would be too near *Stephania*, if the genus of Schreber and Aublet were a good one.

**Stephankowice**, in *Geography*, a town of Poland, in the palatinat of Belz; 34 miles N. of Belz.

**Stephanophorus**, *Crown-Bearer*, in *Antiquity*, the chief priest of Pallas, who presided over the reft. It was usual for every god to have a chief priest; that of Pallas was the Stephanophorus, just mentioned; and that of Hercules was called Dadochus.

**Stephanowze**, or *Stephanestih*, in *Geography*, a town of European Turkey, in Moldavia, at the confluence of the Pruth and the Bafsou; 40 miles N. of Jaffy. N. lat. 47° 53'. E. long. 27° 30'.

**Stephansberg**, a town of Germany, in the principality of Anspach; 4 miles N. of Maynbernheim.

**Stephansdorf**, a town of Sile sia, in the principality of Neisse; 4 miles N.W. of Neisse.

**Stephante**, a town of Asiatic Turkey, in Natolia, on the coast of the Black Sea; 9 miles N. of Sinob.

**Stephanus, Byzantius**, in *Biography*, a grammarian who flourished, as it is conjectured, about the close of the fifth century, was professor in the imperial college of Constantinople, and composed a dictionary containing nouns-adjective derived from the names of places; and designating the inhabitants of those places. Of this work there exists only an abridgment, made by Hermolaius, and dedicated to the emperor Justinian. This work is known by the title *Theon*, de Urbibus; but that of the original was *Ewos*; hence it has been inferred, that the author's intention was to write a geographical work. Much of the value of the original is unquestionably lost in the abridgment; yet learned men have derived considerable light from it; and it has been an object of critical illustration to Casaubon, Scaliger, and Salmasius. It was printed in Greek at Venice, in 1502, under the superintendance of Aldus Manutius. An edition of it, with a Latin version, was published at Amsterdam, in 1678, by Pineda, a Portuguese Jew; and ten years after this, an edition was printed at Leyden, with a translation by Abraham Berkelsuus, who added a very copious commentary. This edition was not completed when the learned editor died, and it was finished by James Gronovius. A fragment of the original, relative to Dodoza, is extant; and an edition of it was given by Gronovius.

**Stephen I., Pope**, succeeded Lucius about the year 234. His pontificate was rendered memorable by his dispute with Cyprian, bishop of Carthage, concerning the baptism of heretics. Stephen had already displayed a degree of temperance, by pronouncing the restoration of Basilides and Martialis, two Spanish bishops, who had been deposed by the other prelates of that country, and who went to Rome to appeal to the pope. Cyprian, in this discussion, maintained that baptism by heretics could not be valid; an
STEPHEN.

an opinion which was confirmed by a council of seventy-one bishops, held at Carthage. Their determination was sent to the pope, who not only rejected their decrees, but enjoined them, under the penalty of excommunication, to renounce their decrees; and he concluded with some severe re-

Stephen II, pope, a presbyter, was chosen in 752 to succeed Zachary, but who died within a few days of his election, and before he could be consecrated. He is omitted by all the ancient authors in the papal catalogue, but by later writers he has been admitted, upon the principle that election alone confers the papal authority, and that he is therefore to be regarded as a real pope. He was suc-

Stephen III, who was elected in the same year. He was a native of Rome, the son of a perfon named Constan-
tine, and had acquired the dignity of deacon of the Roman church, when he was chosen to fill the pontifical chair. At this time Aëtaphus, king of Lombardy, who had made himself master of all the exarchate of Ravenna, threatened Rome, requiring its submifion, and the payment of a tribute. The pope attempted to divert him from his de-
signs, but without effect; the haughty monarch invaded the city, nor could he be deterred from his purpose by the solici-
tation and threats of the emperor Constantine. The ponti-
fiff applied now for the aid of Pepin, king of France, who received him into his court with every mark of respect. Here he was taken ill, but having recovered, he solemnly anointed Pepin, with his queen and two sons, in the church of St. Denis. The king then marched with an army into Italy, taking the pope with him, and besieged Aëtaphus in Pavia, who was obliged to submit to the terms of reftoring to the church all the territories which he had feized from it, and also of relinquishing the exarchate of Ravenna. No sooner, however, had Pepin repelled the invader, than Aëtaphus resumed his arms, and marched to Rome, to which he laid siege. Stephen had again recourse to his protector, imploring him, in the most urgent and pathetic manner, to come to the relief of the holy fee in its imminent danger. He also employed some artifice for rendering effectual his entreaties, which was to write a letter to Pepin in the name of St. Peter, calling upon him in his own perfon, and that of the Blessed Virgin, to hasten and rescue his favourite people. Pepin did not wait for the second invitation, but immediately on hearing of the danger of the pontif, marched without delay, and laid siege to Pavia. Aëtaphus was now obliged to raise the siege of Rome, and enter into a treaty, by which he confirmed the former terms, with some farther sacrifices. Pepin then caused an instrument to be drawn up, signed by himself and his sons, by which he ceded for ever to the holy fee all the places thus yielded up by the Lombard king, including the exarchate, which he had taken from the emperor of Constantinople. He afterwards caufed the incenfe of donation, with the keys of all the cities, to be laid on the tomb of St. Peter in Rome. Stephen had thus the honour of being the founder, or first possessor, of the temporal grandeur of the pontificate. He died in April 757, after having fat in the papal chair somewhat more than five years. Seven letters, and a collection of canonical constitutions, are extant under the name of this pope.

Stephen IV. (III.), born in Sicily, came to Rome in the pontificate of Gregory III., and was in great esteem with several succeeding popes. He was titular priest of St. Cecilia at the time of the death of Paul I., in the year 767. On that event, Toto, duke of Nepi, coming to Rome with an armed band of friends and valets, caused his own brother, Confiantine, then a layman, to be proclaimed pope; and taking him to the Lateran palace, obliged the bishop of Palestrina to ordain him, and afterwards to consecrate him bishop. This usurpation produced great discontent at Rome, and various parties were formed, who elected two popes, of whom one was instantly thrown into prison, and the other as quickly deposed; after which there was a regular election, and the unanimous choice fell upon Ste-

Stephen, who was consecrated in August 768. The first act of the new pope was to send a letter to king Pepin, and his sons Charles and Carloman, requesting their protection, and also defining that some learned bishops might be sent from their dominions, to assist at a council which he proposed to hold at Rome, for the purpose of restoring the ecclesiastical discipline, which had gone to decay during the usurpation. Pepin was dead before the arrival of Sergius; nevertheless, he was received with great respect by Charles and Carloman, who complied with the request of sending bishops to the council. This was assembled in the Lateran; and Confiantine, who had usurped the popedom, and who had been deprived of his eyes, was brought before it, and condemned to confinement for life in a monastery; and all those who had received the eucharist at his hands, among whom was Stephen himself, were obliged to perform penance. The pope was now possessed of the see, but some differences arose between him and Defiderius, king of the Lombards, who had not delivered up all the places to which the church was entitled by the treaty of Pavia, and had nominated a successor to the vacant archbishopric of Ravenna. Defiderius, having a party in Rome, marched towards that city at the head of a body of troops, and he obliged the pope to dismiss his minis-
ters Chri-
topher and Sergius, whom he treated with great cruelty, under the pretence that they were the partizans of Carloman. He also urged Stephen to enter into an alliance with the Lombards, till a solemn embassy from Charles and Carlo-
man, offering to maintain him in the possession of all that their father had bestowed on the holy see, relieved him from his difficulties. A marriage being afterwards proposed be-
tween the daughter of Defiderius, and Charles, the pope opposed it, in a letter which he wrote to the two French princes, filled with declamation, not only against the Lom-
bards, but against the female sex. The match was, how-
ever, determined upon; and Bertrade, the mother of the princes, visiting Rome, was received by the pope with great honour, and was probably instrumental in procuring the de-

Stephen, in the beginning of 772, after having governed the church nearly three years and a half. Three of his letters are extant.

Stephen V. (IV.), pope, succeeded Leo III. in 816. He was of an illustrious Roman family, and had been made deacon by Leo, who, as well as the clergy in general, en-

Stephen had thus the honour of being the founder, or first possessor, of the temporal grandeur of the pontificate. He died in April 757, after having sat in the papal chair somewhat more than five years. Seven letters, and a collection of canonical constitutions, are extant under the name of this pope.

STEPHEN.

son of Charlemagne, and he sent legates into France, to pro-
poe an interview with that sovereign. Rheims was the
place fixed upon for that purpose; and Stephen repaired
thither, accompanied by Bernard, king of Italy. The em-
peror went to meet him upon his approach, and honoured
him by protestations and other tokens of profound reverence.
Stephen repaid his attentions, by solemnly crowning him
and his queen with rich crowns, which he had brought from
Italy. After palling two months in France, he returned to
Rome, where he died about seven months after his election.

Stephen VI. (V.), pope, whose original name was Basil,
was of a noble Roman family, a prebender of the church of
Rome, and highly venerated by all ranks, as well for the
purity of his morals as the sanctity of his life. He suc-
ceeded to the popedom in May, 885, upon the death of
Adrian III., and was forcibly carried for installation to the
Lateran, which ceremony was followed the next day by
his consecration. His election gave great offence to the em-
peror Charles the Grofs, who immediately sent a delegate to
depose the pope, as having been appointed without his con-
dent, or even knowledge; be was, however, pacified by a
solemn embassy bringing the decree of election, signed by
thirty bishops, and all the leading laycmen; and Stephen
was confirmed in his title. The eastern emperor, Basil the Ma-
cedonian, having formerly written a letter to the pope's pre-
decessor Adrian, severely reflecting upon him and the former
pope, Marinus, for refusing to communicate with the pa-
triarch of Constantinople, Photius; Stephen now wrote a
reply to the letter, defending the conduct of his predecess-
or, and strongly expressing his own disapprobation of
Photius. This patriarch being afterwards deposed by the em-
peror Leo the Philosopher, who placed his own brother
Stephen in the see, the pope was applied to by the eastern
bishops and clergy, requesting that he would grant a dis-
pensation for the new patriarch, who had been ordained
deacon by Photius, and would forgive those who had com-
unicated with Photius. The pope expressed much satisfac-
tion in the expulsion of Photius, but refused the dispensa-
tion till he could be more fully informed of the cause, for
which purpose he desired that bishops might be sent to him
from both parties. On the death of Charles the Grofs
without male heirs, in 886, there was a competition for the
succession to the crown of Italy, between Berenger, duke of
Friuli, and duke Bertrand of Spoleto; the eastern emperor,
Romans declared for the latter, who was eventually crowned
emperor by Stephen at Rome, in 891. This pope died
in the same year, after a pontificate of somewhat more than
six years.

Stephen VII. (VI.), pope, a native of Rome, placed on
the pontifical throne on the expulsion of Boniface, in
896, disgraced himself by the treatment which he bestowed
on the dead body of pope Formosus, who had preceded
Boniface. Having assembled a council for the purpose, he
cruelty it to be disinterred, and placed in its episcopal robes
in the papal chair. It was then asked, "Why didst thou
dare usurp the universal see of Rome?" No defence being
set up, Formosus was pronounced guilty of the charge of
intruding by unlawful means into the apostolical see; the
body was stripped of the pontifical ornaments, three of its
fingers were cut off, and it was thrown into the Tiber. At
the same time the council declared, that Formosus having
been incapable of confessing orders, all perfons who had re-
ceived them at his hands must be reordained. Stephen re-
verted the decree of Adrian III., which determined, that
a vacancy, the pope elect should be consecrated without
waiting for the presence of the imperial envoy. He en-
joyed his dignity only a very short time, for in 897 he was
dethroned, hurried into a dungeon, and there strangled.
Two letters to the archbishop of NARBONNE are attributed
to him, but probably without sufficient authority.

Stephen VIII. (VII.), pope, was also a native of
Rome, and elected successor to Leo VI. in the year 949;
he held the pontificate rather more than two years, and then
died, without having done any thing which has been deemed
worthy of record.

Stephen IX. (VIII.), pope, elected in 939, at the
vacancy made by the death of Leo VII., is said to have
been a German, and to have owed his election to the in-
fluence of the emperor Otto the Great. It is related of
this pontiff, that he sent the pallium to Hugh, archbishop
of Rheims, son of count Herbert, who had been expelled
from his see, and restored and consecrated by a council of
bishops, although at that time he was only eighteen years
of age; that he warmly espoused the cause of Lewis d'Out-
tremer against his rebellious subjects, sending a bishop into
France, with letters addressed to the nobles of that country
and Burgundy, in which he exhorted them to submit to their
lawful sovereigns, and then threatened them with excommu-
nication in case of disobedience. He also attempted to me-
date between Hugh, king of Italy, and Albert; and for
that purpose sent for Golo, abbot of Cluny, to Rome;
but both the abbot and he died very soon after, in the
year 943. He held the see of Rome three years and four
months.

Stephen X. (IX.), pope, whose former name was
Frederic, was brother to the duke of Lorraine. In the
time of Leo IX. being archdeacon of the church of Liége,
he was one of the delegates sent by that pontiff to the em-
peror Constatine XI., in order to negotiate a union between
the churches of Rome and Constantinople. On his return he
was created chancellor of the Roman church, and was made
abbot of the monastery at Monte Cassino. By pope
Victor II. he was raised to the dignity of cardinal, whom
he succeeded in the popedom. The election occurring on
the festival of St. Stephen, he assumed the name of that
saint. He immediately undertook the reform of the
clergy, and held councils, in which several canons were made
against marriage, and the concubinage of priests. He
exacted the submision of the church of Milan to that of
Rome, after it had for some years withdrawn itself from
that of Rome; and he held the pontifical chair only a few months.
Two letters of this pope are preferred, one to the archbishop
of Rheims, the other to the bishop of Marf.

Stephen, king of England, the son of Stephen, count
of Blois, by Adela, fourth daughter of William the Con-
queror, was born about 1104. He and his younger brother
Henry were invited over to England by the late king
Henry I., and were loaded with riches, honours, and high
preferments. Henry entered into the ecclesiastical profes-
sion, and was created abbot of Glastonbury, and bishop of
Winchester. But Stephen received higher marks of
favour, and more substantial establishments. He caused
him to be married to Matilda, the daughter and heirs of
Eudes, count of Boulogne, gave him the earldom of Mor-
tisgne.
STEPHEN.

taigue in Normandy, and the forfeited estates of Robert Mallet and others in England. Stephen, by his marriage, acquired a new connection with the royal family of England, as his wife's mother was sister to David, king of Scotland, and also to Matilda, the first wife of Henry, and mother of the emperors. Stephen, in return, professed the most grateful attachment to his uncle; and displayed a marked affection in taking the oath for securing the succession of the empress Matilda, daughter of Henry L., and lawful heir to the crown. In the mean time, however, he continued to cultivate, by every art of popularity, the friendship of the English nation; and the display of some virtues which he seemed to profess, favoured the success of his intentions. By his bravery, activity, and address, he acquired the esteem of the barons: By his generosity, and by his affable and amiable manner, not at all usual in that age among men of his high quality, he obtained the affections of the Londoners, and now entertained the most fanglour hopes, that by accumulating riches and power, and by acquiring popularity, he might in time make his way to the throne. As soon as Henry was dead, in 1135, he hastened from France to England, and was received in London with the loudest acclamations. But in order to obtain a formal coronation, it was necessary for him to gain the concurrence of the clergy; and for this purpose, his brother, the bishop of Winchester, was of material service. Roger, bishop of Salisbury, chief justiciary and regent of the kingdom, was readily brought over to his party; but the archbishop of Canterbury refused, till Hugh Bigod, steward of the household, made oath that the late king, upon his deathbed, had declared an intention of disinheriting his daughter Matilda, and leaving the crown to Stephen, although several of the nobility had been witnesses to a directly contrary declaration. Such was the necessity of the age, or the lax ideas of hereditary succession, that Stephen was solemnly crowned, and allowed to enter upon the exercise of the regal functions, though very few of the barons attended at his coronation. He made many concessions, promised to abdicate certain exactions and arbitrary measures of the reign since the Conquest, and engaged to restore the popular laws of Edward the Confessor. The first opponent of his government was David, king of Scotland, who, either to support the cause of his niece the empress, or to take advantage of the discontent of the faithful of the confraternity of an usurpation, entered the north of England with an army, and took possession of Carlisle and Newcastle. Stephen negotiated with him, and made large cessions as the price of peace. Robert, earl of Gloucester, natural son of Henry II., who was in Normandy when Stephen feigned the crown, fearing lest he should be deprived of his English estates, came over, and took an oath of fealty to the usurper, but under the condition that he should be obliged to keep it no longer than all the engagements made to himself should be complied with. Most of the other nobles, in submitting, stipulated for the right of fortifying their castles, which at length filled England with strong holds for rapine and every kind of disorder.

The success of Stephen was, at first, equally flattering in Normandy. He was invited over to assume the sovereignty of that duchy, and in 1137 he accepted the invitation, and formed an alliance with the king of France. The king of Scotland made a second incursion into England, on the pretext of occupying Northumberland, upon which province his son Henry had a claim; and his demands being rejected, he cruelly laid the country waste with fire and sword. Stephen marched to oppose him, but was recalled by disturbances in the south. The northern barons, provoked at the success of the Scottish arms, raised an army, with which they encountered David at Northallerton, and gave him an entire defeat in the battle of the Standard. Stephen, in the mean time, had involved himself in a dangerous contest with the ecclesiastical power. The bishop of Salisbury, his two nephews, the bishops of Lincoln and Ely, and his natural son, the chancellor of England, had erected strong castles, which they held in defiance of the regal authority. Stephen having called, in 1139, a council of the nobility at Oxford, feigned the bishops of Salisbury and Lincoln, and the chancellor, and in a short time made himself master of the other castles. These violent proceedings caused the assembling of a synod at Westminster, by the bishop of Winchester, Stephen's brother, and legate of the holy see, who felt more for the privileges of his order than the ties of blood. The synod sent a summons to Stephen, who delegated a nobleman to appear for him, and an open breach was prevented only by the firmness of some barons, who regarded the conduct of the bishops as f egitious and unbecoming their character. Discontents were, however, aggrava-

...
ter prince should, on the demise of Stephen, succeed to the kingdom, and to William, Stephen’s son, to Boulogne, and his patrimonial estate. After all the barons had sworn to the observance of this treaty, and done homage to Henry, as to the heir of the crown, that prince evacuated the kingdom; and the death of Stephen, which happened in the next year, after a short illness, prevented all those quarrels and jealousies which were likely to have ensued in so delicate a situation.

“England,” says Mr. Hume, “suffered great miseries during the reign of this prince: but his personal character, allowing for the temerity and injustice of his usurpation, appears not liable to any great exceptions; and he seems to have been well qualified, had he succeeded by a just title, to have promoted the happiness and prosperity of his subjects. He was possessed of industry, activity, and courage, to a great degree; though not endowed with a sound judgment, he was not deficient in abilities; he had the talent of gaining men’s affections; and notwithstanding his precarious situation, he never indulged himself in the exercise of any cruelty and revenge. His advancement to the throne procured him neither tranquility nor happiness; and though the situation of England presented him with many advantages from taking any durable advantage of her confusion, her intellectual disorders were to the last degree ruinous and destructive. The court of Rome was also permitted, during those civil wars, to make farther advances in her usurpations; and appeals to the pope, which had always been strictly prohibited by the English laws, became now common in every ecclesiastical controversy.” Hume. Henry.

Stephen I, king of Hungary, called Saint Stephen, succeeded to the throne in 997, on the death of his father Géza. He was then very young, but had been declared king by the States in the preceding year, which title he is said to have been the first who bore in Hungary. He is celebrated for his piety, which he displayed by his great zeal in the conversion of his heathen subjects. The nobles, adhering strongly to their ancient religion, raised a rebellion against him, headed by the duke of Cusa: their leader was slain, and themselves completely routed. The body of Cusa was divided into four parts, and exposed in four of the principal cities of Hungary. After this great victory, he established twelve bishoprics, richly endowed, and built many churches; and was so devout, as to erect a church at Constantinople, another at Rome, and a monastery at Jerusalem. In the year 1002, Giala, prince of Transylvania, Stephen’s uncle, making an irruption into the adjacent provinces, Stephen marched against him, and in a few months made himself master of Transylvania, which he annexed to the crown. He afterwards repelled an invasion of the Bulgarians, purged them to their own country, and obtaining a signal victory, returned laden with booty. Besides the glory derived from his success in war, he had that of being the legislator of his country. He published a code composed in fifty-five chapters, which, though marked with the barbarism and ignorance of the times, was very long popular among the Hungarians. Towards the end of his reign, it was his intention to reign his crown to his son, in order that he might pass the remainder of his days in a religious retreat, but the premature death of the prince disconcerted this design. He died at Buda in 1034, and was canonized at Rome. His memory is held in profound reverence by the Hungarians, who have preferred the crown sent to him by the pope as the palladium of their kingdom.

Stephen, John, in the Latin tongue Stephanus, a learned Dane, was born at Copenhagen in 1599. He studied at the schol of Herlesholm, and after having twice travelled into foreign countries, was made professor of eloquence at Soroe, in 1650. In 1659 he became professor of history in the same university, and was afterwards appointed to be historiographer by Christian IV. He died in 1670. Among his works are enumerated the following: “Breves Emendationes et Notae in Saxonom Grammaticum,” 1627. “Florilegium Sententiarius ex Saxone,” 1627. “De regno Daniae et Norvagiae, Inulis adjacentibus Translatus varius,” 1629. “Suenonis Agonias Fili Opificula, Notis illustrata, accedunt Leges Castrimenses Canuti magni, et incerti Auctoris Genealogia Regum Daniae,” 1642. “Historia Danicae Libri duo, qui complectuntur res memoratoris dignae, in Dania gestatas, Regnante Christiano III., ab Anno 1550, ad Annum 1550.”

Stevens, in Geography, a river of Vermont, which runs into the Connecticut.

Stevens, Cape, a point of the American continent, opposite to Stuart’s island, situated in N. lat. 63° 33', and E. long. 197° 41'.

Stevens’s Passage, a strait between Admiralty Island, and the continent of America; the outlet is between Point Wincham, from whence it extends about 70 miles north, a little inclining to the west. N. lat. 59° 30'. E. long. 216° 35'.

Stevens’s Island, an island in the North Pacific ocean, about 24 miles in circumference, situated to the north of Pitt’s Archipelago. N. lat. 54° 11'. E. long. 220° 30'.

Stevens’s Island, a small island in the N.W. part of Cook’s Straits, in New Zealand. N. lat. 40° 39'. W. long. 183° 6'.

Stevens’s Islands, two small islands in the Eastern-Indian seas, discovered by captain Carteret in 1767. They had a green pleasant appearance, and were well covered with trees; but whether they were inhabited he did not know. They run about N.W. by W., and S.E. by E.; one is about three miles long, and the other about six. The passage between them appeared to be about two miles broad. S. lat. 60° 22'. E. long. 138° 39'. Hawkeforth’s Voyages, vol. ii. p. 587.

Stevens, Pont, a low rocky point on the coast of New Holland, New South Wales, on the N. side of which is an inlet, called “Port Stephens,” sheltered from all winds, lying in S. lat. 32° 40'. W. long. 20° 51'. At the entrance are three small islands, two of which are high; and on the main, near the shore, are some high round hills, which at a distance appear like islands.

Stevens’s Medicine for the Stone. Mrs. Stevens having sold medicines for the stone in the bladder, or kidney, Dr. Hartley published several cases of their success; and so much was paid of them, that the parliament appointed trustees to examine into the truth of what was alleged in their favour. The report of these trustees being favourable, she had 5000l. hering ordered her, in 1739, for publishing the receipt.

Her medicines are a powder, a decoction, and pills. The powder is fixed parts of fine powder of hen-egg shell, calcined until they become of a greyish-white colour, and of an acid salt taffe, then left two months in an open vessel, to be sufficiently calcined falls into a fine powder, through a current from the groffer parts by paining. To this egg-shell lime add one-sixth part of the powder of finalls, with that burnt in a crucible, till powder of finalls is to be they have smocking. A draught of this powder is to be drank after each dose. If the patient feels pain, is
to be made milder by opiates; if he is acute, gentle laxatives are to be taken, and purging is to be restrained: if the powder is too strong in the above proportion of five parts of the powder of egg-yells to one of snail-powder, it is to be weakened by increasing the proportion of the snail-powder.

To make the decoction, the prepared balls composed of four ounces and a half of the balm Alicant soap, a large spoonful of the powder of asphaltum, burnt to blacknesse, and as much honey as was necessary. She boiled one of these balls laced with cut green chamomile, or chamomile flowers, sweet fennel, parsley, and burdock-leaves, of each one ounce, in two quarts of water, half an hour, then strained it off, and sweetened it with honey. When these herbs are not to be had green, she takes the same quantity of their roots, cut and sliced. These whole stomachs cannot bear this decoction, may take one-fifth part of the ball formed into pills, with every dose of the powder.

The pills are made by taking equal quantities, by measure, of snails calcined as before, of wild carrot-seeds, burdock-seeds, athen-keys, hips and haws, all burnt to blacknesse, and reduced to a fine powder; with a large spoonful of this powder, four ounces of soap, and as much honey as is necessary, bring them to the consistence of pills, of which sixty are to be formed out of every ounce of the composition. In fits of the gravel, five of these pills are taken every hour awake, till the complaints are removed.

During the use of these medicines, the patient ought to abstain from fats, meats, red wines, and milk, drink few liquors, and use little exercise.

Dr. Hartley, leaving out the superfluous part of Mrs. Stephens's prescription, reduces her receipt to a more simple form; for an account of which, see Lithnontriptic.

Dr. Hales, after several trials on the different ingredients, found that the diffusing power of these lay in the lime, which Dr. Rutty confirmed; and Dr. Jurin having taken soap-leaves, the ingredients of which are pot-ash and lime, beginning with a few drops, and increasing the quantity till he took an ounce, or an ounce and a half every day, in a proper vehicle, was cured of bloody urine, pain, &c. and passed several small stones; after which he had no uneasiness.

For other forms of administering soap and lime, and remarks on Mrs. Stephens's medicine, see Lithnontriptic. See also Limes-Water.

STEPHENTOWN, in Geography, a township of America, in the state of New York, situated in the south-east corner of Renfleuer county; 24 miles S.E. from Troy; bounded N. by Berlin, E. by the state of Massachusetts, S. by Canaan in the county of Columbia, and W. by Nafa. This township is hilly, and has a diversity of soil. Its hills in some parts rise to mountains. The central part, between the ridges of the mountains, principally on the east and west, is occupied by an extensive valley, in which rises a fine branch of Lebanon creek, or by hills of a moderate height, and is arable and productive. In the west part, called the Green woods, there are extensive forests of pine, and the soil is of little value. The vale of Stephentown opens northward from that of New Lebanon, in Canaan, and is a very pleasant tract of light timbered gravel. This township affords limewall, and excellent slate for the roofing of houses. The whole population, in 1810, consisted of 2,567 persons, with 257 senatorial electors.

STEPNAIA, a forteress of Russia, in the government of Ufa; 24 miles W. of Troitsk.

STEPNEY, in Geography, an English poet, and political negotiator, was defended from the Steppney of Pendegraft, in the county of Pembroke, and was born at Westminster in 1663. He received the early part of his education at Westminster school, whence he was removed, in 1682, to Trinity college, Cambridge. He made himself known as an academic poet by a Latin ode on the marriage of the princes Anne to George, prince of Denmark, printed with the other Cambridge verses on that occasion. These were followed by a short copy of English verses on the accession of James II. The friendship which he had contrapled at school with Charles Montague, afterwards earl of Halifax, engaged him with the Whig party after the revolution, and brought him into public employments, in which he chiefly spent his life. He was sent envoy to the elector of Brandenburg, in 1692; to the imperial court, in 1693; to the elector of Saxony, in 1694; to the king of Poland, in 1699; again to the emperor, in 1702; and to the States-general, in 1706. As a reward for his services, he was made one of the commissioners of trade in 1697. He died at Cheles in 1707, and his remains are honourably interred in Westminster-Abbey, where a monument was erected to his memory. The poems of this author were composed at an early age. He published some political tracts, three of which are printed in lord Somers's Collection.

STEPNEY, or Stobunbhs, in Geography, a large and populous parish in the hundred of Offulton, and county of Middlesex, England, may be regarded as a suburb of London, as it is connected with the eastern side of that metropolis. This parish now comprises the hamlets of Mile-End, Ratcliffe, and Poplar and Blackwall; the whole of which contained in 1811, 6,116 houses and 35,199 inhabitants.

The origin of the name of Stepney is very doubtful, but is supposed to have been derived from the Saxon steb-hyche, a timber-wharf; or from Stiben, a corruption of Stephen. It is bounded by the parishes of Bromley, Stratford-Bow, Hackney, Bethnal-Green, Spitalfields, St. George in the East, and Shadwell; all of which, about a century since, were parts of the parish of Stepney. In the year 1794 it contained, as Mr. Lysons remarks, "about 3,510 acres of land, (exclusive of the site of buildings,) of which about 80 were then arable, about 50 occupied by market gardeners, and the remainder meadow, pasture, and marthy land." But since that year, the increase of buildings has produced a considerable diminution in the ground appropriated to agricultural and horticultural purposes.

In 1595, Edward I. held a parliament here, in the house of Henry Walleis, lord mayor of London, and gave his confirmation to the great charter. The manor of this place was formerly polluted by the bishops of London; and Roger Niger is thought to have died at the monastical residence in 1241. It passed, however, from that fee to king Edward VI. by gift from the ill-fated Ridley; and after having been granted to lord Wentworth, detecended through him to Thomas, earl of Cleveland; by whose influence with the king it was endowed with a court of record, a weekly market at Ratcliffe-Croif, and an annual fair on Michaelmas day. Stepney manor is now vested in the family of Colebrook. Exclusive of this the principal manor, the Domef-day Survey states that the parish of Stepney contained several smaller ones: all these were held, with the exception of two, of the bishop of London, and were entitled Stepney-Hulkars, Pomfret, Lord Wake's, Helles, Poplar, Cobham, Mile-End, Ewell, and Rumbolds. In 1567, a water-course, which had formerly belonged to the convent of Friars-Minors, was granted to William, marquis of Winchester, with
with liberty to conduct its firearms to his mansion-house in London.

Almost opposite the present rectory-house, Henry, first marquis of Worcester, poissified a large mansion in 1663, of which the buildings are devoted to the family of Mead; and in this dwelling Dr. Richard Mead was born, and first commenced the practice of his profession. The church, dedicated to St. Dunstan and All Saints, is large, and consists of a chancel, nave, and two aisles, separated by columns and pointed arches. At the west end is a square tower. Tombs of several illustrious characters are to be found in this place, especially those of Sir Henry Colet, lord mayor in 1486 and 1495, the father of Dr. John Colet, who founded St. Paul's school; Sir John Berry, a distinguished officer in the reign of Edward II., by whom he was knighted; Jane Nevill, lady Dethick; and Sir Thomas Spert, comptroller of the navy to Henry VIII., and founder of the Trinity-house. The font stands on a circular pillar, surrounded by four others of a smaller size. On the south side of the church are sculptures of the crucifixion, and of a figure in the posture of adoration before the Virgin and the infant Saviour. The wall of a porch towards the north-east contains a stone, on which verses dated 1663, flate to have been brought from Carthage. The church contains, with many other celebrated names, those of Dr. Richard Mead, and his father. A short distance from the west of this edifice is an ancient wooden mansion, built, it is supposed, in 1534, by Sir Henry Colet, and leased to Thomas, earl of Essex. It is now considerably altered, divided into several small tenements, and its name changed from the Great Place to Spring Garden coffee-house. Another of these relics of antiquity stands on Mile-End Green, and is now let in separate apartments. This latter, with some other contiguous habitations, are held under Clare-hall, Cambridge. The brick wall, which enclosed the site of the ancient rectory, still remains. Sir John Colet, before mentioned, who was vicar of Stepney, lived at the north end of White-Horse Street, Ratcliffe. Some time after his resignation, it was received by Dr. Pace, who died here in 1532, and was buried in Stepney church. This parish likewise contains several dissenting and Methodist meeting-houses: these are Sion-chapel, a chapel belonging to the Society of Friends in Brook Street, Ratcliffe, one of Mr. Whitfield's at Mile-End, that formerly occupied by Mr. Brewer, and some others of recent erection.

Poplar and several other charitable subscriptions, belonging to public bodies, are also situated on this road, viz. the Trinity alms-houses, founded by that corporation in 1605; Bancroft's hospital, founded in 1727; the Pinners' alms-houses, built in 1628; and the vintners', and three others, for the benefit of the whole parish collectively. A lazard-house existed here in the 16th century.

In this hamlet is Brewer's meeting-house, (now Ford's,) and a Methodist chapel. On the north side of the road are two Judaic cemeteries, entitled "The house of the living," where the dead are interred in rows, divided into certain spaces; and no grave is ever opened a second time. There is also a hospital built in 1793, and an adjoining alms-house near the same spot.

southern part, consist chiefly of the pinus sylvestris, fir, and birch; and on the elevation beautiful larches. On this level are several lakes and rivers.

The steppe of the Dnieper comprehends a large plain, which lies in the government of Ekaterinoslaff, between the Dnieper and the Bogue; the Crimean steppe on the left side of the Dnieper, and the whole space which extends over the Donetz, as far as the Don, and the sea of Azof, and the Euxine. This extensive steppe, comprehending the greater part of the governments of Ekaterinoslaff, Taurida, and a part of Voroneth, Korkhof, and Kief, is in general of a very dry and sandy quality, and contains many salt-lakes and salt-plots, but is little inhabited.

The steppe of the Volga and Volga comprises the whole space between the Don, the Volga, and the Kuban, and is a large, very arid steppe, altogether defitute of wood and water; it has few inhabitants, and contains several salt-lakes and salt-plots. It spreads through the greater part of the government of Caucasus, and into those of Ekaterinoslaff and Saratoff, where, in its sandy and calciferous mountains, it contains coals, sulphur-pyrites, and warm baths. Within the confines of this steppe lies what is called the Kuman steppe, comprehending the whole space from this steppe to the spot where the Kuma flows out of the mountains, and reaches southward to the banks of the Terek and the Caffian seas, northward to the other side of the Sarpa, and eastward as far as the Volga. In this steppe the salt-lakes of Altrakan, some bitter lakes, warm springs, &c. This steppe, it is said, has all the appearance of a dried-up sea: it is a sandy, part clayey and salt plain, without trees. Many circumstances render it probable that it might really have been sea-bottom, as the flat shores of the Caffian and Azof seas, and the shalows of their coasts, the low situation of the steppe, the saline lakes, and the sea-shells, &c.

The steppe of the Volga and Ural is extensive, and comprehends, between the rivers Volga and Ural, that whole flat country which formerly bore the name of the Kalmyk steppe, and between the Ural and the Yeniza, a part of the Kirghizii steppe lying within the Russian borders. The above-mentioned steppe is called the Kalmyk steppe, because it was left in possession of a horde of that nation, by whom it was inhabited till the time of their flight in 1771. It consists of a far-stretching ridge of sand-mountains, called Narym, and is said to be between 50 and 150 versts in breadth, extending from the Ural mountains, through the middle of the steppe, quite to the Caffian sea. The soil consists of sand, marie, and clay, often mixed with sea-shells, which indicate this to have been, like the Kuman steppe already mentioned, the bottom of the sea. But to return to the steppe of the Volga and Ural. This to the south makes the margin of the Caffian sea, and to the north it skirts the foot mountains that run out from the Ural chain. This plain, for the most part sandy, is very deficient in fresh water and wood; but so much the richer in rock-felt, and salt-lakes that are very productive. It contains many districts well adapted to the purposes of agriculture and the breeding of cattle; but is very poorly inhabited. One part of it lies in the Caucasian, and the other in the Ufimskian government.

The steppe of the Irtysh denotes that large plain which extends between the Tobol and the Irtysh, and between the latter and the Alay and Oby, as far as the influx of the Irtysh into the Oby, including an enormous territory. It abounds with lakes of several kinds of falls, among numerous forests of pines, fir, and birch, and is in most places well suited to pasturage and agriculture; but, in proportion to its extent, very thinly peopled. Between the Irtysh and the Oby, this plain incloses all that fine well-watered level called the Barabinian steppe, on which are seen many considerable lakes; extending in length from north to south above 600 versts, and in breadth 400 from west to east. Its plain has generally a good black soil, enlivened on its surface by many pleasant forests of birch: hence it has been concluded, that the Barabs must have been one general bed of waters, and far more morass and abounding with lakes than at present. Another part of the large plain constituting the steppe of the Irtysh, between the Ichiham and the Irtysh, is called the Ichim steppe, and is found to abound in bitter lakes, but in other respects resembling the Barabinian steppe, in both which many ancient tombs occur. The greatest part of the whole steppe of the Irtysh lies in the government of Tobolisk, but the other part in that of Kolhyan.

The steppe of the Oby and Yenissei includes the whole of that large tract between the Tobol and the Tubul (which falls into the Oby), between the Oby and the Yenissei, and extends to the shores of the Frozen ocean. The best forests are found towards the south; on the northernmost margin of the Frozen ocean the wood is low and short. The whole of this steppe lies in the government of Tobolisk.

The steppe of the Yenissei and Lena is a large tract of desert, bounded by the Yenissei, the Tungulka, and the Lena; reaching northward, like the former, to the Frozen ocean, and reembling in it nature and quality. One part lies in the government of Tobolisk, and the rest in that of Irkutsk.

The steppe of the Lena and Indighirka is a vast extended plain along the shores of the Frozen ocean, between the Lena and the Koymsa, to the two sides of the Indighirka, and is wholly in the government of Irkutsk. Tooke's Russ. Emp. vol. 1.

STERA, in Anatomy, a word used by some of the barbarous writers to express the uterus. It seems to have been only a corruption of the word hyfera.

STERANG, in Geography, a town of Norway, in the province of Angerhausen; 13 miles N.N.W. of Christiania.

Gen. Ch. Cal. Perianth inferior, of three or five, roundish, concave, acute leaves. Cor. Petals three or five, roundish, notched, ungulate, longer than the calyx. Stem. Filaments numerous, capillary, inserted into the receptacle; anthers roundish. Gif. German superior, ovate; style long, incurved at the tip; stigma capitate, concave. Pet. Ligneum ciliolatum, long, corticifo, fleshy, one-celled, not bursting. Seed numerous, large, angulate, incumbent on each other, imbedded in the pulp.

Eff. Ch. Calyx of three or five leaves. Petals three or five. Ligneum corticifo, not bursting. Seeds numerous, imbricated, imbedded in the pulp.

1. S. laterifera. Wild. n. 1. (Singara guianensis; Aubl. Guian. t. 250.)—Native of woods in Guiana, where it flowers, and bears fruit in September. —This fœnum is remarkable for throwing out numerous, knotted, creeping roots or fœna, which run in a scattered manner over other trees, and are much branched. Leaves nearly opposite, stalked, ovate, acute, smooth, entire. Flowers corymbose, scattered,
STERCORARIANS, or STERCORARIUM, formed from fuscus, dung, a name which tho' of the Roman church recently gave to such as held that the host was liable to digitation, and all its consequences, like other food.

STERCORARIUM Pluvis, the dung-fish, in Ichthyology, the name of an East Indian fish; so called from its frequenting necessary-houses which are over the water, and other places where the like naughtiness is to be found. It is, for this reason, supposed unwholesome by some, but is really a very well-talked fish, and eaten by most people where it is to be had. It is a broad and thin fish, of about six or seven inches long, and nearly as much in breadth. Its back is variegated with spots of deep brown; its belly is bluish.

STERCORARY, in Agriculture, a place properly secured from the weather for containing dung. In collecting manures from time to time, as they come to hand, farmers generally keep them together and then they call dung-hillcs, where they remain exposed to the heat of the sun, the washing of rain, and the drying winds; by which means a great deal of their virtue is dissipated and lost. The making of ferces has, therefore, been advised, which may be done by digging a square or oblong pit, of the size suited to the quantity of the compost wanted, or proportioned to the extent of the ground intended to be manured; the fide next the field or place where taken away being made flowering, so as to receive a cart to load or unload easily. The bottom should be well paved, and both the fides lined with pure clay, (unless it be made in a bed of clay or chalk,) that it may be capable of retaining water like a cistern; as it is of great importance for the dung to have a proper degree of moisture. And where channels or gutters can be directed to the pit, from the fides and other offices about the house, they will be of great service. Some think that they should be covered, so as at least to hinder rains from falling upon them; but if care be taken to make the pit in a place where no running water or springs can come to it, and if the farmer covers the dung, as it is collected, with a coat of mould, to prevent the fun's exhaustion or the rains washing away its richness, the quantity of water which falls in rain may not be more than requisite to moisten the mixture, and bring on that putrid fermentation which is necessary for the due incorporating and perfecting of the compost. It will, however, be right to have a shed to put over it occasionally, in case the leaflon should prove extremely wet. It has been observed by Columella, that the Romans covered their ferces with hurdles; but he does not speak of covering them with mould, in the manner mentioned above. See COMPOST, FARM-YARD, and MANURE.

Gen. Ch. Cal. Perianth inferior, of one large, coloured, rather coriaceous leaf, deciduous; somewhat turbinate at the base; its limb in five deep, pointed segments. Cor. six. Ovul. of imbrication elevated on a cylindrical and curved column, various in length, but always much shorter than the calyx. Stam. Filaments scarcely any; anthers from ten to fifteen, clustered, inserted into the notched margin of the top of the column, roundish, of two distinct lobes. Fil. Germ. sessile above the anthers, roundish, of five lobes; style vertical, deflexed, cylindrical, not half the length of the column; stigma obtuse, notched. Petals five, spreading, ovate, oblong, large, coriaceous, or woody, furling along the upper side. Seeds several, oval, attached to each margin of the follicle.

St. Ch. Calyx in five deep segments. Corolla none. Germen and anthers elevated on a column. Follicles five, with many seeds.

Obst. Many of the flowers, on the same or a different plant, have no pistil. In those with a pistil, the anthers are sometimes, but not always, imperfect. Several of the follicles in each flower, as well as many seeds in each follicle, are liable to prove abortive, at least in gardens. The margin of the column is scarcely discernible in some species, nor is it, in any, conspicuous enough to be taken for the filament of the flower. We would therefore not concur with Schreber and Willdenow in the classification of this genus. The style is sometimes divided down to the base into five parts.

1. S. lanceolata. Lanceolate Chinefe Sterculia. Cavan. Diff. n. 416. t. 142. f. 1. Willd. n. 1. Lamarck n. 2. — "Leaves lanceolate. Follicles oblong."—Native of China. A very uncertain species, adopted by Cavanilles from a Chinese drawing, in which the stems were represented about one inch and a half long, and half an inch broad; the follicles about the same length, narrow, crimson, with three or four black seeds in each. If such be the natural figure of the parts, the plant is different from any other known Sterculia. A familiar representation, however, of various dimensions, is common on Chinese papers, and we suspect it may, in every instance, be meant for a species hereafter described by the name of nobilis.

2. S. Balangbas. Balanghas Sterculia. Linn. Sp. Pl. 1430. Willd. n. 2. (S. foliis ovalibus integerrimis alternis petiolatis, floribus paniculatis; Linn. Zeyl. 165. Cydonia arbor, Balanghas dicta; Burm. Zeyl. 84. Nux reginae zeylanica minor bifida, flore purpureum; ibid. 170. Nawaghass; Herb. Zeyl. 25. Telabo; Syen in Rheede Hort. Malab. v. 1. 90, note!)—Leaves exactly elliptical, with a small point; very slightly downy beneath. Panicles much shorter than the leaves. Calyx hairy on both sides; densely fringed at the margin.—Native of Ceylon. The stem is arborescent, with round, smooth, pale branches, leafy at the end. Leaves alternate, filiform, five or six inches long; and two and a half or three broad, very exactly oval, rather coriaceous, entire, as in the whole genus, tipped with a small blunted point, scarcely half an inch in length; furnished with one longitudinal, and many transverse, ribs, all pale and smooth, connected by innumerable minute reticulations; their upper surface bright green, shining, and smooth; under very little paler, forfith to the touch, from scarcely discernible hair down. Footstalks smooth, an inch or more in length, with a fort of joint at the summit. Panicles axillary, about the ends of the branches, many-flowered, twice as long as the footstalks; their branches alternate, thread-shaped, green, hairy. Flowers solitary at the end of each partial stalk, small, said to be very fetid. Base of the calyx cup-shaped, smooth within; segments of its limb converging, and connected by their points, hairy on both sides, and particularly hispid at the edges, resembling, in the dried specimens, purple velvet or fluff. A specimen of this, communicated by Thunberg to Linnaeus, and marked Sterculia Balanghas, seems to be the
STERCULIA.

The real plant described with "oval leaves" in the Flora Zeylanica, from Herbart's herbarium. But in writing the Species Plantarum, Linnaeus uses the term "ovate," from a view probably of the figures, which he considered as belonging to this species, not having then a specimen before him. What those figures represent, we shall endeavour to ascertain hereafter. We have been the more precise in describing what we take for the genuine Balangbars, because no recent author seems acquainted with this plant; though its name, in every body's mouth, is applied to several very different from it and from each other.

3. S. rubiginosa. Rufty Sterculia. Veneta. Malmaif. sub fol. 91. Laminec. n. 4. (S. Ballanghas; Wild. n. 26.) Cavan. Diff. n. 415. t. 144, 111. Bad. Cavala; Rheeide Hort. Malab. v. i. 89. t. 49. Nux malabarica fulcata mucilaginosa fabacea; Pluck. Almag. 265.)—Leaves elliptic-oblong, taper-pointed, plant; downy and rufty beneath. Panicles much longer than the leaves. Calyx hairy on both sides, fringed at the margin.—Native of Malabar, Chittagong, Java, and perhaps of Africa, near Sierra Leone. A tall tree, with copious spreading branches. Rheeide. The young branches, clothed with rufty down, are leafy and copiously flowery at their extremities. Leaves from three to five inches long, (on downy rufty flarks about an inch in length,) plant, not rigid or coriaceous; rounded at the base, though gradually contracted towards that part; dilated upwards to the breadth of one and a half or two inches; then tapering into a point; entire, though somewhat wavy, at the margin; furnished with one longitudinal rib and many transverse ones, connected by reticulations; the upper side green, shining, nearly or quite smooth; under paler, opaque, soft with rufty hairy down, which is very copious on the ribs and veins. Panicles numerous, axillary, nearly twice as long as the leaves, alternately and repeatedly branched, spreading, with slender, downy rufty flarks, and scattered, lanceolate, downy, deciduous bracteas. Tube of the calyx short, shallow, nearly hemispherical, very hairy externally, rough within; limb three to long, converging as in the last, most hairy at the edges, well compared by Rheeide to red violet, which has a texture of the dried flowers, though the colour is browner, or more faded, than in our S. Balangbars. Follicles resembing those of a Peony, two inches and a half long, coriaceous, pointed; finely downy and rufty at the outside; smooth, reddish, and wrinkled, internally. Such is the plant sent by Dr. Buchanan from Chittagong, exactly agreeing with Commerfon's Java specimem, in fruit, and not less accurately with the plant of Rheeide; whose figure, we must observe, is copied, or rather perverted, by Cavanilles. What was raised from Sierra Leone seeds, in lady Amelia Hume's hothouse, appears by the leaves to be our rubiginosa, though their pubescence is less copious and less rufty than in dried specimens. Their texture is plain, not coriaceous. This may however be a distinct species. The seeds of the present, as well as the foregoing, are much eaten, like our chufnuts, in India. They seem, by Pluknet's synonymy, to be the real Malabar Nut; a name which, by some accident, has been vulgarly applied to Justicia Adhatoda. Perhaps a similarity between the leaves of the two plants, raised from seed, may have led gardeners into this error.

3. S. arcuolata. Pitcher-flowered Sterculia, or Wild Chocolate. (Clompanus minor; Rumph. Amboin. v. 3. 169. t. 107.)—Leaves elliptic-oblong, acute, plant; pale and finely downy beneath. Panicles close, hardly longer than the footstalks. Calyx pitcher-shaped, hairy all over.—Sent, in 1797, by Mr. Christopher Smith, from the island of Honimos, near Amboyna, where it is called Wild Chocolate; but whether from the resemblance of its seeds to those of real chocolate in shape, or from their being roasted and used as such, we know not. We conceive Rumphius's synonymy, hitherto misapplied to the Balangbars, must belong to this species. Our specimens are distinguished by the longer proportion of their footstalks, which sometimes measure more than two inches. The leaves, though shaped like the lalt, are pale at the back, being very minutely downy with whitish, not rufty, hairy hairs. The flowers are much fewer in each panicle, and more crowded, the hairs of the flarks, calyx, and especially the margin of the latter, being hoary or white, not red or rufty. Bracteas ovato-lanceolate, with long points. Tube of the calyx pitcher-shaped, constricted at the mouth, and nearly as long as the limb. We have seen no fruit. Rumphius describes its plant with whitish flowers, whose scent is oppressive, but not lalting; the fruit of a fine crimson.

4. S. nobilis. Great Chinese Sterculia. (S. Ballanghas; Adn. n. 1. S. monopetra; Veneta. Malmaif. t. 91. Laminec. n. 3. Southwellia nobilis; Salt. Parad. t. 69, excluding all the synonyms, except Veneta.)—Leaves elliptical, obtuse, with a small point, coriaceous, very smooth and shining on both sides. Panicles spreading, longer than the leaves. Calyx somewhat hairy.—Supposed to be a native of China, from whence it was imported in 1787, by lady Amelia Hume, and flowered in her hothouse for the first time in England, in the spring of 1789. By her ladyship's liberality it was quickly dispersed among the collections of this country, and found its way into France, being easily raised from seeds, which are ripened in the etove or conservatory. The stem is arborescent, of quick growth, round, with many smooth branches. Leaves from four or five inches to a foot, or more, in length, three or four inches in breadth, when full grown very smooth, and copiously reticulated, of a rigid or coriaceous texture. Footstalks smooth, stout, above an inch long. Panicles drooping, very large, and copious, repeatedly subdivided; their flarks pale, slender, downy and rather vilid, very tender. Flowers drooping, of the same pale buff hue as their flarks. Tube of the calyx bell-shaped, nearly smooth, limb downy, and sparingly hairy, with converging combined points. Anthers yellow. German red. Follicles two inches long, crimson within. Seeds blue-violet, three or four in each follicle, it having been merely from partial abortion that Ventenat's plant bore solitary seed. This fruit is sometimes seen delineated on Chinese papers, along with others in common use. Nothing can afford a more striking appearance than this tree in a hot-house, whether in April, when covered with flowers, or in the latter part of summer, when laden with its large black seeds, standing on the edges of the red and brown seed-veils. It is cultivated in the botanical garden at Calcutta, by the name of S. Balangbars.

5. S. longifolia. Long-leaved Sterculia. Veneta. Malmaif. sub fol. 91. Laminec. n. 13.—"Leaves ovato-oblong, smooth, segments of the calyx erect, internally hairy."—Native of Java. La Haie. The branches are said to be smooth. Leaves resembling S. rubiginosa in shape, but perfectly smooth on both sides, plant, pointed, six to eight inches long, at least two broad, with whitish ribs. Footstalks slender, smooth, an inch long. Flowers small, in spreading terminal panicles, whose branches are smooth and very slender. Calyx bell-shaped, slightly pubescent; its segments downy and whitish on the inner side. Such is Poiret's description, in Lamark, from a dried specimen.

STERCULIA.

Inum very short. Styles five, reflexed. — Native of the Mauritius, Comorin. Branches round, dark brown, smooth and polished, leafy at the summit. Leaves fix or eight inches, or more, in length, four at leaf in breadth, coriaceous, with a long point, smooth and shining, strongly veined. Footstalks thick, two inches long. Panicles large and spreading, somewhat cymose, with thick, compressed, very smooth branches. Calyx large, with five, widely spreading, smooth, lanceolate, coloured segments. German nearly sericeous, armed with five reflexed styles or ligulas, which cause a doubt concerning the genus of this species. 

Poirier.

Calyx very short. Native of the coast of Africa, from whence we have a specimen in flower, gathered by Dr. Afzelius. The branches of this tree are round and smooth, leafy at the ends. Leaves imperfectly opposite, three or four inches long, one and a half or two inches broad, strongly veined, firm; rufous, though quite smooth, beneath. Footstalks an inch or inch and half long, smooth. Panicles lateral, below the leaves, solitary, forked, dense, of about ten or twelve large flowers, their filaments, as well as the outside of the calyx, rough with dense flaky hairs, or rather a form of deciduous malacine. Calyx spreading, an inch broad, in five, sometimes six, broad, ovate, obtuse segments; smooth and coloured within. Columns scarcely any. German rough, five-lobed. Stigmas five, reflexed. We do not find the calyx has more than five divisions; Poirier describes fix. The filaments are said to be five, with solitary reddish seeds. The five ligulas, or styles, agree with the leaf. Probably this character, and the nearly sericeous leaves, to say nothing of the spreading calyx, may indicate a generic difference. The seeds of this species, known by the name of Cola, have long been celebrated by voyagers, as possessing a high degree of value among the natives of the Guinea coast, who are reported to take a portion of one of them to enhance the flavour of any thing they may subsequently eat or drink. Dr. Afzelius found these seeds in high estimation at Sierra Leone, and was not a little pleased to procure specimens of the plant, though he had no idea of its genus. If we mistake it, he brought it alive to this country, but it has not lately been heard of.

8. S. nitida. Shining Sterculia. Venten. Malm. sub fol. 91. Lamark n. 17. — "Leaves lanceolate-oblong, pointed. Segments of the calyx spreading, Cola, scarcely any." — Native of Africa cultivated in the island of Mauritius. Ventenat supposed the flowers to be dioecious. This may possibly be different from the last species, but we have not sufficient information to form an opinion on the subject.

9. S. crinata. Hairy-fruited Sterculia. Cavan. Diff. n. 413. t. 142. Wild. n. 3. Lamark n. 5. Ait. n. 2. (S. Iria; Swartz Ind. Occ. 1160. Iria pruriens; Aubl. Guian. 695. t. 279.). — Leaves ovate, acute, entire. Panicles as long as the leaves. Segments of the calyx lanceolate, pointed, spreading. Follicles hairy at the base; finely serrated. Native of the woods of Guiana, flowering in October and bearing fruit in May. Aublet. One of the largest trees of that country, its trunk being fifty or sixty feet high, and four or five in diameter. The bark is reddish, thick. Wood white, not compact. Leaves from six to twelve inches long, firm, thick; green and smooth above; opaque, somewhat glaucous and roughish at the back. Panicles about the ends of the branches repeatedly compound, downy, spreading. Calyx yellow and downy on the outside, red and smooth within. Columns nearly as long as the calyx. Anthers ten. Follicles three, four, or five, large, almost woody, clothed at the base with a tuft of long reddish hair; their cavities filled with fine, rigid, pungent, red bristles, enveloping the black seeds, and causing an indescribable itching, when ineffectually handled.

10. S. frondosa. Wasty-leaved Sterculia. Richard Afl. Soc. Hist. Nat. Paris, v. 1. t. 111. Lamark n. 6. — "Leaves crowded, oblong-obovate, very blunt, somewhat wavy, smooth and shining. Panicles axillary, on long stalks." — Native of Cayenne. Richard. We suspect this plant may have been confused with the latter, even by Dr. Swartz. A specimen gathered by M. De Ponthieu, in the West Indies, and given us by sir J. Banks, having very large and wavy leaves, answers so far to Richard's description. Some of its leaves seem moreover to be slightly ribbed; and as Dr. Swartz cites De Ponthieu, it should seem that corresponding specimens to ours have been his only authority. Thus Willdenow has been led to alter the specific character of S. crinata for the worse.

11. S. cordifolia. Heart-leaved Sterculia. Cavan. Diff. n. 1414. t. 143. f. 2. Willd. n. 4. Lamark n. 7. — "Leaves roundish heart-shaped, oblong three-lobed, five-ribbed, smooth. Follicles downy at the outside, brightly within."—Brought from Senegal by Adanson, and preserved in Jussieu's herbarium. The above characters sufficiently mark this species. Its leaves are two or three inches long, and almost equally broad. Footstalks not an inch in length. Flowers not observed.

13. S. macrophylla. Large-leaved Sterculia. Venten. Malm. sub fol. 91. Lamark n. 10. — "Leaves roundish heart-shaped, somewhat wavy, rather coriaceous; downy beneath. Follicles very smooth within, with two seeds." — Native of Java. La Haie. The leaves are about eight inches broad, round, or slightly oval; heart-shaped at the base; thick and rather coriaceous; smooth and dark-green above; downy, and reddish or whitish beneath, with strong branching lateral ribs; their margin entire, slightly wavy. Footstalks filiform. Panicles terminal, moderately branching. Follicles strong, reddish, wrinkled, obtuse. Flowers not observed. Poirier.

14. S. colorata. Coral-flowered Sterculia. Roxb. Coromand. v. 1. t. 26. t. 25. Willd. n. 5. Lamark n. 12. — Leaves palmate, five-lobed, pointed; somewhat downy beneath. Calyx downy, club-shaped, with yellow upright lobes. Follicles filiform, membranous, oblong, reticulated, expanded, smooth. — Native of mountains in the East Indies, bearing its leaves during the cold season, and flowers in April, soon after which fresh leaves appear. The name of the Centoo, or Teltinga, name is Karaka. This is a very large tree, with smooth greyish branches, leafy at the end. Leaves on long stalks, more or less deeply five-lobed, heart-shaped above; at the base, five-ribbed, minutely reticulated; smooth above; at the base, five-ribbed, minutely reticulated; smooth above; at the base, five-ribbed, minutely reticulated; smooth above; at the base, five-ribbed, minutely reticulated; smooth above; at the base, five-ribbed, minutely reticulated; smooth above; at the base, five-ribbed, minutely reticulated; smooth above.
pound, dense, their stalks, as well as the calyx, thickly clothed with flary pubescence, of a bright orange-scarlet. Calyx half an inch, tubular, erect, gradually tapering down into the flalk. Column longer than the calyx, slender. Anthers crowded and confluent. German five-lobed, with five short recurved stigmas, rather like separate styles. Follicles five, pendulous, converging, each on a partial stalk near an inch in length, their form lanceolate-oblong, obtuse, nearly flat, three inches in length and almost one in breadth, their texture membranous, with one rib and many reticulated veins, their surface smooth, thinning, pale purple externally, yellow within. Seeds two, oval, smooth, yellow, the size of a large pea, attached one to each margin of the follicle an inch above the base.

15. S. sanguinea. Stinging Sterculia. Roxb. Coromandel. v. 1. 25. t. 24. Willd. n. 6. Lamarck n. 11. Ait. n. 3. — Leaves five-lobed, pointed, very downy; deeply heart-shaped at the base. Calyx bell-shaped. Column conical. Follicles seseile, coriaceous, rough with pungent bristles. Native of mountainous parts of the coast of Coromandel, flowering during the cold season, and putting forth leaves, as the fruit advances, in the beginning of the hot weather. This is a very large tree, whose soft spongy wood scarcely serves but to make Hindoo guitars. The branches have the odor of violets. Leaves measuring from nine to twelve inches each way, much less deeply lobed than the leaf, on long stalks. Panicles repeatedly compound, shorter than the leaves, with a linear brown bract among each subdivision. Such bracteas however are not, as Wildenow supposes, peculiar to this species, though they are usually so to deciduous, in many instances, as to escape notice. The flowers are small, greenish-yellow. Column short and thick. Anthers ten, supported by a more dilated membrane than in many others of the genus. Style filiform, short and thick, with a five-lobed stigma. Follicles five, greenish-brown, an inch and a half long, oval, coriaceous, concave, clothed with copious tinging bristles, so as not to be touched with impuinity. Seeds four or five, oval, the size of a pea, rosetted and eaten by the Hindoos.

16. S. villifera. Villous Sterculia. Roxb. Mss. — Leaves five-lobed, pointed, toothed, very downy, seven-ribbed; heart-shaped at the base. Calyx deeply five-cleft, spreading. Column cylindrical. Follicles coriaceous, rough with flary hairs. Native of the coast of Coromandel. Our specimen was given by Dr. Roxburgh to lord vificot Vaux. The flowers are of a very fine color, not so strong and abundant as at one time. The leaves much larger than those of S. sanguinea, with a longer and more slender column, as well as style; the latter, like the German, very hairy. Calyx widely spreading, downy, with deep ovate segments. follicles covered with rigid flary pubescence, but no tinging hairs.

17. S. platamifolia. Plane-leaved Sterculia. Linn. Suppl. 233. Willd. n. 7. Lamarck n. 9. Ait. n. 45. Cavan. Diff. n. 17. t. 145. Vahli Synb. v. 1. 80. Sterculia Jacq. 81. in Ait. Nov. Helvet. v. 1. 40. t. 5. 3. 4. T. somentosa; Thum: Ic. Pl. Jap. dec. 4. "Firmiana; Marfil in Ait. Acad. Patav. v. 1. 106. t. 11. 9." Calhounia; Forik. Africa. 96. Hibiscus simplex; Linn. Sp. Pl. 977. — Leaves palmate, smooth, five-lobed; heart-shaped at the base. Segments of the calyx linear, very deep. Follicles stalked, membranous, ovate, reticulated, concave, roughish. — Native of China and Japan, from whence it has been diffused over many parts of the East Indies, and introduced into the gardens of Europe. At Radus it ripens seeds in the open air. In England it is a hardy greenhouse plant, flowering in July. The tree in its native soil is said to attain a vast size. The leaves are broader than long, measuring from ten to eighteen inches across, on long smooth stalks; with acute entire lobes, and rounded sinuses; smooth above; rather papyraceous, and sometimes sparingly downy, beneath; their ribs and veins strong with axillary, tubular, hairy pores. Panicles terminal, a foot long, much branched, spreading, downy. Calyx pale yellow, hairy externally; its segments reflexed and twisted, above half an inch long. Column smooth, slender, a quarter of an inch in length. German pyramidal, hairy, as well as the simple cylindrical style. Follicles molt like those of S. colorata, n. 14, but green, much broader, and more concave. Seeds two or three, globoso. Jacquin says the flowers are fragrant, most of them perfect, a few males only being interperfused.

18. S. satis. Fetid Sterculia. Linn. Sp. Pl. 1421. Willd. n. 8. Lamarck n. 8. Ait. n. 5. Cavan. Diff. n. 412. t. 141. Sonnerat Ind. Occ. v. 2. 254. t. 132. (Clompanus major; Rumphi: Amboin. v. 3. 168. t. 107.) — Leaves digitate. Segments of the calyx oblong, very deep, hairy. Follicles woody. — Native of the East Indies. Sonnerat says it is planted before houles, on the coast of Malabar, for the sake of its thick shade. The roasted seeds taste like oheafuts, and are eaten by the Indians. The tree is straight and tall. Leaves from seven to nine lanceolate, a finger's length, entire, smooth, on a long common footstalk. Clusters terminal, compound, drooping, with smooth stalks. Flowers smelling like human excrement, larger than the leaf, widely expanded; moss hairy, and of a brownish-red, on the upper side; brighter red underneath. Column cylindrical, near half an inch long, much dilated, or cup-shaped, at the top, where the anthers are inserted. German roundish, five-lobed, very hairy, as well as the simple style. Follicles oval, obtuse, wooly, nearly as big as the leaf. Seeds numerous along each margin, Karl, Rhode Malab. v. 4. t. 35, cited by Linnaeus, seams rather of the order of Ysicus.

A superficial confederacy of this very curious and remarkable genus might lead us to think nothing more easy than to divide it into several; but however strikingly different certain parts of the fruitification may be in some species, such differences do not support each other. Thus, the follicles of S. colorata and platamifolia are so unlike all the rest, and agree together so remarkably in their partial development of the fruit, that we should at once consider them as a distinct genus. But when we consider their sepals and styles, all particular relationship seems dissolved; for they accord better, in those parts, with many other Sterculia than with each other. Whether the simple or manifold styles, when properly understood, may lead to generic distinctions, we have not, as yet, materials to decide. The length of the column, very different in different species, does not appear of any generic importance.

The stipulas of this genus have hardly been noticed, because so fugacious, but we believe they are always originally present, in pairs, at the base of the footstalks, and usually of a lanceolate or scale-shaped figure. The bracteas, frequent under the branches of the panicles, are larger, but nearly as quickly deciduous as the stipulas, at least in most of the species.

STERCULIUS, in Mythology, one of the names given to Saturn, because he was the first that laid dung upon lands to make them fertile.

STERCUTUS, the god of ordure.

STERE, in Commerce, the unit for solid measure in the new French system. See Measures and Standard.
STEREOBATA, or Stereobates, formed from *Stereo-
Caume*; solid prop. in the Ancient Architecture, the baulk, or
foundation, whereon a column, wall, or other piece of building
is raised.

This answer pretty well to the continued foces or base-
ment of the moderns. See Socle.

Some confound with the ancient *sylobata, or pedestal*,
(which see); but, in effect, the Stereobata is that to the
sylobata, which the sylobata is to the spire or base of the
column.

STEREOCAULON, in Botany, from *Stereo*; hard and
solid, and *caulo* a fem. a name singularly applicable to this
genus of the Lichen tribe, invented by Schreber in his Gen.
Pl. 768.—Achar. Meth. 314. Lichenogr. 113. t. 12. f. 3. 4.
Lichenes.

Eff. Ch. Tubercles turbinated, coloured, convex, bor-
ted, terminating the branches of the solid cartilaginous frond.

As it stands at present, in the newly-published *Symphoric* of
Acharius, where nine species are enumerated, this has every charac-
ter of a natural genus. Its firm, branching frond, attached by a slender but very tenacious root, is formed to
occupy the interstices of crumbling granite, and especially the
cells of volcanic scoria. Hence it is the first of its tribe
that clothes the flowly decaying lava of Vesuvius and other
burning mountains.

Of the nine species of Stereobata above-mentioned, we
feel safe to exempt the genus.

t. 157.) Engl. Bot. t. 282. Coralloides crispus et botry-
forme alpinum; Dill. Mufe. 114. t. 17. f. 33. C. pach-
chale; Hoffm. Pl. Lich. v. i. 23. t. 5. f. 1.)—Frond gla-
cious-grey, branched, granulated, minutely fibrous, with
short, crowded, much-divided segments. Tubercles fatter,
cluttered, somewhat pointed, dark brown.—Native of the
highest mountains of Europe, in a mucaceous soil.
The *fema* form dense, very firm and tenacious tufts, from
one to three inches high, and are round, white internally,
quite solid. Their branches, much subdivided, are engrailed
with grey, warty, leafy segments, and tipped with numerous
little brown tubercles, sometimes compound, or lobed.

Such is our only certain British species. What occurs on
the lava of Vesuvius, and which we did not, in gathering it,
discover to be at all different, is called by Perlocco S. *ves-
uvianum*, and made a variety by Acharius of his own S. be-
trypsum, n. 3. a Swiss species, unknown to us, whose charac-
ters indeed do not found very distinct.

STEREOGRAPHIC Projection of the Sphere, is that
in which the eye is supposed to be placed in the surface of
the sphere. For the fundamental principles and chief proper-
ties of this kind of projection, see Projection, Stereo-
graphic.

The method and practice of this projection in all the
principal cases, viz. on the planes of the meridian, equino-
cial, and horizon, are as follow.

STEREOGRAPHIC Projection on the Planes of the Meridian.
Let Z Q N E (Plate XIV. Geometry, fig. 10.) be the
meridian; Z and N the poles, as also the zenith and nadir;
E Q the equinoctial and horizon; Z N the equinoctial cu-
ture, and prime vertical circle; Z 15 N, Z 30 N, Z 45 N,
&c. are hour-circles, or meridians, and also azimuths, be-
cause the pole is in the zenith. To describe these circles,
find the points 15, 30, 45, 60, &c. in the equinoctial, by
setting the half-tangent of their distance from $\gamma$; and then
their centres are found by setting their co-fecantes both ways,
from their points of intersection with the equator: $\omega$, $\varphi$, and $\psi$, $\zeta$, are the northern and southern tropics, which are
described by setting the half-tangent of 30° 30′ from $\varphi$ each
way; then the tangent of its complement, $\omega$, 60° 30′, each
way from thence on the colure produced, gives their centres.
By this method all parallels of declination may be drawn.
Or you might have set the co-fecant of the parallel from
the centre of the primitive, which would also have found
the same point for the centre of the parallel, whose radius
is equal to the tangent of its distance from its pole.

The parallels in this projection are also alimacants, or
parallels of altitude; $\omega$, $\psi$, is the ecliptic, which must be
divided from the division on the scale of half-tangents; but
denominated according to the signs in the zodiac, reckoning
50° to each sign.

STEREOGRAPHIC Projection on the Plane of the Equinoctial.
Let S C (fig. 11.) be the meridian, and folliollar colu-
E N the equinoctial colure, and hour-circle of 60° P the
north pole; $\omega$, $\varphi$, the northern tropic; E W N the north-
ern half of the ecliptic (whose centre is found by setting off
the fecant of 30° 30′ from $\omega$); and its pole is at $\alpha$, the
intersection of the polar circle and meridian, being the place
through which all circles of longitude must pass; and
E Z N the horizon of London, which is described thus: set
the half-tangent of the colatitude from P to Z; then the
tangent of the fame, from P to O, or its fecant from Z
to O, gives its centre; and its pole will be at $b$, 36° 30′
in the (half-tangents) diffrant from P, where $b$ is at the
zero.

To draw any other circles in this projection. 1. For cir-
cles of longitude—which must all pass through $a$, and the
several degrees of the ecliptic; set the tangent of 60° 30′,
from $a$ downwards, on the meridian produced, which will
find a point, through which a perpendicular, drawn to the
meridian, shall contain in it the centres of all the circles of
longitude, whose distances set off to the radius P $\alpha$, shall be
the tangents of the degrees of their distances from the meri-
dian S P C (which is that belonging to 180°). 2. All
parallels of declination are drawn, by setting off the half
of their tangents of their distances from P. 3. All azimuths,
or vertical circles, must pass through $b$ at the zenith: since,
therefore, the zenith is 38° 30′ diffrant from P, set the co-
fecant of that (or the fecant of 51° 30′) from $b$ on the
meridian extended below, and that will find the point $a$, the
centre of the azimuth of east and west; $\text{vis. E 6 N}$; and the
centres of all the rest are in a line that is perpendicular to
the meridian, and drawn through $a$. 4. Circles of altitude, or
alimacants, are lesser circles, whose poles are not in the plane
of the projection; thus the circle $O 6$ is a parallel of alti-
itude 50° above the horizon. 5. All hour-circles are straight
lines from the centre to the limb.

STEREOGRAPHIC Projection on the Plane of the Horizon.
First draw a circle representing the horizon, and quarter it
with two diameters; then will $a$ be the zenith of the place;
$12 \pm 12$ the meridian; $6 \pm 6$ the prime vertical, or azimuth
of east and west (fig. 12.) Make $a P =$ half-tangent of $38° 30′$ (or tangent of 10° 15′); and $P$ shall be the
pole of the world. Make $a E =$ half-tangent of 51° 30′ (or
tangent of 26° 45′); and $E 6 =$ fecant $\frac{1}{3} 38° 30′$; then shall $a$ be the
centre of the equinoctial 6 $E 6$.

In this projection alimacants are all parallel to the prin-
time circle; and azimuths are all right lines passing through
the centre of the primitive, to the equal divisions in the
limb. Parallels of declination are all lesser circles, and parallel
S T E

let to the equinoctial, and their intersecions with the meridian are found, by setting the half-tangent of their distance from the zenith, southward or northward, or both ways from it. Their centres are found by bisection the distance between these two points; for the middle will be the centre of the parallel. Thus, $\pi = \text{half-tangent of } 28^\circ 00' = \text{distance of the tropic of } \varphi \text{ from the zenith}$; and $\pi \cdot \varphi = \text{half-tangent of } 75^\circ$ to the southward, or $\varphi$ from the zenith from the northward.

And the intersection again with the north of the meridian, is at $105^\circ 30'$ for $\varphi$ to the northward, or upward from $\pi$.

For the hour-circles, make $\pi \alpha = \text{tangent of } 51^\circ 30'$, or $\pi \alpha = \secant of 51^\circ 30'$; draw $G \alpha T$ perpendicular to the produced meridian; then, if from $\alpha$, with the radius $\pi \alpha$ you set off the tangents of $15^\circ, 30^\circ, 45^\circ$, &c. both ways, you will have the centres of the several hour-circles, 7 and 5, 8 and 4, &c.

Note, in all stereographic projections, all diameters are measured on the scale of half-tangents; and this is the ground of all dialling, or the true projection of the hour-circles of the sphere on any given plane. See Perspective, Projection, and Spheres.

STEREOMETRY, is that branch of solid geometry which demonstrates the properties, and shews the construction, of all solids which are regularly defined.

It explains the methods for constructing the surfaces in planes, so as to form the entire body, or to cover the surface of a given solid; or, when a solid is bounded by plane surfaces, the inclination of the planes is determined by the rules of stereometry. The sections of solids are also a branch of stereometry; but this we shall refer to the article Stereotomy, with which it is more intimately connected.

Mr. Hamilton has denominated the principles of perspective by the name of stereometry; but in this sense the term is too limited, as perspective is only a branch of the doctrine of solids, and extends only to the sections of pyramids and cones, and the representations of solids. See Perspective.

The eleventh and twelfth books of Euclid, which treat of the properties of solids, may be looked upon as the elements of this branch of geometry; and to them we shall refer our readers for the first elements to be acquired.

It is somewhat singular, that though the first principles of solids have long been demonstrated, no practical application to mechanical constructions has been made. The knowledge of solids is of the greatest importance in the constructive parts of architecture, as in masonry, bricklaying, carpentry, &c.

To be proficient in the art of construction, this branch of geometry is indispensable, and contains the very essence and foundation of the whole in abstract.

Definitions.

1. A solid is that which has length, breadth, and thickness.

2. The exterior surface of a solid is called its superficies.

3. A straight line is perpendicular or at right angles to a plane, when it makes right angles with every straight line meeting it in that plane.

4. A plane is perpendicular to a plane, when the straight lines drawn in one of the planes, perpendicularly to the common section of the two planes, are perpendicular to the other plane.

5. The inclination of a straight line to a plane is the acute angle contained by that straight line, and another drawn from the point in which the first line meets the plane, to the point in which a perpendicular to the plane drawn from any point of the first line above the plane meets the same plane.

6. The inclination of a plane to a plane is the acute angle contained by two straight lines, drawn from any of the same points of their common section at right angles to it, one upon one plane, and the other upon the other plane.

7. Two planes are said to have the like inclination to one another, which two other planes have, when the fad angles of inclination are equal to one another.

8. Parallel planes are such as do not meet one another, though produced.

9. A solid angle is that which is made by the meeting of more than two plane angles, which are not in the same plane, in one point.

10. Similar solid figures are such as have all their solid angles equal each to each, and which are contained by the same number of similar planes.

11. A prism is a solid of which the ends are similar and equal plane figures, and the sides parallelograms.

12. When the ends of the prism are perpendicular to the sides, it is called a right prism; but if otherwise, it is termed oblique.

13. When the sides and ends of the prism are equal squares, it is called a cube.

14. When the ends are parallelograms, the prism is called a parallelepiped; and when the sides of the parallelepiped are at right angles to each other, then the prism is called a rectangular prism.

15. When the ends of the prism are circles, it is called a cylinder; but if the ends are ellipses, and alike situated, the prism is then called a cyllindroid.

16. The straight line extended between the centres of the two bases is called the axis.

17. A solid having any plane figure for its base, and its sides plane triangles terminating in the same plane, is called a pyramid.

18. A solid having a circle for its base, and terminating in a point, such that a straight line extended from any part of the circumference of the base to the terminating point may be in the surface of the solid, is called a cone; and the surface which lies between the circumference of the base and the terminating point is called the conic surface.

If the plane of a circle be supposed perpendicular to a given plane, with its circumference or edge upon that plane; and if there be a straight line passing any other point perpendicular to the said plane; and if another straight line be made to move parallel to the plane on which the circle stands, so as always to touch the circumference and the straight line, beginning at any given point, and proceeding entirely round until it arrives at the same plane; then the solid bounded by the circle, and the surface passed over by the straight line contained between the circumference of the circle and the straight line, is called a conoid, and the surface generated by the straight line is called a conoidal surface.

A sphere is a solid formed by the revolution of a semicircle upon its diameter.

The centre of a sphere is the same with that of the semicircle.

The diameter of a sphere is any straight line which passes through the centre, and is terminated both ways by the superficies of the sphere.

A cube is a solid figure contained by six equal squares.

A tetra-
STEREOGRAPHY.

A tetrahedron is a solid figure contained by four equal and equilateral triangles.

An octahedron is a solid contained by eight equal and equilateral triangles.

A dodecahedron is a solid contained by twelve equal pentagons, which are equilateral and equiangular.

An icosahedron is a solid contained by twenty equal and equilateral triangles.

The solids defined in the last five definitions are called the five regular solids.

Properties of Planes and Solids demonstrated in the eleventh Book of Euclid's Elements, useful in Stereography.

PROPOSITIONS.

I. One part of a straight line cannot be in a plane, and another part above it.

II. Two straight lines which cut one another are in one plane, and three straight lines which meet one another are in one plane.

III. If two planes cut one another, their common section is a straight line.

IV. If a straight line stand at right angles to each of two straight lines in the point of their intersection, it shall all be at right angles to the plane which passes through them.

V. If three straight lines meet all in one point, and a straight line stands at right angles to each of them in that point, these three first straight lines are in one and the same plane.

VI. If two straight lines be at right angles to the same plane, they shall be parallel to one another.

VII. If two straight lines be parallel, the straight line drawn from any point in one to any point in the other is in the same plane with the parallels.

VIII. If two straight lines be parallel, and one of them at right angles to a plane, the other shall also be at right angles to the same plane.

IX. Two straight lines which are each of them parallel to the same straight line, and not in the same plane with it, are parallel to one another.

X. If two straight lines meeting one another be parallel to two other that meet one another, and are not in the same plane with the first two, the first two and the other two shall contain equal angles.

XI. Problem.—To draw a straight line perpendicular to a plane from a given point in space above the plane.

Draw any straight line in the plane and from the given point above the plane; draw a second straight line at right angles to the first straight line; from the point where the perpendicular meets the first straight line draw a third straight line in the plane, at right angles to the said first straight line; and, lastly, from the given point in space draw a fourth straight line at right angles to the third straight line; and the fourth straight line, thus drawn, is perpendicular to the plane.

XII. Problem.—To erect a straight line at right angles to a given plane from a given point in the plane.

From any given point above the plane draw a straight line perpendicular to the plane, and through the given point in the plane draw a straight line parallel to the other straight line; and the second line, thus drawn, is the perpendicular required.

XIII. From the same point in a given plane there cannot be two straight lines at right angles to the plane, upon the same side of it; and there can be but one perpendicular to a plane from a point above the plane.

XIV. Planes to which the same straight line is perpendicular are parallel to one another.

XV. If two straight lines meeting one another be parallel to two straight lines which meet one another, but are not in the same plane with the first two; the plane which passes through these is parallel to the plane which passes through the others.

XVI. If two parallel planes be cut by another plane, their common sections with it are parallels.

XVII. If two straight lines be cut by parallel planes, they shall be cut in the same ratio.

XVIII. If a straight line be at right angles to a plane, every plane which passes through it shall be at right angles to that plane.

XIX. If two planes cutting one another be each of them perpendicular to a third plane, their common section shall be perpendicular to the same plane.

XX. If a solid angle be contained by three plane angles, any two of them are greater than the third.

XXI. Every solid angle is contained by plane angles, which together are less than four right angles.

XXII. If every two of three plane angles be greater than the third, and if the straight lines which contain them be all equal, a triangle may be made of the straight lines that join the extremities of those equal straight lines.

Properties of Solids arising from the Definitions.

In a prism, all parallel sections which cut the sides are similar and equal figures; or, all parallel sections which would cut the plane of the base, if produced, are similar and equal figures.

In a pyramid, all the parallel sections which are not parallel to the plane of the base are unequal similar figures.

The properties of a cone are numerous and interesting. If the cone is cut parallel to the plane of the base, the section is a circle; if it be cut in any direction through the apex, the section is a plane right-lined triangle; if the cone be cut by a plane inclined to the plane of the base at any given angle, the section is an ellipse; if the cone be cut by a plane parallel to any straight line within the solid passing through the apex, the section is denominated a hyperbola; if a cone be cut by a plane parallel to another plane which touches the curved surface, the section formed by this position of the cutting plane is called a parabola.

For the purposes of stereography, we shall suppose the cone a right cone, and consequently the abscissa of the curves or sections will bisect all the double ordinates at right angles.

If any semi-conic section be supposed to revolve upon its abscissa, so as to perform an entire revolution, the surface generated by the curve line is called a conoid, and the abscissa the axis.

If the semi-conic section be a semi-ellipse, the solid generated is called an ellipsoid.

If the generating figure be a semi-parabola, the solid is called a paraboloid.

If the generating figure be a semi-hyperbola, the solid is called an hyperboloid.

All solids whatever, generated by revolving plane figures upon an axis, are called solidos of revolution.

All parallel sections of conoids are similar figures.

General Principles of Stereographic Constructions.

Definition.—Solid angles which consist of three plane angles are called trihedral.

In the construction of trihedral, besides the three plane angles which form the boundaries of the solid, are the three inclinations.
STEREOGRAPHY.

Inclinations. These inclinations are, by way of distinction, called the angles, and the three boundaries are called the sides, and the sides and angles are indifferently called parts, any three of which, excepting the three angles, may be found by the following constructions. We shall first show the construction of right-angled trihedral, not only as being the most useful, but as being necessary to the construction of oblique trihedral.

Problem I.

In a right-angled trihedral are given the two sides containing the right angle, to find the acute angles, and the side or hypotenuse which subtends the right angle.

Make the angle $EBH$ (Plate 1. Stereography, fig. 1.) equal to one of the given sides, and the angle $EBF$ equal to the other; draw $EH$ perpendicular to $EB$, and $EI$ perpendicular to $BF$, cutting $BF$ at $F$: from $B$, with the radius $BH$, describe an arc, cutting $EI$ at $F$, and join $BI$: then $BI$ is the hypotenuse: from $E$, with the radius $EF$, describe an arc, cutting $EB$ in $G$, and join $GH$: then $EGH$ is the angle contained by the hypotenuse and the side $EBF$, or the angle opposite the side $EBH$: or make $FI$ equal to $GH$, and join $BI$.

In the same manner the angle opposite the side $EBF$ may be found.

The reason will appear thus: raise the plane of the triangle $BEF$ upon $BE$, so as to be perpendicular to the plane $BEH$; raise the triangle $EGH$ upon $EH$, until $EG$ fall upon $EF$; then the plane $EGH$ will become perpendicular to $BF$: revolve the plane $BEF$ upon $BF$, and $FI$ will describe a circle, whose plane is also perpendicular to $BF$, from the point $F$; therefore, the plane of the circle and the plane $EGH$ will be both in the same plane; therefore, since the point $F$ coincides with $G$, the straight line $FI$ may be made to coincide with $GH$: let this coincidence take place; and because $FI$ is equal to $GH$, and the point $G$ falls upon $F$, the point $I$ will fall upon $H$; therefore, the straight line $BI$ will fall upon $BH$; and the angle $FBI$, joining $FB$ and $BH$, is the hypotenuse.

Again, it is evident from the planes thus raised, that the angle $EGH$, contained by the planes $BEF$ and $FBI$, and perpendicular to $FB$, their common intersection, is the measure of the angle contained by the planes $BEF$ and $FBI$.

Problem II.

Given one of the sides containing the right angle and the angle opposite, to find the remaining side which contains the right angle.

Let the given side be $EBE$ (fig. 2.): in $BE$ take any point $F$, and make $EFH$ equal to the angle required; draw $HE$ perpendicular to $EB$; from $E$, with the radius $EF$, describe an arc $FG$: draw $BG$ a tangent at $G$, and $EBG$ is the side required. The demonstration is evident from the last.

Problem III.

Given one of the sides containing the right angle and the inclination or angle adjacent, to find the remaining side which contains the right angle.

Make $ABD$ (fig. 2.) equal to the given side: in $AB$ take any point $E$; draw $EG$ perpendicular to $BD$, cutting it at $G$, and $EH$ perpendicular to $AB$; make $EF$ equal to $EG$, and $EFH$ equal to the given angle; draw $BHC$, and $ABC$ will be the measure of the plane angle opposite.

The following propositions shew the construction of all the cases of trihedrals or spherical triangles, which are all represented by right-lined triangles. In each of the cases it will be found, that two of the sides of the spherical triangle are represented by the tangents of the arcs drawn from the same angle; and the angle included by these tangents is the measure of the spherical angle. The representation of the third side is a line joining the extremities of the tangents; the other two angles are measured by this proposition. If each of the three plane angles be denominated a side, and each of the three inclinations an angle, the geometrical construction will be the same as that of a spherical triangle, and the manner of expressing the data of the one is the same as expressing that of the other. The sides are always measured by the three plane angles of the fold angle.

Problem IV.

Given two sides and the contained angle, to find the other parts.

Make the angle $ABC$ (fig. 3.) equal to the contained angle: draw $BD$ perpendicular to $AB$, and $BE$ to $BC$; make $BD$ and $BE$ equal to each other, the angle $BDA$ equal to one of the containing sides, and $BEC$ equal to the other. Upon $C$ as a centre, with the distance $CE$, describe an arc $F$; and upon $A$ as a centre, with the distance $AD$, describe another arc, cutting the former at $F$. Join $FA$ and $FC$, then the angle $AFC$ will be the measure of the third side.

Now if the triangle $ABD$ be turned round the line $AB$, the triangle $CBE$ round $CB$, and the triangle $ACF$ round $AC$, until the points $D$, $E$, $F$, coincide, each of the two planes, $ABD$ and $CBE$, will be perpendicular to the plane $ABC$; thereore, there will be given two of the sides of a fold angle, one perpendicular to the other, to find the inclination of the vertical plane with that of the hypotenusal. Proceed, therefore, as in the last problem, and find the angle $GKH$, which will be the inclination of the two planes $CBE$ and $CAF$. In the same manner may the inclination of the planes $ABD$ and $ACF$ be found.

Note. The triangle $ABC$ represents the spherical triangle, of which $AB$ and $BC$ are the tangents of two arcs; and the angle $ABC$ is the spherical angle contained by the arcs, of which $AB$ and $BC$ are tangents.

Problem V.

The three sides of a spherical triangle being given, to find the angles.

Make the three angles, $ABC$, $CBE$, and $EBF$, (fig. 4. No. 1 and 2.) equal to the three sides of the spherical triangle, that is, to contain the same number of degrees. On $B$ as a centre, with any radius $AB$, describe an arc $AF$; draw $AC$ and $FE$ tangents at $A$ and $F$; join $CE$; draw the straight line $G$ equal to $CE$. On the centre $G$, with the tangent $AC$, describe an arc at $T$; and on the centre $H$, with the tangent $FE$, describe another arc, cutting the former at $I$. Join $GI$ and $HI$, draw $IK$ and $IL$ perpendicular to $IG$ and $IH$, making them equal to $AB$ or $BF$; join $KG$ and $LH$. Now if the triangles $GIK$ and $HIL$ be raised on the lines $GI$ and $HI$, until the points $K$ and $L$ coincide; then each of the triangles $GIK$ and $HIL$ will be perpendicular to the triangle $GHI$. Proceed, therefore, as in the fifth proposition, to find the angles, which in the representation of the spherical triangle $GHI$ are represented by $G$ and $H$.

Scholium.—Since each of the extreme angles may be made the middle angle in No. 1, the triangle $GHI$, No. 2, may be
STEREOGRAPHY.

be laid down in three different figures, each of which will have three different angles included by each two tangents. These three angles, made in each separate triangle, are the measures of the three spheric triangles; but this mode requires more lines than that described in the above proposition.

There is another method of finding the angles of a spheric triangle, when the three sides are given, pointed out by Bishop Horley, at page 215 of his Elementary Treatises. The substance of it is as follows: Draw a right angle, and make one of the legs equal to the difference of the colines of the sides containing the required angle, the hypotenuse equal to the chord of the third side. Upon the remaining perpendicular side, as a base, construct a triangle, whose two other sides are equal to the sides of the sides containing the required angle; then the angle contained by the sides will be the measure of the spheric angle. This may be very easily accomplished by means of a scale of lines and chords from Gunter's scale.

PROB. VI.

Two angles and a side opposite to one of them being given, to find the other two sides and the remaining angle.

Make the angle $\angle ABC$ (fig. 5) equal to the spheric angle next to the given side; draw $BD$ and $BE$ perpendicular to $BA$ and $BC$; make $BD$ of any length, and $BE$ equal to it; and make the angle $BDA$ equal to the measure of the given side. Draw $AF$ perpendicular to $BC$, cutting it in $F$; make the angle $FAC$ equal to the complement of the other given angle. On the centre $F$, with the distance $FG$, describe an arc $GHI$. Draw $CHE$, a tangent to the arc at $H$, the same as in the second proposition. Join $AC$, and the angle $CEB$ will be the measure of the included side. On the centre $C$, with the distance $CE$, describe an arc at $K$; and on the centre $A$, with the distance $AD$, describe another arc, cutting the former at $K$. Join $AK$ and $KC$; then will $AKC$ be the measure of the third side of the spheric triangle.

PROB. VII.

Given two angles, and the contained side, to find the other three parts.

Make $\angle ABC$ (fig. 3) one of the given angles. Draw $BE$ perpendicular to $BC$. Make $BEC$ equal to the number of degrees contained in the given side. In $BC$ take any point $G$. Draw $GI$ perpendicular to $CE$, cutting it at $I$, and $GK$ perpendicular on the other side of it. Make $CH$ equal to $GI$, and the angle $GHK$ equal to the other given angle. Draw $CKA$ (as in Prop. III.), then $ABC$ is a plane triangle representing the spheric one.

Now, because $ABC$ is the angle included by the tangents, draw $BD$ perpendicular to $BA$, and equal to $BE$, and join $DA$; then $BDA$ is the measure of the side, of which $AB$ is the tangent. On the centre $A$, with the distance $AD$, describe an arc at $F$; and on the centre $C$, with the distance $CE$, describe another arc, cutting the former at $F$. Join $FA$ and $FC$; then $AFC$ is the measure of the third side.

PROB. VIII.

Two sides, and an angle opposite to one of them, being given, to find the three remaining parts.

Draw $AC$ (fig. 6.), representing the side adjoining the given angle, and $AB$ perpendicular to it. Make the angle $ABC$ equal to the given side. In $AC$ take any point $E$. Draw $ED$ perpendicular to $BC$, cutting it in $D$, and $EG$ perpendicular to $AC$. Make $EF$ equal to $ED$; and the angle $EFG$ equal to the given angle. Draw the line $CGH$. On $A$ as a centre, with the tangent of the other given side, describe an arc $KH$; which, if it cut the straight line $CH$ in two points, $H$ and $K$, join $AK$ and $AH$. Draw $AI$ perpendicular to $AH$, and equal to $AB$. Join $IH$. On the centre $H$, with the distance $HI$, describe an arc at $M$; and on the centre $C$, with the distance $CB$, describe an arc, cutting the former at $M$. Join $HM$, $MK$, $CM$; then the angle $CAM$, or $CAH$, is the measure of the spheric angle. The measure of the angle $AHC$, or $ACK$, representing the spheric angle opposite the given side, thrown by the tangent $AC$, is found by Prop. I. The angle $CMH$, or $CMK$, is the measure of the remaining side, viz. that opposite the angle included by the tangents.

N.B. This case is not always ambiguous; for if $AH$ be equal or greater than $AC$, the arc $KH$ will only cut $HC$ in one point; and, therefore, there can only be one triangle; or, if the angle $AHC$ be a right angle, $AH$ will only touch $HC$; in this case also there is only one triangle.

PROB. IX.

The three angles of a spheric triangle being given, to find the three sides.

Take the supplements of each of the angles, and describe a triangle by Prop. V., whose sides are equal to these supplements; then the measure of the angles of this triangle will be the supplements of the sides of the triangle sought. This is demonstrated by writers on spheric trigonometry.

Though the writer of this article has not given formal demonstrations of the preceding propositions relating to the geometrical construction of spheric triangles, as it would have swelled the article too far, he hopes that enough has been said to enable any one, who has a clear conception of the parts of a spheric triangle, to describe the representation of it, and to find the measure of its parts in the most easy manner, without having recourse to the projection of the sphere, which frequently runs into conic sections, and, from their difficulty of description, renders the projection very inaccurate. The representation of the spheric triangle belonging to the preceding propositions, is nothing else than a plane triangle, which is a tangent to the sphere at one of the spheric angles, and whose sides are bounded by the intersections of the planes of the three great circles of the sides of the spheric triangle; consequently two of the sides of the representative triangle are always two tangents from the same spheric angle. The included angle by these tangents in the representative triangle is the measure of the spheric angle contained by the sides which the tangents represent. And the third side in the representative triangle is a line joining the extremities of the tangents, as has been already mentioned. In another point of view, the whole may be conceived to be a pyramid, whose sides are planes from the centre of the sphere, passing through the three arcs of the spheric triangle; and the base a triangle, a tangent of the sphere at one of the angles, which meets the sides. The vertical angles of the sides of this pyramid are the measures of the sides of the spheric triangle; the angles of the pyramid are the measures of the spheric angles; and the base of the pyramid is the representative triangle. Consequently one of the angles of the pyramid is always perpendicular to the base. The angle intercepted by the two planes upon the base is equal to the inclination of the planes.

The triangle belonging to the preceding propositions is such, that when all the parts are completed, the sides may be turned
STEREOGRAPHY.

turned up upon the base, which is the representative triangle, until the edges of all the triangles forming the sides are united in one common vertex. A pyramid will then be formed, equal, similar, and similarly situated to that above.

The Rev. George Walker, in his ingenious doctrine of the sphere, Prop. I. p. 256, shews, that “if there be a spheric triangle, and a plane quadrilateral figure be formed, two of whose sides are the two segments of two of the sides of the spheric triangle, and the angle comprehended by the segments be measured by the spheric base, the angle comprehended by the tangents shall be the measure of the spheric angle opposite the base; the diagonals of the quadrilateral shall intersect each other at right angles; the segments of the diagonal joining the angle of the base, and the angle of the tangents, shall be the tangent and tangent of the spheric perpendicular, drawn from the vertical angle to the base; the angle which this diagonal makes with the segments shall be measured by the spheric segments of the base; and the angles which this diagonal makes with the tangents shall be the measures of the spheric angles which the perpendicular makes with the sides.” This theorem is very analogous to Prob. V.; but the properties shewn by it do not apply to the construction from any given data, nor can all the parts be found from any one datum; they may be very well applied when two sides and the contained angle are given, or when the three sides are given, by varying the triangle, as has been here shewn, in order to find the other two angles; but this is both troublesome and inelegant.

From what has been said, it will be easy to construct any solid similar to any other solid given, whose sides are planes, by constructing each solid angle, that is, by dividing it into as many solid angles, each consisting of three plane angles, wanting two, as the number of plane angles bounding the whole solid angle; then completing the figure of any side, of which a plane angle of the described solid angle is one similar to the side of the solid given. From the several angles of this figure construct other solid angles in the same manner.

PROB. X.

In a solid, such that all sections parallel to the base are similar and regular polygons, there are given the base of the solid, a vertical section perpendicular to the base through its centre, and to the sides of the polygon, to find the angular or common section at the meeting of every two equal and similar prismatic parts.

From the centre of the base draw a line at right angles to the sides of a polygon; apply the base of the perpendicular section to this straight line, which now call the base of the perpendicular section. Draw a line from one of the next angles to the centre of the base; call this the diagonal line. Take any number of points in the base of the perpendicular section, and draw lines parallel to that side of the polygon to which it is perpendicular, till they cut the diagonal line. From these intersections draw perpendiculars to the diagonal line. Draw perpendiculars also to the base of the perpendicular section, till they cut the curve of this section. From all the intersections of the diagonal apply all the perpendiculars of the section; through the points now found draw a curve, and it will be the section of the diagonal plane required. This will be evident, if the perpendicular, and diagonal sections are raised perpendicular to the plane of their bases.

Example.—Plate II. fig. 2. No. 1, is the hexagonal base of a solid, whose perpendicular section is ABC. Draw the diagonal BC. In BC take any number of points, s, through which draw the lines ef parallel to BD, cutting the diagonal line in the points f. From the points e draw the lines eg perpendicular to BC, cutting the curve AB in the points g; and from the points f draw the lines fb perpendicular to DC. Make all the lines fb equal to the lines eg; and through points D, b, b, &c., draw a curve, and CD I will be the diagonal section required.

This process may easily be reversed, by having the angular section given. In the same manner are the sections of figs. 2 and 3, No. 1, to be found, which, from what has been said, are plain to inspection.

In order to give a clearer idea of these solids, their elevations are shown at No. 1.

PROB. XI.

To find the covering of a cylinder, such as may be generated by a rectangle.

Make a rectangle; one of whose dimensions is the length of the axis, and the other the circumference of the base of the cylinder.

Example.—A B C D (fig. 4. No. 1.) is the elevation of a cylinder, G, (No. 2.) the base. The side DE, of the rectangle C D E F, is made equal to the circumference of G, and the breadth CD is the height of the cylinder.

If C D E F be wrapt round the cylinder A B C D, the edge E F will coincide with C D, D E with the base A D, and C F with the base B C: this is so evident that it wants no demonstration.

PROB. XII.

To find the covering of a cylindrical ungula, having the base of the cylinder; and the axis-section perpendicular to the inclined section of the ungula.

Let A c c e c c B (fig. 5.) be half the circumference of the base. Divide it into the equal parts A, c, c, c, c, c, &c.; and let E D F G be the axis-section, whose base D G is placed parallel to A B, the edge D E in a straight line with the extremity A, and G F in a straight line with the extremity B. Draw the lines e b parallel to D E, cutting the inclined line E F in the points b. Produce D G to L. On G L make the distances G n, n n, n n, &c., and n L, equal to B e, e, e, &c. Draw the lines n n parallel to D E, as a L I; and the line b L perpendicular to it. Through all the points k to I draw a curve, and G F I L will be half the covering: for imagine the part D F G E to represent the ungula, and the covering F G L I wrapt round F G D E; then, because that all the distances G n, n n, n n, &c., are equal to B e, e, e, &c., the points n will fall upon those of e, which are described in the elevation; and because that all the figures O b k n are parallelograms, all the lines n k will be equal to the lines o b, and the lines n k will fall upon those represented by o b, and the points k will fall upon those of h, and the part F G L I will cover half the ungula represented by F G D E.

PROB. XIII.

To find the covering of the curved superficies of a cone, such as may be generated by the revolution of a right-angled triangle about one of its perpendicular legs.

With a radius equal to the slant side of the cone describe an arc. Make the length of this arc equal to the circumference of the base. Draw two right lines from the centre to each extremity of the arc, then the sector comprehended by the two radii and the arc will be the curved superficies required.

Example.—Let A, (fig. 6.) be the base of the cone; B D C the
STEREOGRAPHY.

the elevation, which also represents a section of the cone through the axis.

On, as a centre, with the slant side DC, describe an arc CE. Make the arc CE equal in length to the circumference of A. Join DE and DC, and the sector EDC is the covering required.

For CE being equal to the circumference of the base, when DEC is bent round the cone DBC, the straight line ED will meet CD, and all the points on the arc CE will coincide in the same plane with the base BC, since the superficies of the cone may be conceived to be divided into an indefinite number of isoclines triangles, whose vertex is the point D, and whose bases are in the base of the cone. The sector DEC may be conceived to be divided into as many isoclines triangles, which, when bent round, will respectively coincide with those of the cone.

PROB. XIV.

To cover a conical ungula, the cone from which it is a part being such as may be generated by the revolution of a right-angled triangle about one of its perpendicular legs, a section through the axis at right angles to the plane of the inclined section of the cone being given.

Let ABCD (fig. 7) be the section given. Produce AD and BC to meet it in E. Bisect the vertical angle AEB by EI, cutting A B at K. On the centre I, with a radius AK or KB, describe a circle FMGN. Draw the diameter FG parallel to AB. Divide the semi-circumference FMC into any number of equal parts, Fo, oo, oo, &c. Draw the lines op parallel to EI, cutting A B in the points p; the lines qn, qr, &c. parallel to AB, cutting BE in the points r. Make all the distances Bi, it, it, it, &c. on the arc BH, equal to Fo, oo, oo, &c. Draw EB, Ei, Ei, Ei, &c. On the centre E, with the radii ER, describe arcs, cutting the lines Et in the points t. Draw the curve line Ciss, &c. and BCLH will be the covering required; for the sector EHH will be the covering of the whole cone; Brii, &c. will coincide with the base; the lines Et will coincide with the lines Ep, and all the lines r will fall upon rq.

PROB. XV.

To cover a solid generated by the revolution of a semicircle, the section through the axis being given.

Produce any side AB (fig. 8) to the axis produced in C. On C as a centre, with the radii CA and CB, describe arcs AE and BD. Draw the radius EDC, and AEBD will cover a part of the frustum of a cone, represented by ABGF, as is evident from what has been said.

PROB. XVI.

In a solid, whose parallel sections to the base are all similar figures, and whose base is a regular polygon, there are given the base and the perpendicular section to find the covering of one of the curved sides.

Let ABCDE (Plate III, figs. 1, 2, and 3.) be the base, FGH the perpendicular section, G its base, drawn from the centre F, perpendicular to the side AE. Divide the curve GH into any number of equal parts Gi, ii, ii, &c. Draw the lines ii parallel to AE, cutting FG in the points k, and FE in the points l. Produce FG to P, making GP equal to the arc GH, and divide GP into the same number of parts in the points m, as GH is divided into the points k. Draw the lines mn at right angles to GP, and the lines in parallel to it; or make the lines mn equal to k, and through the points a draw a curve; then APE will be the covering of one of the curved superficies required.

If GHF be a quadrant, each edge of the covering will be the same as a part of that of a cylindrical ungula of the same diameter, cut at the same inclination as the angle FE C.

From what has been said it will be easy to conceive that any of these coverings must fit the surface they are made for. If the section G HF be raised upon the base GF until it becomes perpendicular to the plane ABCDE, and the covering APE bent round; the points m will coincide with those of it, and the lines mn will fall upon the lines kl.

There is another geometrical method of finding the superficies of a solid in plane, much more convenient in practice. The data for this method are the length of the curve of the perpendicular section; the figure of the perpendicular section; one of the terms or sides of the base of the solid. This rule is as follows: on the given term or side describe a figure similar to the perpendicular section of the solid, the term or side being the base of the similar section. Produce the vertical edge of the similar section indefinitely from the base. Upon this indefinite line set the length of the curve of the perpendicular section. Divide this line and the curve of the similar section both into the same number of equal parts. Through all these points draw lines parallel to the term or side of the base of the polygon, those of the similar section being cut at the perpendicular side. Take all the respective lengths of the sides, beginning with those next the base first of the similar section, and let them on the respective parallels in the same order from the base on each side of the line, cutting the parallels. A curve being traced through the points on both sides, will, with the base, be the boundaries required.

This is exemplified in figs. 4 and 5. ABC is the similar section to the perpendicular one; AB representing its base, BC its perpendicular, BD the length of the curve of the perpendicular rib, AE the side of the base of the solid. The manner of describing these coverings is plain to inspection. ABC (fig. 4.) is for a curve of contrary flexure; ABC (fig. 5.) is to answer a quadrant.

It may be remarked, that by whatever mode the curve of the perpendicular section is described, the same mode may be applied to describe the similar one ABC: if the outer edge of the perpendicular rib be a curve of contrary flexure, as in fig. 6, described from the fuzmuts of equatorial triangles; the similar rib ABC (fig. 4.) may be described in the same manner. To find the height BC, find a fourth proportional to the base, the perpendicular height of the perpendicular rib, and the side of the base of the solid; that is, suppose FGH (fig. 7) to be the perpendicular rib, GH its base, GF its height. Make AB to BC (fig. 4.) as HG to GF; that is, H G: G F: A B: B C.

To demonstrate the truth of the above method, it is only necessary to shew, that if the lines ip (fig. 1.) are drawn parallel to GF, intercepted by the line HF, all the lines kl, as they recede from GE are proportional to the lines ip, as they recede from GF.

Draw HK (fig. 7) perpendicular and equal to HG. Join KG. Make HK equal to AB (fig. 4.) that is, equal to half the breadth of a side of the base of the solid, and join IG. Draw L, M, N, O, P, from the points L, M, N, O, P, in the curve FH, parallel to GH, cutting GF in the points w, v, x, y, z, s, and let L, M, N, O, P, be parallel to HG, cutting the points v, w, x, y, z, s, and L, M, N, O, P, be parallel to HG, cutting the points v, w, x, y, z, s, and L, M, N, O, P, be parallel to HG, cutting the points v, w, x, y, z, s, and L, M, N, O, P, be parallel to HG, cutting the points v, w, x, y, z, s, and L, M, N, O, P, be parallel to HG, cutting the points v, w, x, y, z, s, and L, M, N, O, P, be parallel to HG, cutting the points v, w, x, y, z, s, and L, M, N, O, P, be parallel to HG, cutting the points v, w, x, y, z, s, and L, M, N, O, P, be parallel to HG, cutting the points v, w, x, y, z, s.
G, G, G, O, G, G, T, G, U, are respectively equal to \( v \), \( M, x, N, y, O, z, F \); and because the similar triangles \( K H G, B O G, C H G, B O G, A O G, \) and \( A O G, \) and because \( K H G \) is equal to \( H C G \); \( U E T, D, \) \( S, R, B \); and \( Q, A \), are respectively equal to \( U, T, G, S, R, G, \) and \( Q, G \); therefore \( U E, T, D, S, R, B \), and \( Q, A \), are respectively equal to \( z, P, O, N, x, M, v \), and \( v, L \). Now \( H I, U, Z, T, Y, S, X, R, W, Q, \) and \( O, V, Q, \) are to one another as \( H K, U E, T, D, S, R, B \), and \( Q, A \); therefore \( H I, U, Z, T, Y, S, X, R, W, Q, \) and \( O, V, Q, \) are as \( P, x, M, v, \) \( L, v \); but \( A, B, c, d, e, f, \) \( g, b, i, k, l, m, \) \( (f \text{ fig. } 4) \) are to one another as \( P, x, M, v, \) \( L, v \); therefore \( H I, U, Z, T, Y, S, X, R, W, Q, \) \( (f \text{ fig. } 7) \) are also as \( A, B, c, d, e, f, g, b, i, k, l, m, \) \( (f \text{ fig. } 4) \); but \( H I \) is equal to \( A, B, \) \( (f \text{ fig. } 4) \); therefore \( A, B, c, d, e, f, g, b, i, k, l, m, \) are equal to \( H I, U, Z, T, Y, S, X, R, W, Q, \).

From what has been said, the geometricalian will soon perceive that the coverings \( A D E \) \( (f \text{ fig. } 5 \text{ and } 6) \) are what is called the figure of the lines.

Example.—Let \( A B C \) \( (f \text{ fig. } 8 \text{ N}^\circ 1, \text{ and } f \text{ fig. } 9 \text{ N}^\circ 2) \) be the generating plane, \( A B \) its axis, \( B C \) its base, \( B D \) half the base of the fold, \( B F F \) \( D \) the curve line of the section, \( A \) the equidistances \( B, f, f, f \); \( c, d \); and on the centre of the base \( G \), describe and cutting \( B C \), \( C \) the base of the section, in the points \( G \) draw the lines \( b \) perpendicular to \( B C \), cutting the curve in the points \( K \). Make \( I K \), \( (N^\circ 2 \text{ fig. } 9) \) equal to \( B, f, f, f \); \( c, d \); and let the points \( l, \) \( l \) in \( I K \), be those which correspond to \( f, \) \( f \); \( c, d \) \( (f \text{ fig. } 9 \text{ N}^\circ 1) \). Draw perpendiculars \( b \) to \( I K \), equal in length to \( B, f \), \( c, d \); and the curve \( K, m, m, m, I \), being drawn, will give the superficies of the prismatical part.

STEREOLOGY, \( \gamma \tau \epsilon \rho \iota \sigma \mu \alpha \kappa \varepsilon \tau \iota \gamma \mu \), formed of \( \sigma \mu \iota \varepsilon \), solid, and \( \mu \iota \varphi \gamma \sigma \rho \varepsilon \), measure, that part of geometry which teaches how to measure solid bodies, \( i, \) \( a, \) to find the solidity or fold content of bodies; as globes, cylinders, cubes, vases, ships, etc.

The methods hereof see under the respective bodies; as GLOBE, SPHERE, CYLINDER, etc. See also GAUGING.

STEREOTOMY, formed from \( \tau \iota \sigma \varepsilon \gamma o \), and \( \tau \iota \sigma \varepsilon \), section, is the science and art of cutting solids under certain specified conditions.

Stereotomy may be regarded as a branch of stereography, which is the science of folds in general. Mr. Hamilton has entitled his complete body of perspective, Stereography, which perhaps would have been more properly entitled Stereotomy, as the perspective representation of every object in nature is the section of a pyramid or cone of rays. But as it has not been the object of the writers on perspective to shew the rules for finding the sections of solids in general, under certain specified conditions, the cutting plane, nor of finding any other sections besides those of cones and pyramids, it is the express intention of this article to explain the general principles of the science for any given law, by which the surface of the fold may be constituted of straight lines, or that the surface may agree with the common section of two planes disposed in given positions. And as nothing of the kind has yet appeared, perhaps this attempt may be the more acceptable, particularly as it is in its principles the whole art of dialling is included, and the mechanical arts of masonry and carpentry. The art of stone-cutting, the squaring and cutting of timbers, and the formation of hand-rails, depend entirely upon the sections of solids.

PROB. I. Plate I. Fig. 1.

Given the fact, \( A, B, \) of the intersection in space of two planes, having a given inclination, and the intersection, \( A, C, \) of one of them in a given plane, \( Y \); also the inclination of the common intersection of the two planes to the plane \( Y \); to find the intersection of the other plane with the plane \( Y \).

Make \( B A D \) equal to the inclination of the intersection of the two planes: from any point \( D, \) draw \( D E \) perpendicular to \( A D \), cutting \( A B \) at \( E \); make \( E B \) equal to \( E D \); draw \( E C \) perpendicular to \( A B \); make the angle \( C B F \) equal to the inclination of the planes, of which the foot of their intersection is \( A B \); let \( B F \) meet \( E C \) in \( F \); and join \( A F \); then will \( A F \) be the intersection required.

Or thus: Through any point \( E \), in \( A, B, \) draw \( E \) \( C \) perpendicular to \( A B \); make \( E A D \) equal to the inclination of the intersection; draw \( E D \) perpendicular to \( A D \); make \( E B \) equal to \( E D \); join \( B C \); make the angle \( C B F \) equal to the inclination of the planes, which have \( A B \) for the foot of their intersection; let \( B F \) meet \( C E \) in \( F \); and join \( A F \); then will \( A F \) be the intersection required.

Demonstration.—Imagine the triangle \( ADE \) to be turned upon \( A, E \), until it becomes perpendicular to the plane \( Y \): let the plane \( Z \) be turned upon \( C \), until \( E \) falls upon \( D \); that \( E \) will upon \( E \) is evident, for \( E \) in revolving upon \( E \), will always be in a plane passing through \( E \) perpendicular to \( C \), and \( E \) is also in a plane passing through \( E \) perpendicular to \( C \); and since \( E \) is equal to \( E \), \( E \) must fall upon \( E \), and the point \( B \) upon \( D \); and the plane \( AED \) will be perpendicular to the two planes \( CA \) and \( CB \); therefore \( A \) will be perpendicular to the plane \( CEB \); whence it is manifest, that \( CBF \) is in a plane perpendicular to the common intersection, and is the measure of the inclination of the planes.

PROB. II. Fig. 2.

Given \( IN \), the intersection of a plane, \( W \), with another plane, \( X \), and their inclination, the fact, \( A, B \), in the plane, \( X \), of a line in space infiting at \( A \), and the inclination of the line to the plane \( X \); to find the section of the line in the plane \( W \).

Through any point \( B, \) in \( A, B, \) draw \( BS \) perpendicular to \( IN \), cutting \( IN \) at \( E \); make the angle \( BEF \) equal to the inclination of the plane: draw \( BG \) perpendicular to \( BS \); make the tangent of the radius \( A, B \); draw \( GF \) parallel to \( BS \); through \( A, \) draw any two lines \( AJ \) and \( AK \), cutting \( IN \) at \( J \) and \( K \); make \( ES \) equal to \( EF \); through \( S, \) draw \( VL \) parallel to \( IN \); produce \( BS \) to \( P \); make \( SP \) equal to \( PG \); draw \( PV \) parallel to \( AK \), and \( PL \) parallel to \( AJ \); and join \( KV \) and \( JL \), cutting each other at \( i, \) and \( a \), the section of the line in the plane \( W \), as required.

For imagine the triangles \( BFC \) and \( CBF \) in the same plane to be turned upon \( BE \), so that their plane may be perpendicular to the plane \( X \); then \( BG \) will be perpendicular to the plane \( X \), and the point \( G \) will fall in the line in space: imagine also the plane \( W \) to be revolved upon \( IN \), until \( ES \) fall upon \( EF \), as is evident for the same reasons as given in the first problem, and the point \( S \) will fall upon \( F \); then the line \( VL \) will become parallel to the plane. In revolving the plane \( W \) upon \( IN \), imagine the plane \( Y \) to revolve upon \( VL \) at the same time, so that the plane \( Y \) may always continue parallel to the plane \( X \); then \( VF \) will continue parallel to \( AK \), and \( LF \) parallel to \( AJ \); then, as in perspective, \( X \) is the original plane, \( W \) the plane of the picture, \( Y \) the vanishing plane, \( G \) or \( P \) the place of the eye coinciding therewith, \( IN \) the intersecting line, \( VL \) the vanishing line, \( J, K, \) the intersecting points.
STEREOTOMY.

points, V L, the vanishing point, and the original line would then be a visual ray; therefore, by the theory of perspective, a is the representation of the point A.

**PROB. III.**

The same things being given, and the constructive lines remaining as in the preceding problem, as also the point a, the section of the line in space to find the feet of the line in the plane W, and its inclination to the said plane.

Draw G Q (fig. 3.) perpendicular to E F, meeting E F in Q ; in E P, make E T equal to E Q, and join T a: draw T R perpendicular to a T: make T R equal to Q G, and join R a; then will T a be the feet of the line in the plane W, and T a R its inclination to the said plane.

**Demonstration.**—For when E S is made to coincide with E F, as in the last problem, the plane F C G will be perpendicular to the plane of the section W, but the line F C being now in the plane W, and Q G being perpendicular to F C, Q G will also be perpendicular to the plane W: but the point G, that is, R, is a point in the line whose feet is A B, and the point a is another point in the line whose feet is A B: therefore, R and a are two points in the line whose feet is A B: then join a R, which will be the part of the line in space on the other side of the plane W, and a R its feet.

**Scholium.**—This amounts to the same thing as the feet and distance of the eye being given with respect to the original plane, and the position of a point in the said plane; to determine the feet and inclination of the visual ray.

**PROB. IV.**

Two straight lines, A B and C D, (fig. 4.) tending to an inaccessible point, being given, through a given point E, to draw a third straight line, to tend to the said inaccessible point.

From any point A, in A B, draw a straight line, A E, from A to the given point E, cutting C D in C; and through any other convenient point B, draw B F parallel to A E, cutting C D in D; join D F, a fourth proportional to A C, C E, B D, and join E F; then will the lines A B, C D, and E F, tend to the same point of concurrence.

**Scholium.**—It sometimes happens, that a number of lines radiate from the same point, and that from a given point it is required to radiate other straight lines, so as to meet the radiations given in a given straight line: some or many of the former radiations, according to their number, will be inaccessible; and though they may be all found by this problem, yet if the several operations are combined in one, much trouble will be saved.

Thus, let the radiations (fig. 5.) be A B, A C, A D, A E, A F, tending to the straight line B C; and let a be a given point, from which it is required to radiate other straight lines to meet or tend to the said points in B C, with those drawn from A. Join A a, cutting B C in G; and through any convenient point C in B C, draw F c parallel to A a; make c C equal to G a, and c C in Q in B C, produced to a, equal to G a; join P Q. Now let A D, A E, meet C F in D and E; draw D M, E n, F o, parallel to P Q, cutting B a at m, n, o; make C d equal to C m, C e equal to C n, c f equal to C o; draw d a, e a, f a, which are the lines required. This might also be nearly effected by the proportional compasses; but the centrelined, invented by the author of this article (Mr. P. Nicholson), is much preferable. It is described under the article SCANOGRAPHY, but has of late been much improved, and made to set at the first time.

**Example 1.**—Given the meridian A B (fig. 6.) in the plane of the horizon X, the latitude of the place, the intersection, I N, of the plane W, with the horizontal plane X, and the inclination of the plane W, to that of the horizon X; to construct a dial in the plane W.

In A B, take any point, A, for the foot of the style; then A B will be the feet of the style, or of the line tending to the pole of the world; the latitude of the place is its inclination. Find a the representation of A, that is, the section of the style of the dial in the plane W, by the second problem: produce A B to meet I N in D: draw D a in the dial-plane W; then, by the third problem, find a T, the feet of the style in the plane W, and the angle of elevation T a R: and by the first problem, find the intersections, U a, Y a, Z a, &c. of planes passing through the style, making angles respectively of 15°, 30°, 45°, 60°, &c. with the vertical plane passing through the meridian A B; that is, with the plane whose intersection is T a: the inaccessible lines are also found by the last problem; and the dial is constructed as required. a T is the feet of the style, whose intersection is T a; T a R its inclination; a D is the 12 o'clock line; and U a, Y a, Z a, &c. are the hour-lines. Another method of finding the sub-styles is thus: produce G Q to meet P E in H; join H A, which produce to N: draw N a the subfialyer line.

Thus, upon one common principle, the sections of lines, planes, and solids may be found. The sections of solids are found by means of the sections of planes: the construction of a dial is only finding the sections of planes, whose positions are given. This method is, perhaps, of all others the easiest to consider and to construct.

**Example 2.**—Given the base, A N Q R, (fig. 8.) of a pyramid, in the plane X, and the whole feet, A B, of one of its angular lines, the intersection, I N, of the cutting plane W, and the inclination of the planes W and X; to find the section of the pyramid.

Find the vanishing line, V L, of the plane X, and the vanishing points, V and L, of the lines A R, N Q, A N, R Q: produce A R to K, N Q to M, A N to J, and R Q to L, to meet the intersecting line I N; join K V and M V, also J L and L L; then angr will be the section of the pyramid inscribing upon A N Q R.

**Example 3.**—To find the section of a prism (fig. 7.), the same things as before being given. Find the vanishing points, V and L, of the lines A J and A K, and the representations, K V and J L, as before: draw L r parallel to J L, and M s parallel to K V, and q n a r will be the section of the prism required.

Plate II. fig. 3. To find the section of a cuneoid or cono-cuneus, the same things as before being given, the base of the fold being a b c d e f g h.

Let G a be the section of the plane, passing through the apex, and the centre of the base in the original plane, cutting the base of the fold in a and e: divide each half on each side of the diameter, a e, into any number of equal parts, as four: through the points of division draw lines parallel to a e, which produce to meet the intersecting line; and let a e meet it in G; then having drawn another series of lines at right angles, also to meet the intersecting line, find the vanishing points, V and L, of each of these series of lines: join G V: from the intersecting points of the lines parallel to a G, draw lines parallel to G V: also from the intersecting points of the other series of lines, draw lines to the vanishing point L; then the figure a b c d e f g h, formed by the intersections of these lines, will be the section of the cuneoid.

**Fig. 3.** shows the method of finding the section of a cylinder upon the same general principle, only with the difference,
STEREOMETRY.

... that having found the vanishing points V and L, and the lines GV and HL; one set of lines is drawn from the intersecting points parallel to GV, and the other set is drawn from the vanishing point to HL; and by this means the figure abedfgb is the section of an oblique cylinder, whole set is i b.

Fig. 7. shows the section by the same general principle, differing from fig. 2, in this respect, that, instead of the lines being drawn from the intersecting points parallel to GV and HL, they are drawn from the point V and L as vanishing points, and by this means form the section abedfgb of the cone.

In the same manner may be found the section of a cone, when the cutting plane is parallel to one of its sides, that is, to a plane touching one of its sides, and thus giving the parabola for its section; and when the cutting plane is parallel to any plane within the cone passing through its apex, and forming the section into an hyperbola.

Figs. 4, 5, 6, 7, are other methods, not differing in principle, but in the manner of laying them down, which is very convenient in the practice of stereotomy.

IN is the intersecting line, IP the base of a plane perpendicular to the intersect line IN, and IE the inclination of the plane: the point E is found as in the former cases: draw I E perpendicular to IE.

In fig. 4, B is the earth of the axis of a cone, whose section is thus found: for the sake of simplicity, divide the base, or its half, into equal parts, and draw one series of lines perpendicular to IN, to meet IN, and another through the base points perpendicular to IP, to meet IP: from these points, draw lines to D, to meet IE; and from these lines in IE, draw lines parallel to i n: make IN equal to IN, and n p equal to IN, n q equal to N Q: draw n E, p E, q E: let the same distances on the other side of a on I n produced from those points: draw lines again to E, and the figure abedfgb in the plane Z will be the section of the cone.

The same manner, the section of a cylinder may be found by drawing lines parallel to the middle line G, instead of being drawn to the point D. The truth of this method may be conceived by raising the plane Y upon IP, so as to be perpendicular to the plane X; then turning the plane Z at a right angle with the plane Y, so that I n will fall upon I N, the point E will be the apex of the cone; then, if a set of planes be supposed to pass through the axis parallel to the intersecting line, and another set of planes to pass through the plane parallel to IP, and both sets through the same points (a, b, c, d, e, f, g, h) of the original figure; it will be evident that these planes will cut the sectional plane by their intersections with each other in the points, a, b, c, d, e, f, g, h.

Fig. 5. is an example of this method in a right cone, in which only one half of the section is shown.

Fig. 6. is an example in a cylinder, which only differs from the cone in the planes being parallel. Having found the middle line GD, and E, as in the description of fig. 4, from the points of section in IP, draw a line parallel to GD, to cut IE: from the points of section in IE, draw lines parallel to I n, cutting n E: from the points p, g, b, d, e, f, c, of section in n E, and upon the lines parallel to I n, make p b, p m, equal to p b or p m: make p c, p l, equal to p c or p l: make p d, p k, each equal to p d or p k: make p e, p l, each equal to p e or p l: make p f, p b, each equal to p f or p b; then the points a, b, c, d, e, f, g, h, the extremities of the diameter, are the sections of the extremities of the plane passing through a, b, and consequently abedfgbiklm is the section of the whole figure.

Fig. 7. shows the section by the same general method, when the cylinder is a right cylinder.

PROB. V.

Given the plane X, the facts A, B, C, (fig. 8.) in the plane X, of three points on the surface of another plane Y in space, and the heights of the points in the plane Y, above the given plane X; to find the intersect of the plane Y with the plane X.

Draw the three parallel lines A D, B F, C E, through the points A, B, C: make A D equal to the height of the point whose fact is A; B F equal to the height of the point whose fact is B; and C E equal to the height of the point whose fact is C: join A C, and produce it to H; join D E, and produce D E to H; draw B G parallel to A H, and F G parallel to D H, and join G H; then will G H be the intersect of the plane Y upon the plane X.

Demonstration.—Suppose A D perpendicular to A H, and consequently B F perpendicular to B G; then let the plane A D H be raised upon H to A H: the plane becomes perpendicular to the plane X; and at the same time let the plane B F G be raised upon G B, until it becomes also perpendicular to the plane X: then, because the triangle B F G is similar to the triangle A D H, and since both the planes A D H and B F G are perpendicular to the plane X, and their intersections A H and B G, with the plane X, are parallel, F G will be parallel to D H; and because A D and C E are perpendicular to A H, A D and C E will be both perpendicular to the plane X, and for the same reason B F is perpendicular to the plane X: therefore the points A, B, C, in the plane X, are the seats of the three points D, F, E, raised to the plane Y; and because F G and D H are parallel, all the points in F G and D H are in the plane Y; therefore the points G and H, which are common to the plane X, and to the lines D H and F G, are also in the plane Y; and because the points G and H are common to both the planes X and Y, therefore the straight line G H is common to the planes X and Y; whence the straight line G H is the intersect of the planes X and Y.

PROB. VI.

Given the seats A, B, C, (fig. 9,) of three points on the curved surface of the segment of a right cylinder in the plane of the base X, and the heights of the points; to find the section of the cylinder.

Find the intersect G H, X, in the fifth problem; let AC be the base of the plane of the segment, which is perpendicular to the plane X: draw A I and C K parallel to G H; and draw C L perpendicular to A I, cutting A I in L; make L I equal to the height upon the point A, and K E equal to the height upon the point C; and join I K. In the base A B C take any intermediate points a, b, c, d, e; and draw the lines a f, b g, c h, d i, e k, meeting I K at f, g, h, i, k: through the points f, g, h, i, k, draw f a, g b, h c, i d, k e, each perpendicular to I K: make I A, f a, g b, h c, i d, k e, respectively equal to L A, f a, g b, h c, i d, k e: join A K, and draw the curve A b c e f k, and A b c e f k A will be the section of the cylinder, as required.

Demonstration.—Imagining a series of planes to pass through the points A, b, c, d, e, C, parallel to G H, and perpendicular to the plane X of the base; also a plane to pass through L C perpendicular to the said plane X; then all these planes will be parallel to the axis of the cylinder, and the plane standing upon L C will be perpendicular to the planes passing through the points A, b, c, d, e, C, as well as to the intersect of the plane X and Y. Suppose, therefore,
The idea of stereotype printing is not of modern origin. That it was prior to the art of printing by moveable types there can be no doubt, since this latter mode of printing was first suggested by the Catholicon, which was printed with wooden tablets, in a series, and composed in forms. This mode of printing, except in China, where it is still practiced, was laid aside soon after the invention of the common letter-press printing.

The history of the modern stereotype is involved in some obscurity. In the Philosophical Magazine is the following account: "Above a hundred years ago, the Dutch were in possession of the art of printing with solid or fixed types, which were in every respect superior to that of Didot's stereotype. It may, however, be easily understood, that their letters were not cut in so elegant a manner, especially when we consider the progress which typography has made since that period. Samuel and J. Leuchtmans, bookellers at Leyden, have in their possession the forms of a quarto bible, which were constructed in this ingenious manner. Many thousand impressions were thrown off, which are in every body's hands, and the letters are still good."

The inventor of this useful art was J. Vander Mey, who resided at Leyden about the end of the 16th century. With the assistance of Muller, the clergyman of the German congregation there, who carefully superintended the correction, he prepared and called the plates for the above-mentioned bible, in 4to. This bible was published likewise in folio with large margins, ornamented with figures, the forms of which are still in the hands of Elwe, a bookseller at Amsterdam; also in an English New Testament, and Schap's Syriac Dictionary, the forms of which were melted down; likewise a small Greek Testament, in 18mo. As far as can now be ascertained, Vander Mey printed nothing else in this manner; and the art of preparing solid blocks was lost at his death, or at least was not afterwards employed."

The Dutch editor supposes, that the reason why Vander Mey's invention was dropped was, that the process was too expensive.

In the year 1781 was printed, by Mr. Nicholas of London, a pamphlet, entitled "Biographical Memoirs of William Ged," including a particular account of his progress in the art of block-printing. The first part of the pamphlet was printed from a MS. dictated by Mr. Ged just previously to his death: the second part was written by his daughter, for whose benefit the profits of the publication were intended: the third is a copy of proposals issued by Ged's son, in 1751, for reviving his father's art; and to the whole is added Mr. More's narrative of block-printing.

It should seem from this publication, that in the year 1755, Mr. Ged began his scheme of block-printing. In 1777 he entered into a contract with a person who had a small capital, but who, alarmed at the supposed risk of losing the little which he had, abandoned the concern, after he had expended little more than twenty pounds. In 1729 he entered into a more promising partnership with a Mr. Fenner, Mr. Thomas James, a type-founder, and John James, an architect. Some time after a privilege was obtained from the university of Cambridge to print bibles and prayer-books; but it appears, that one of his partners was actually averse from the plan, and, to thwart the project, engaged such people for the work as he thought most likely to spoil it. One of his people who was entrustted with the secret, avowed, that all the books printed in stereotype had been purposely made incorrect, in consequence of which they were fuppressed at the university, and the plates sent to the king's printing-house, and thence to Caldon's foundery. "After much ill usage," says the writer.
STEREOTYPE.

writer in the Philosophical Magazine, "Ged, who appears to have been a person of great honesty and simplicity, returned to Edinburgh. His friends were anxious that a specimen of his art should be published, which was done by subscription. His son James, who had been apprenticed to a printer, with the consent of his master set up the forms in the night-time, when the other compositors were gone home, for his father to cast the plates from, by which means the first was finished in 1736." A copy of this work is in Mr. Tilloch's possession, and also a plate of one of the pages from which it was printed. Another work was also printed from plates manufactured by Mr. Ged; this was the well-known book entitled "The Life of God in the Soul of Man," which has the following imprint: "Newcastle, printed and sold by John White, from plates made by William Ged, goldsmith in Edinburgh, 1742."

Fifty years after the invention of plate-printing by Mr. Ged, Mr. Tilloch tells us he made a similar discovery, without having at the time any knowledge whatever of Ged's invention. He was aided in bringing his discovery into practice by Mr. Foulis, printer to the university of Glasgow. They overcame every difficulty, and were able to produce plates, the imperfects of which were as perfect and handsome as those of the types from which they were cast. Though we have reason to fear, says Mr. Tilloch, from what we were told, that our efforts would experience a similar opposition, we persevered in our object, and took out patents for England and Scotland, to secure to ourselves, for the usual term, the benefits of our invention; for the discovery, he adds, was as much their own, as if nothing similar had been practiced before. Ged's knowledge of the art may be laid to have died with his son, whose proposals for reviving it, published in 1751, not having met with encouragement, he went to Jamaica, where he died. Owing to circumstances of a private nature, not at all connected with the stereotype art, the business was laid aside after some few volumes had been stereotyped and printed under the direction of Meffra of Tilloch and Foulis.

Some time elapsed, when M. Didot, a French printer, applied the stereotype art to logarithmic tables, and afterwards to several of the most popular classics, such as Virgil, Horace, &c. and to various French publications. On this account, the French lay claim to the invention, but surely without even the appearance of justice. About the year 1800, Mr. Wilson, a printer in London, manufactured, after the directions of Mr. Ged, an apparatus for bringing the stereotype art into general practice. His lordship is said to have had some communications with Mr. Tilloch on the subject, and afterwards to have received the personal attendance of Mr. Foulis at his seat, at Chevening, in Kent, where the noble earl was probably initiated into the practical part of the operation, and for which, he has heard, he paid 700£ as a remuneration.

After some years application, Mr. Wilson, who at that time lived in the neighbourhood of Lincoln's-Inn-Fields, but who afterwards removed to St. Pancras, and carried on the business on a very extensive scale, announced to the public, that the genius and perseverance of earl Stanhope had overcome every difficulty; and that accordingly, the various processes of the stereotype art had been so admirably contrived, combining the most beautiful simplicity, with the most desirable economy, the ne plus ultra of perfection, with that of cheapness, as to yield encouragement to the public for looking forward to the happy period when an application of this valuable art to the manufacture of books would be the means of reducing the price of all standard works, at least thirty, and in many cases forty, per cent.

In 1804, Mr. Wilson offered, upon certain terms advantageous to himself, the stereotype art to the university of Cambridge, for their adoption and use in the printing of bibles, tellaments, and prayer-books. Some differences between the syndics and the printer caused the contract to be dissolved. Into these disputes it is not our business to enter; it will be sufficient to add, that at present, at Oxford as well as at Cambridge, the stereotype art is adopted, and thousands of bibles, &c. die annually from their presses, printed on that plan.

The practice of stereotype printing is readily described: a page of any work is set up in the usual mode of printing, (see the article Paravision) from which a mould of plasters, similar to plasters of Paris, is taken off, and from this a plate in type metal, from which the stereotype print is worked. Of course the whole is set up in distinct pages, which are to be put together in the usual way before a sheet is worked at press.

It is evident, therefore, that the beautiful specimens of stereotype printing sometimes exhibited, and which have induced many persons to ascribe that merit to the art, does not in reality belong to it. A stereotype printing is a fac simile of the page from which it was taken, and consequently cannot exceed in beauty the original. Stereotype, therefore, can give no additional beauty to printing; this depends on the taste of the letter-founder, and the care of the compositor. Those who produce fine specimens of stereotype printing, could also give others equally good with the moveable types from which the plates are cast.

The metal of which the plates are to be cast is a compound of regulus of antimony and hard lead, or sea-cheet lead. The general method of mixing the metal is to take one hundred weight of regulus of antimony, and break it into small pieces, separating from it all dust and dirt, and then add to it from five to eight hundred weight of hard lead, according as the metal is required to be more or less hard. The lead is to be melted over a flow fire, and when melted, and the scum taken off, the regulus is to be put in. To every hundred weight of lead may be added a pound or two of block-tin, but this is not necessary.

In casting the plates, as in every other casting, a mould must first be made, so as to form the counterpart of the original type. The substance required for this must be of oxide of lead, a little twisted, to deliberate a texture when soft, as to be capable of receiving an impression from the finest lines: and when dry, it must be capable of bearing the action of melted metal. These qualities will be found in gypsum or plaster of Paris. Gypsum in the rock, as it is called, which is the best, is plentiful in Nottinghamshire. It has been observed, that this substance, when pulverized and mixed with water, soon becomes very hard, and will bear almost any degree of heat; but it contracts when exposed to fire, and is liable to warp. It is also extremely difficult to expel the air and moisture which it rapidly absorbs, and tenaciously retains. These are defects respecting the processes of casting, which require to be corrected by compounding it with other substances less absorbing than itself. But whatever be added to it must be capable of a fine surface, so as to preserve a perfect polish on the plate to be cast. The following process has been recommended: dissolve a quantity of common whiting in a tub of clean water, and make it of the consistence of what is generally used in white-washing. Mix the plaster with this solution, and it will contract but little from the heat; the air and the moisture will be expelled with greater ease.
and the mould will not be so liable to crack as the plaster would alone.

In making a perfect mould for the page to be cast, a frame of cast-iron must be prepared, nearly half an inch wider and longer than the page or pages locked up in the chases. The frame determines the thickness and strength of the mould, and requires to be nearly an inch deep. To this frame are added four cubic pieces of metal, whose height should be exactly four-fifths of the height of the letters. On the height of these, the thickness of the stereotype plate depends. The pages in the chases are now to be laid flat upon the moulding table, and the letter, if necessary, to be planed down to a flat surface. In the openings of the four corners of the page are to be placed the four pieces of metal, on which the frame is to rest when laid over the page.

To prevent the adherence of the plaster, it will be necessary to oil the face of the page with a soft brush; then take a quantity of the white-wash into a wooden bowl, and add to it so much fine plaster as will make it into a thin paste. When reduced to an equal consistency, apply it to the face of the letter with a letterer’s brush, so as to fill every cavity, and then pour on the remainder of the plaster to fill the frame. When beginning to harden, strike off the superfluous plaster with a slanting metal rule, and the back of the mould will be smooth and regular. The mould is next to be separated from the page, and to be dried in an oven.

In casting the plates, the dried mould is to be laid in a pan about two inches deep, with the face upwards, and a small movable screw is to be placed at each side or end of the pan to furnish a press on the frame which contains the mould, and prevent the rising up, and the metal is applied over the mould in the pan, and carried to the oven, in which it should remain from one to two hours, to acquire an equal degree of heat; for on the principle of equal temperature between the metal and moulds, the success of the operation wholly depends. And unless the oven be kept sufficiently hot to raise the temperature of the moulds to that of the melted metal, the experiment cannot succeed.

Such is the fineness of the composition of the moulds, and the accuracy of the process, that plates may be cast from the finest engravings as perfectly as the copper-plate itself, and might be worked in the same manner, could it be cleaned after each operation with the same facility, and if the metal did not discolour the paper. Wood-cuts, ornaments, &c. are cast in the same manner, perfectly correct. The art has also been applied to the printing of music.

When the pages are returned from the foundery, they require to be thoroughly cleaned; for if the oil be suffered to remain on the letter, it will not only be disagreeable to distribute and compose, but the dirt which adheres to it will spoil the next mould to be made from it; hence it is necessary that the letter be thoroughly cleaned with boiling water and a brush, which increases the expenses attached to this art very considerably.

After a plate has been cast, a few small imperfections will frequently be discovered; such as that the eye of the e, or similar letters, may have been full of dirt when the mould has been taken; or of course the plate will exhibit those parts filled with metal, which now require to be corrected. A workman, called a picker, takes the plate, and after clearing it of all superfluous metal, pulls a proof, marks the defects, and proceeds to make the requisite alterations in a manner that will now be easily understood. If, in the course of the work, any damage be done to the plate, or any letter or word be broken, the picker cuts it out, and inserts in its place a moveable type. This is very practicable, and only requires the letters to be cut square, so that the type may exactly fit the place. In this way a letter, a word, or even a line, may be taken out and corrected without injuring the plate. The plate is now ready for the press, and may be laid on blocks, and fastened down with a slip of brass and a screw.

With respect to the advantages to be obtained by the stereotype over the common mode of printing, it may be observed, that the calculations of Mr. Wilton, already referred to, of an actual saving of 30 or 40 per cent. seem to have been much over-rated. Mr. Brightly, who practised the method of stereotype for some years, having made several estimates, and being himself a printer as well as publisher, could have no inducement to give an exaggerated statement on either side of the question, seems to doubt if there be any saving whatever by the new process. Among others, he has given the estimate of the expenses of a work printed in both ways, equal to twenty sheets octavo, of which 1000 copies are fold annually. Here he assumes, that in the common mode, the 4000 copies must be worked at once, but according to the stereotype plan, 500 copies are to be worked every six months, to save the interest of money. Supposing the paper in both cases to be thirty shillings per ream, the calculation is as follows:

Brought forward  
Cost of the first five hundred, second, and  
of each subsequent five hundred, will be  
38l. 5s. 3d.  
} 267 16 9

Common printing  -  -  -  -  -  -  -  386 17 2
Balance against stereotype, after four years  
50 13 3

The next edition of four thousand copies  
by common printing will cost as before  336 4 6
Ditto on stereotype eight times 38l. 5s. 3d.  
306 2 0
Balance in favour of stereotype in the  
second edition  -  -  -  -  -  -  -  30 2 6

Hence it appears, that it will require more than ten years  
to clear the expense of the plates only, and after that it will  
yield a profit of 3ol. 2s. 6d. on every subsequent edition of  
4000 copies.

From the foregoing estimate, and several others given by  
the same author, which are not more favourable to the new  
mode of printing, other advantages must be looked for than  
those which result from pecuniary savings; but new discoveries  
can render the process more economical than it is at present;  
thus, if the pages could be set so true, that they  
might go to press, and be worked with the same ease and  
expence as moveable types; and if a substitute could be  
found for oiling and brushing the pages so as not to wear  
the type, or increase the labour of the compositor, more  
decided advantages would result from the introduction of  
stereotype: such as the following.

1ft. On books published in parts or numbers. Purchasers  
frequently take in the early parts and leave off; by which  
the sets become broken and uneven, and a great loss is incurred  
by the waffle of paper. This might be prevented by stereotype,  
which so remarkably facilitates the perfecting any  
parts or numbers that are found deficient.

2dly. On new books of doubtful sale. The plan of casting  
plates would not involve an expense of more than sevenpence  
for an octavo page, besides the metal, which will still retain  
its value. So that a hundred, or a less number of copies,  
might be struck off to ascertain the opinion of the public.  
If it did not sell, the loss on a work of 20 sheets would  
not be more than about 8s., besides the composition; but if 500,  
or 750 copies were printed in the common way, and not, fold,  
the loss would be from 3ol. to 4ol.

3dly. The principal advantage is unquestionably on rock  
books, whether bibles, prayer-books, or school-books,  
particularly works of arithmetic, and other branches of mathematics.  
These, by means of the stereotype, may be brought  
to perfect accuracy; and having once attained to that standard,  
may be kept to without the possibility of deviation; for  
this excellence, the public would not grudge even an extra  
price.

STEREOXYLON, in Botany, fromStereos, hard and  
and xylon, wood, a name given by Ruiz and Pavon in  
their Flora Peruana, to the genus which had long before  
been called by Linneaus Escallonia, (see that article,)  
in honour of one of their distinguished botanical countrymen.  
Of this prior appropriation of the genus, they seem not to  
have been aware. Poiret, however, in Lamarck's Dictionary,  
v. 7. 434, has followed their error, and described eleven  
species of the genus in question, all natives of Peru or Chili,  
in cold, moist, shady, sometimes very elevated, situations.

Their habit is shrubby; their leaves simple, more or less oval  
or obovate, finely or coarsely ferrated; flowers white or red,  
sometimes fragrant; young branches, and buds, often refrin-  
ous, aromatic, or bitter.

STERILE LANDS, in Agriculture, those sorts which are  
unproductive in consequence of their particular nature and  
qualities; or which contain only small portions of nutrient  
substances in their compositions.

In the examination of the constituent parts or matters of  
sterile lands, in the intention of ameliorating and improving  
them in regard to their fertility, any sort of component  
material, which is known as a cause of barrenness or unproductive  
properties, should be well and carefully attended to and  
considered; and if the whole of their composition can be nicely  
compared with that of some good and productive lands, in  
nearly the same situation and vicinity, the differences in  
the component substances of them may, in different instan-  
ces, point out the most proper and ready methods of  
improving them.

Where lands of this sort become so in consequence of  
their too stiff clayey nature, they may be improved and  
brought into a productive situation by the use and applica- 
tion of sandy, earthy, calcareous, marly, and other similar  
matters. Where lands are deficient in fertility, on account of  
their abounding too much in calcareous matter, they may be  
greatly improved and rendered more fruitful by the putting  
of sandy or clayey materials upon them. Where lands are  
unproductive, in consequence of abounding too much in  
fandy matters, they may be improved in their texture  
and other qualities, as well as rendered more capable of  
producing good crops, by the applying clay, clayey marl,  
and earthy vegetable materials to them. The application of  
peaty or turfy matters over the surfaces of light burning  
fandy lands, has been found to be attended with immediate  
and permanent good effects in many instances. Where lands  
are sterile in nature, from containing too great quantities  
of ferruginous, ochry, or saline, iron, and acid matters  
in their compositions, they may be greatly benefited in their  
productive properties by the use of quicklime in suitable proportions.  
In lands of otherwise good qualities and textures, which were  
sterile from containing too large proportions of the  
phosphate of iron, it has been found that they have been rendered  
productive, by having quicklime laid over the surfaces of  
them, as that substance has the property of converting this  
fort of phosphate or vitrified iron into a manure, which  
serves as the food of the plants upon them.

Where lands become infertile from the deficiency of earthy,  
vegetable, or animal matters, the obvious means of removing  
it is the free use of suitable substances of the manure kind  
in proper proportions. Where the excess of vegetable or  
other such matters causes improprieties in the growths of  
the crops, it is capable of being reduced readily by the  
practice of burning, or of being altered and improved by the  
suitable application of proper earthy materials of different  
kinds.

Where boggy, peaty, moony, or marshy lands are to be  
improved in their fertility and productive properties, the first  
steps to be taken for the purpose are most safely of properly  
cultivating, and laying aside the superabundant moisture or wet- 
ness, both of which greatly contribute to these defects; and  
the latter promotes the growth of all sorts of nourishing kinds  
of plants, by the removal of injurious stagnant moisture.  
Some soft black peaty kinds of land, which have undergone  
this last operation, are not unfrequently rendered fertile and  
productive, merely by the application of sandy or clayey  
matters over their surfaces in due proportions; and repeating  
them as there may be a necessity. Where such peaty  
lands
lands are of a four acid nature and quality, or contain ferruginous, ochry, and saline matters, the use of lime, or other calcareous materials in sufficient quantity, is indispensably necessary for bringing them into a proper state of culture, and for rendering them productive, either in the arable or grazed state. When they abound with ligneous matters, and different coarse vegetable products, which prevent their being made productive, they are to be removed or reduced by burning the superficial parts; in which last case, the ashes thus afforded may supply earthy materials suited to the improvement of the texture and other qualities of such lands.

In short, in this business the farmer should constantly follow, as much as he possibly can, the lefens and methods held out to him by nature, in her means of improving different lands of this sort; and the result of his labours will be the rendering them permanently more beneficial by their increased fertility; by their requiring less expense in drellings afterwards; and by the value of the lands being for ever after greatly augmented.

The particular nature and causes of sterility in lands, have been stated and explained in speaking of soils. See Soil.

STERILITY, formed from sterilitas, of sterilis, barren, the quality of a thing that is barren; in opposition to fructifery.

Sterility was held a grievous affliction by the wives of the ancient patriarchs. Nature has annexed sterility to all monstrous productions, that the creation might not degenerate. Hence the sterility of mules, &c.

Women frequently become sterile after a miscarriage, or a difficult labour, by reason the uterus, or some other of the genital parts, are injured thereby.

STERIPHIA, in Botany, so named by Dr. Solander from ςεμφος, in allusion, perhaps, to the mean and dry integument of its fruit, which, though at first sight resembling a berry, proves unprofitable, in that respect, to the gatherer.

—Gent. v. 2. 81. t. 94.—Clavis, and order, Piantandra Dijymia.

This is no other than Dichondra of Forster. (See that article.) Garrant speaks of it as a very difficult and singular genus, having the habit of Stilborphia europaea, but in the number of its parts of fructification, nearly agreeing with Schrebarea. Now it happens that the Schrebarea alluded to is, as we have said in its proper place, merely a Cucuna, growing on a Myrica. Whether Solander or Garrant made this allusion to it, they could only have in view its artificial characters and place in the Linnaean system, for the plant itself was, at that time, unknown to them.

STERIS, a Linnaean name, of whose meaning or application we have no information; nor is it a matter of any consequence, the plant which bears this name, S. javana, Linn. Mant. 8. and 54, being the same with Nama acyanica, Linn. Sp. Pl. 327, and in fact a species of Hydrolea. See that article; fp. 4.

STERKEL, J. F. X. Ahati, in Biography, first chapelmaster to the elector of Meinz, was born at Wurtzburg in 1743, went into Italy at the expense of his patron in 1761, where he chiefly resided at Rome and Naples, in which cities he was much esteemed for his amiable character. He formed his style on the taste of the Italian school, to which he has constantly adhered.

Besides many compositions for the harpsichord and piano forte, which he produced in Italy, he composed at Naples the opera of "Farace."

In 1782 he returned to Germany, and the next year published at Vienna, we think his best and most pleasing work, "Six Sonatas for the Piano Forte or Harpsichord, accompanied by a Violin and Violoncello obligato, dedicated to his most eminent Highness the Elector of Mayence. Op. XVII." These sonatas, when well accompanied, are extremely interesting and amusing. The abbé Sterkel there, as in all his compositions for keyed instruments, has manifested that he did not visit Italy unprofitably; his productions, though not very laboured or learned, are full of spirit, taste, and pleasing passages; and he has not only collected all the vocal flowers of the greatest opera-fingers of the present times, but scattered them liberally through his works. His violin accompaniments generally confit of passages of effect, and such as give importance to the player. Indeed his pieces, though not very original, are left tinted with Bachins, or Haydnins, than those of his countrymen who have not visited Italy; and though less solid, and less his own property than those of many modern composers, yet they are more easy to execute, and more intelligible to unlearned readers. We have been afforded by some of his scholars, that he played on the clavichord and piano forte, with such taste, expression, and cleverness, as few performers, except Emanuel Bach, ever arrived at.

STERLING, a term frequent in the English commerce. A pound, shilling, or penny stierling, signifies as much as a pound, shilling, or penny, of lawful money of England, as settled by public authority.

Antiquaries and critics are greatly divided as to the origin of the word stierling. Buchanan fetches it from the castle of Strielving, or Stirling, in Scotland, where a small coin was anciently struck; that in time, according to him, came to give name to all the rest. Camden derives the word from stierling, or stierling; observing, that in the reign of king Richard I. money coined in the east parts of Germany began to be of especial request in England by reason of its purity, and was called stierling money, as all the inhabitants of those parts were called stierlings; some of whom, skilled in coinage, were soon after, vis. in the reign of king John, sent for over to pervert the English money, or reduce it to its due fineness, which was thence forwards denominated from them, stierling, or stierlings; not, says Camden, from Strielving in Scotland, nor from Stellas, a star which some dream to have been coined upon it; for in old deeds, the English species are always called nummi stierlingus, which implied as much as good and lawful money, &c. Clarke, in his Connexion of the Roman, Saxon, &c. Coins, p. 80. observes, that the Saxon or English pound was called the pound stierling, because their ancestors brought it from the most eastern parts of Europe, the shores of the Euxine; and that they called it libra stierlingorum, the pound stierling or stierling; to distinguish it from the Roman pound, which, to preserve the same distinction, was called libra accita, or the western pound. Somner, again, derives the word from the Saxon stiora, a rule or standard; intimating, that this, as to weight and fineness, was to be the common standard of all current money.

In Stow, and some other of our ancient writers, stierling, or stierling, is also used for a certain coin, in value amounting nearly to our silver penny; and on some occasions we find the same word stierling used in the general for a piece of money, it being observable, that for a good while together, there was no other coin but pennies, with which stierlings or stierlingers were become synonymous; much as, among the ancients, the words demarius and nummus were used.

STERLING, in Geography, a plantation in Kennebec county,
STE and state of Maine, N.W. of Hallowell.—Also, a township of Connecticut, in Windham county, 44 miles E. of Hartford; containing 1101 inhabitants.—Also, a township of Franklin county, Vermont, containing 122 inhabitants.—Also, a town of Worcester county, in Massachusetts, incorporated in 1781, and containing 1472 inhabitants; 62 miles N.E. from Worcester.

STERLINGVILLE, a post-town in Granville county, North Carolina; 467 miles from Washington.

STERLITAMATZK, a town of Russia, in the government of Upha. N. lat. 54° 40'. E. long. 55° 54'.

STERN of a Ship, denotes her posterior face; or that part which is presented to the view of a spectator, placed on the continuation of the keel behind. It is terminated above by the taffarel, and below by the counters: it is limited on the sides by the quarter-pieces; and the intermediate space comprehends the galleries and windows of the different cabins.

STERN, among Hunters, is the tail of a wolf, or a greyhound.

STERN-CHASE. See CHASE.

STERN-FALL, aboard a Ship, some fastenings of ropes, &c. behind the stern of a ship, to which a cable or hawser may be brought or fixed, in order to hold her stern to a wharf, &c.

STERN-FRAME, in Ship-Building, the strong frame of timber, composed of the stern-post, transoms, and fashion-pieces, which forms the backs of the whole stern.

STERN-LADDER, are made of rope and rope-nails, and hang over the stern of ships, to come on board by in very rough weather.

STERN-MAST, in Sea Language, usually denotes that part of a fleet of ships which is in the rear, or farthest a- stern, as opposed to head-mast.

STERN-POLE, in a Ship, a great timber let into the keel at the stern of a ship, somewhat sloping, into which are fastened the after-planks; and on this pole, by its pintel and gudgeons, hangs the rudder.

It is usually marked, like the stem, (which see,) with a scale of feet from the keel upwards, in order to ascertain the draught of water at that part of the vessel. The difficulty of procuring a stern-post of sufficient breadth in one piece, has introduced the practice of fixing an additional piece behind it, which is strongly bolted to the former. The hinges, which support the rudder, are accordingly fixed to this latter, which is also tenoned into the keel, and denominated the back of the pole. It is half the breadth of the stern-post at the keel, but diminishes gradually towards the upper end, where it is one-third narrower. The stern-post is strongly attached to the keel by a knee, of which one branch extends along the keel, being scarfed and bolted to the dead-wood, and fore-locked under the keel, while the other branch inclines upwards, and corresponds with the infide or fore-part of the stern-post, to which it is also bolted in the same manner. Falconer.

STERN-SHEETS, that part of a boat which is contained between the stern and the aftmoat, or hindmost part of the rowers. It is generally furnished with benches to accommodate the passengers. Falconer.

STERN-WAY, in Sea Language, the movement by which a ship retreats, or falls backward, with her stern foremost. See WAY.

STERNA, in the Tern, in Ornithology, a genus of birds of the order Anseres, of which the generic character is: Bill fumbulate, straitish, pointed, a little compressed, without teeth; nostrils linear; tongue pointed; wings very long; tail mostly forked. Twenty-five species of this genus are enumerated by Gmelin: they are mostly inhabitants of the ocean, and feed on fishes. Many of them are found on the shores of large lakes and rivers. Four of the species are common to our own country. They breed among small tufts of rushes, and lay three or four eggs of a dull olive colour, spotted with black. The birds belonging to this genus are at all times clamorous and gregarious, but more particularly in the spring of the year, during the time of nestling. At this period they assemble in large flocks, and their activity seems greatly increased, for they repeat with eagerness their sharp piercing notes so incessantly, that persons cannot approach the place where they breed without being almost stunned with their noise. With us the terns are migratory, leaving our shores regularly on the approach of winter.

Species.

CASPIA. The Caspian tern has its body above of a plumeous ash; beneath and neck white; the bill is scarlet; the frontlet and legs are black. It is found, as its specific name denotes, on the Caspian sea, and is nearly two feet in length. It frequents the sea-shores and banks; feeds on small fish and sea-infusoria, hovering over the water, and suddenly darting into it for its prey. The bill is red; irides dusky; tail short, forked; quill-feathers tipped with black; the legs are brown. There are three varieties: 1. Crown black, spotted with white; tail-feathers with brown bars. It inhabits Bombay, and is twenty-one inches long; its bill is red; and legs black. 2. Crown black; hind-head sub-crested; outer tail-feathers white from the middle to the tip; the bill is yellowish; and the legs black. It inhabits China, and the Sandwich islands. 3. The bill in this is white; frontlet varied black and white; ears black; back and wings cinnereous; quill and tail-feathers tipped with black.

CAYANENSIS; Cayenne Tern. Cinerceous; the feathers edged with reddish; beneath they are white; the hind-head is black. It inhabits Cayenne, and is sixteen inches long.

SURINAMENSIS; Surinam Tern. Bill, head, neck, and breast, black; back, wings, and tail, cinerceous; belly whitish; legs red. It inhabits Surinam, and is about fifteen inches long.

FULIGINOSA; Sooty Tern. Black; beneath, cheeks, front, and shafts of the quill and tail-feathers, white. It inhabits the Atlantic and Antarctic seas, and is fifteen inches long. The bill and legs are white; the eggs yellowish, with brown and violet spots; outer tail-feathers white, except at the tip.

AFRICANA; African Tern. White; bill and legs black; crown, wings, and tip of the tail, spotted. It is an African bird, and is about the size of the 8. fuliginosa. The crown is spotted with black, the wings with brown, and the tail with white; quill-feathers blueish-ash.

STOLIDA; Noddy. Body black; front whitish; eyebrows black; bill and legs black; the hind-head is cinnereous. It is fifteen inches long; found chiefly within the tropics; is clamorous; seldom goes far from shore, and always rests at night. It builds on rocks; and its eggs are excellent food.

PHILIPPINÆ; Philippine Tern. Claret-grey; cap white; band through the eyes, wings, tail, bill, and legs, black. It is found on the shores of the Philippine islands; and is about twice as large as the common fawnanor.

SIMPLEX; Simple Tern. Above plumbeous; beneath, crown,
STERNA.

crown, greater and middle wing-coverts, white; band behind the ears and quill-feathers black. A variety has the bill and legs black. It inhabits Cayenne; and is fifteen inches long. The bill and legs are red; some of the wing-coverts edged with brown.

NITOTICA; Egyptian Tern. Cinereous; beneath white; head and neck with blackish spots; orbits black, dotted with white. It inhabits Egypt; and is above the size of a common dove. The bill is black; and the legs of a flesh colour.

* CANTIACA; Sandwich Tern. White; back and wings hoary; cap black; front with white spots; quill-feathers blackish, with a white shaft. The bill is black, but yellowish at the tip; the legs are black; wings longer than the tail; the egg is of an olive-brown, purplish and crowded spots; it is full eighteen inches long, and is found on the Kestrel coast, generally appearing about Romney in the middle of April, and leaving the country in September. It is rather common at Sandwich, where it was first noticed by Mr. Boys. There are two varieties of this species: 1. Tail hardly forked; body variegated; ears with a black spot. 2. Above black, varied with paler colours; beneath white; tail forked; bill and legs black. This last is found in Finland.

* HIRUNDO; Common, or Greater Tern. The two outer tail-feathers are half black and half white. There is a variety that has black legs, outer tail-feathers entirely white. The greater tern is about thirteen inches from the tip of the bill to that of the toes; its breadth, when the wings are spread, is about two feet. It is of a slender form, but elegant, with the beautiful plumage which is adorned. The back is covered with a grey mantle; the breast is of pure white, richly contraltered with a large black spot upon the crown of the head, resembling a hat; the bill and legs are red. Early in the spring this species arrives on our own coasts, and sometimes is seen a considerable way from the shore, in the interior parts of the country, hovering about the lakes and rivers. They are observed by sailors during the whole passage from Britain to Madeira. They are the most active fishermen of all the aquatic tribes; inoffensively darting upon the prey which they observe from a great height in the air. After having dived and caught the booty, they as suddenly rise again to their former elevation.

The action of the stomach which this tribe exhibits is amazingly powerful; the fish being so completely digested in an hour, that they are ready to swallow a new meal. Those parts of the food that are nearest the bottom of the stomach are disolved, and make way for the reff, which soon undergoes the same process.

Immediately after the arrival of this species of the tern, the pairing season commences; during which each female chooses a warm bed of sand, where the deposits three eggs, of a size far superior to what might be expected from a bird of her dimensions. The eggs of the tern are of different colours, fome grey, others brown, and some of a greenish hue. The manner in which their eggs are hatched is as singular as their external appearance, for it is accomplished chiefly by the heat of the sun. If the weather be dry and warm, the female seldom hatches by day, but resumes her maternal functions regularly about the time that the influence of the sun begins to decrease.

The young are not all protruded at the same time, but in the order in which the eggs were laid; and at the interval of a day between each of the three birds. The young terns leave the nest, and follow the parent bird, who supplies them with small morrels of the fish upon which they themselves feed. During the whole period of incubation, the parent birds display great solicitude for the safety of their eggs and their young. Should a peril at this period approach their nest, both parents dart down from the air, and flutter about him, uttering all the while the most piercing screams, expressive at once of their fear, anxiety, and rage. These paternal cares soon cease; the young foons become capable of pecking their own food when provided for them. For a few days they are fed by the mother's bill; afterward, what food the parents provide, they swallow without even alighting upon the ground. Fond of indulging in their aerial excursions, they drop down the food upon their young, that are waiting below to receive it.

Terns are provided with very large wings, and from this circumstance the young are not soon able to fly, their wings not being strong enough to accommodate them for flight. In this circumstance they resemble the swallow, which remains longer in the nest than any bird of its size, and leaves it more completely feathered. During this period of nonage, the parent terns continue to shower down plentiful supplies of food to their young, who at a very early period begin to dispute for their prey, displaying that infatuable gluttony which characterizes their race. The colour of the first plumage is a whitish-grey; the true colour is not obtained till after the first molting.

PANAYENSI; Panayan Tern. Beneath white; crown spotted with black; wings and tail brown; beneath paler. This species inhabits Panay, and is the size of the last. The bill and legs black.

CINEREA; Cinereous Tern. This species is cinereous; the head and chin are black; the lower tail-coverts and upper edge of the wings white. It inhabits Italy, and is thirteen inches long. The bill is black; legs red; chin sometimes spotted with white.

ALBA; White Tern. Entirely white; the bill and legs white. It inhabits the Cape of Good Hope.

OSTcura; Brown Tern. Above brown, beneath white; head black; wings variegated with brown and cinereous. This is probably the young bird of a former species.

NIGRA; Black-headed Tern. Body hoary; head and bill black; legs red. It inhabits Europe; and is a very small bird.

AUSTRALIS; Southern Tern. Cinereous; beneath grey; front yellowish-white; the quill-feathers are white. It inhabits the Nativity islands; and is from seven to nine inches long. The bill is black; the legs blackish; and the connecting membrane tawny.

SINENSIS; Chinese Tern. White; back, wings, and tail, cinereous; crown with a black band reaching as far as the nape. It inhabits China; and is about eight inches long. The bill is black; the legs tawny.

METOPOLIUS; Hooded Tern. Head and neck black; back blackish, hoary; wings cinereous; front, body black; neck, and tail, white. It inhabits Russia and Siberia; and is about nine inches long. The bill is yellow, and red at the base; the legs are of a fine fawn colour.

MINUTA; Lesser Tern. Body white; back hoary; front and eye-brows white. It is found in divers parts of Europe and America; and is the size of the last.

STRIATA; Striated Tern. White; hind-head and nape black; body above and wings with transverse black streaks. It inhabits Zealand. The bill is black; the legs are of a lead colour.
S T E N A T I A; Wreathed Tern. Cinereum; crown black; surrounded with white; the rump, vent, and tail, are white; the bill is red; and legs tawny. A variety has a cinerea

tail, with white shafts. It is found in Nativity island.

SPADICEA; Brown Tern. Reddish-brown; vent white; bill and claws black; tail and quill-feathers dusky; the secondaries tipt with white. It inhabits Cayenne, and is

fifteen inches long.

FUSCATA; Dusky Tern. Body blackish, without spots; bill brown, and legs red. It is found in the island of Hif-

paniola.

* FISIPES. Black; back cinerea; belly white; legs reddish. It inhabits in different parts of Europe and America; and is about ten inches long.

STERNATIA, in Geography, a town of Naples, in

the province of Otranto; 10 miles E.N.E. of Nardo.

STERNBERG, a town of Bohemia, in the circle of

Kauzim; 10 miles S. of Kauzim.—Alfo, a county of Weltphal, which takes its name from an old citadel; 10 miles E.N.E. of Lempurg.—Alfo, a town of Moravia, in

the circle of Olmutz; 9 miles N.N.E. of Olmutz. N. lat.

49° 40'. E. long. 17° 13'.—Alfo, a town of the duchy of Wurzburg; 6 miles E. of Lauringen.—Alfo, a town of Brandenburg, in the New Mark; 24 miles S.E. of Cufria. N. lat. 52° 23'. E. long. 15° 17'.—Alfo, a town of the duchy of Mecklenburg, situated on a lake; 16 miles S.E. of Wismar.

STERNE, Laurence, in Biography, the son of Roger

Sterne, a lieutenant in the army, and grand-nephew of Sterne, archbishop of York, was born at Clonmell, in Ireland, in November 1713, put to school at Halifax in 1722, and entered at Jesus college, Cambridge, in 1732, with a view to the church. After he had taken orders, he was presented to the living of Sutton, in Yorkshire, through the intereat of his uncle, Dr. Sterne, prebendary of York. In 1741

he was married, and by the fame uncle's intereat obtained a prebend in York cathedral. By means of his wife he became poiseed of the living of Stillington, where, and also at Sutton, the place of his residence, he performed duty for nearly twenty years. During this time, as he informs us, he amused himself with books, painting, fiddling, and floating. About this time, the only production of his pen was a little piece entitled "The History of a Watch-Coat," printed, but not published, about 1738, describing with humour some squabbles among the dignitaries of York, after the manner of Swift. In 1759 appeared two volumes of his "Life and Opinions of Tristram Shandy," a kind of peculiar novel, which was much read, and generally admired. Some commended and some cenured it. However, it secured profit to himself, as it was bought by the book-sellers, and as it was the means of procuring for him the presentation of the curacy of Coxwell. Several volumes appeared in succcession, and the last, or 9th, in 1766. This is an eccen-

cratic performance, formed upon the idea of a kind of self-taught philosopher, in the person of an elderly country gentleman, full of odd and singular notions, which he displays chiefly in the plan he forms for the education of an only son, commencing from, or rather before, his birth. The work is original in its composition and style; and abounds with a variety of characters, observations, and exquisite touches of the pathetic, intermixed with a sufficient quantity of the delicate and indecorous. It was new in its plan and execution, and though it has been often imitated, nothing entirely resembling it has yet appeared. To lay more about it is altogether needless; and to vindicate the confidence of the character of a clergyman with such a work would be an absurd attempt. In 1768 our author published another work, entitled "Sentimental Journey," in 2 vols. 12mo., which exceeded the former publication in popularity. With regard to purity and decorum, it is chargeable with the same, though perhaps not with equal, blemishes with the former. In 1760, availing himself of his fame, he published two volumes of "Sermons of Mr. Yorick," and two more in 1766. Sterne had long contended with a tendency to pulmonary consumption, which at length be-

came a confirmed disease, and terminated his life in March

1768. He left a widow and a daughter. The latter married a French gentleman, and published, in 1775, a collection of her father's letters, in 3 vols. 12mo., to which were prefixed "Memoirs of his Life and Family." In the same year an anonymous editor published "Letters from Yorick and Eliza," which were regarded as an authentic correspondence of Sterne with Mrs. Draper, an East Indian lady. We regret that at the close of this sketch of Sterne's life and writings, we are under a necessity of adding, that his private and domestic character did not comport either with the clerical profession, or with those traits and effusions of virtuous sensibility and benevolence which occur so frequently, and delight us so much in the perusal of his works.

STERNEN, in Geography, a town of Switzerland, in

the canton of Schwitz, the residence of Werner Stauff-

fach, one of the Swiss patriots, whose wife was also cele-

brated for her courage; 4 miles N.W. of Schwitz.

STERNO-CLEIDO-MASTOIDEUS, (sterno-masto-

doides and cleido-mastoideus of Albinus; sterno-clai-

roideus, mastoideus), in Anatomy, a muscle of the head, situated obliquely on the lateral and anterior part of the neck, where it makes a very conspicuous prominence in the living sub-

ject, and extending from the upper edge of the sternum, and the neighbouring part of the clavicle, to the mastoid process, and the ridge of the occipital bone. It is elongated, flattened on the surfaces, about two inches broad, and divided into two portions below. It is covered externally by the latissimus dorsi, the external jugular vein, and several branches of the cervical nerves, being interposed. At the upper part it is covered, for a small extent, by the parotid and the skin. Its internal surface lies on the sterno-clavicular joint, the sterno-hyoides and thyroideus, and omohyoides muscles, the internal jugular vein, and common carotid artery, the anterior branches of the cervical nerves, the nervus accessorius, the levator scapulae, the splenius capitis and digastricus. The anterior edge extends from the middle of the upper bone of the sternum, where it lies very near the opposite, and elevates the skin very sensibly, particularly in thin persons, along the side of the neck, separating more and more widely from the opposite muscle as it ascends, to the front of the mastoid process, where it is thick and prominent, and partly covered by the parotid gland. The posterior edge is thin, and a little concave, reaching from the clavicle to the upper ridge of the occiput. The lower extremity of the muscle is divided into two portions; an anterior or internal, called the sternum; a posterior or ex-
}

ternal, called clavicular. The former, narrow and thick, is attached to the anterior and upper part of the sternum; the latter, much broader and thinner, is fixed to the pos-

terior edge of the upper surface of the clavicle, close to its connection with the sternum. The sternum portion ascends much more obliquely than the clavicular; hence the two

foot meet and decussate, the latter being considerably co-

vered by the former. A little dissection will generally sepa-

rate them half way along the neck, or more; and they are

always
always so far different, that Albinius describes them as two muscles. They are confounded together above, and attached to the apex and outer surface of the mastoid process, to the mastoid portion of the temporal bone, and to the superior curved line of the occiput. The temporal portion commences by a strong tendon, rising in front of the muscular fibres; the clavicular part originates by short aponeuroses. The upper extremity terminates by a broad strong aponeurosis, common to both parts; thinner in front than behind. All the muscular fibres go obliquely between the aponeuroses.

The sternox-clidomastoideus, by drawing the mastoid process forwards, rotates the head and the atlas on the axis, so as to turn the face to the opposite shoulder; in which effect it concurs with the opposite splenius, and obliquus inferior capitis. It will then incline the head and neck on the sternum. When the two act together, the head is not rotated, but bent, with the neck, directly forwards on the sternum. This operation of the sternox-clidomastoidei is more particularly observed in the recumbent attitude of the body; the head and neck are then raised in direct opposition to their gravity, and the recti and obliqui abdominis contract to fix the sternum and ribs, and thus to render the contraction of the sternox-clidomastoidei more effectual. In the erect attitude, the weight of the head naturally inclines it forwards.

STERNO-CLIDOMASTOIDUS, in Surgery. For an account of the division of this muscle in cases of wryneck, see TORTICOLLIS and WRYNECK.

STERNO-COSTALIS, in Anatomy, a muscle passing between the sternum and ribs. See INTERCOSTAE MUSCLES.

STERNO-HYOIDES, a muscle of the larynx. See HYOIDIA.

STERNO-MASTOIDEUS, in Anatomy. See STERNO-CLIDOMASTOIDEUS.

STERNOPTYX, in Ichthyology, a genus of fishes of the order Teleostomi, in which the generic character is as follows: Head obtuse, teeth very minute; no gill-membrane; the body is compressed, without apparent scales; breast cartilage, folded; belly pellucid. A single species only is mentioned by Gmelin, viz.

DIAPHANA. This is found in the American seas; it is small, compressed, truncate before, narrowed and silvery behind. The eyes are large, and of an amber colour: the mouth is perpendicular; the tongue thick and rough; the upper lip is short, lower perpendicular, with four semi-circular depressed cavities from the ridge, and three others under the aperture of the gills; the aperture is oblique, with soft covers; the folds of the branch form a pellucid ridge; the back is of a greenish-brown colour, gossipy behind the fin, with a double ridge diverging towards the softs; it has no lateral line; the dorsal fin with an obsolete, strong, spiny, immoveable ray, joined to which is a membrane very finely toothed at the edge: pectoral fins of a fine amber colour; tail bidual.

STERNESTEIN, in Geography, a town of Bavaria, with a ruined citadel, which gives name to a county. The country lies divided in the Upper Palatinate, and the town is situated 17 miles N. of Namburg.

STERNUM, in Anatomy, the breast-bone. It is the flat piece occupying the middle and front of the chest, and receiving the cartilages of the ribs in a series of small cavities on each side. See the description of the chest under the article LUNG.

STERNUM, Fractions of, in Surgery. See Fracture.

STERNUM OF BIRDS. See Anatomy of Birds.

STERNUTATIVE, or STERNATORY, such substances as polishes the quality of exciting freezing. It is not by the freezing which they excite, however, that these substances are useful medicinally; but by producing a discharge of fluids from the veins of the membranes lining the nostrils, by which some kinds of swellings of the head are relieved. In this quality they are more commonly denominated errhines, which see. See also SNEERING.

STERTOR. See SNEERING.

STERZINGEN, in Geography, a town of the county of Tyrol, celebrated for its manufacture of sword-blades: near it are silver-mines; 10 miles N.W. of Brixen.

STESICHORUS, in Biography, a Greek lyric poet, was born at Himera, in Sicily, and flourished about the year B.C. 612, being a perfour of some conformance in his name, and he is said to have died in the year B.C. 556. His works were numerous, and much esteemed by the ancients. They were composed in the Doric dialect, but they have all perished, except a few fragments, amounting to 50 or 60 lines, printed in the collection of Fulvius Ursinus, Ant. 1568. The general character of his writing is represented as confiting in force and dignity. Horace speaks of "Stesichori graves camonens"; and Dionysius says that he possessed all the excellencies and graces of Pindar and Simonides, and that he surpassed them both in the grandeur of his subjeets, in which he has well preserved the characteristics of manners and persons; and Quatras represents him as having displayed the sublimity of his genius by the felection of weighty topics, such as important wars, and the actions of great commanders, in which he has sustained with his lyre the dignity of epic poetry. Accordingly, Alexander the Great ranks him among those who were the proper study of princes. To him we owe the first introduction into the ode of the triple division of strophe, antistrophe, and epode, which were called in a Greek proverb "the three things of Stesichorus," from which he is said to have derived his name, as signifying the chorus, which was before "Tifias." Suida. Moreri.

STETTEN, in Geography, a town of Germany, in the margraviate of Anspach; 8 miles N.N.W. of Anspach.

STETTEN, New, a town of Hinder Pomerania, situated in the midst of lakes, built in the 14th century by duke Ratislaus IV., as a defence of the frontier against Prussia; but it has never flourished; 46 miles S.E. of Colberg. N. lat. 55° 42'. E. long. 10° 38'.

STETTIN, or Old Stettin, a town of Anterior Pomerania, and capital of that part which belongs to Prussia, situated on the Oder, which it divides into four branches. The town is large, handsome, and well fortified; and contains several manufactures, together with a dock for the building of ships. Its trade with England, Holland, France, Spain, Denmark, Sweden, Norway, Prussia, Danzig, Mecklenburg, Lubeck, and Hamburg, is very considerable. It contains five parish-churches, a college of physicians, a board of health, a chamber of commerce, a court of admiralty, &c. and about 20,000 inhabitants. It is rendered to the French in 1806; 12 miles W.N.W. of Stargard. N. lat. 54° 25'. E. long. 14° 44'.

STEWART, Sir James, in Biography, the only son of Sir James Stewart, bart., solicitor-general of Scotland to queen Anne and George I., and grandson of Sir James Stewart, lord-advocate of Scotland in the year 1692; was born
born in 1712, and after a regular course of education at Edinburgh, devoted himself to the study of the law. In conformity to the fashion of the times he undertook a foreign tour, and having spent five years abroad, returned to his native country, an accomplished gentleman, in 1740. About three years after his return he married lady Frances, the daughter of the earl of Wemyss, and retired to his seat at Coltness. Having formed an acquaintance with the Pretender at Rome, he renewed his connection with him at Aix-la-Chapelle in the year 1751, but the hopes of the exiled prince being frustrated, Sir James removed to France, and remained at Sedan until the year 1754. In the following year he removed to Flanders, and began to communicate to the public the fruits of his literary labours. In 1757, during his residence at Frankfort-under-the-Main, he published "A Vindication of Newton's Chronology"; and having settled in the same year at Tubingen, in Germany, he there published his "Treatise on German Coins," in the German language. This was followed, in 1761, by "A Dissertation on the Philosophy and Principles of Money," as applied to the German Coin; and in the same year he so far made his peace with the British government, as to obtain for his son a cornetcy in the English service. From Tubingen he removed to Antwerp; but on an excursion to the Spa, he fell under suspicion, and being arrested by the French, was sent prisoner to the fortresses of Charlemon. A remonstrance having been presented to the British cabinet, and peace being reestablished, Sir James regained his liberty. Under assurances of protection in his native country, he settled at Coltness in 1763; and in this retirement he probably snuffed his work entitled "Inquiry into the Principles of Political Economy," on which he had bestowed the labour of eighteen years. In 1769 he again presented to the public, under the name of Robert Frame, "Considerations on the Interests of the County of Lanark." His full pardon passed the great seal in 1771; and in the following year he printed the "Principles of Money applied to the present State of the Coin of Bengal." He also wrote "A Plan for introducing an Uniformity of Weights and Measures," published after his death; and engaging in metaphysical speculations, he published "Observations on a Short Essay on Truth," and "Critical Remarks on the Atheistical Fallacies of Mirabeau's System of Nature," 1779; and soon after, "A Dissertation concerning the Motive of Obedience to the Law of God." He died in November 1780, at the age of 67, leaving one son, Sir James Stuart Denham, bart. a general in the army, and colonel of the 12th dragoons. His collected works were printed at London in 1805, in six vols. 8vo.

STEUBEN, in Geography, a county of New York, erected from the S. part of Ontario in 1796, and so named in honour of baron Steuben, an officer in the revolutionary armies. Its form is regular, being about 40 miles square; and it is bounded N. by Ontario county, E. by the southern part of Seneca county, or by Seneca lake, and by Tioga county, S. by the state of Pennsylvania, and W. by Allegany county. Its area is 1641 square miles, or 1,650,240 acres; and it is situated between 42° and 43° 30' N. lat., and 7° 30' and 8° 30' W. long. from New York. Its towns are Addison, containing 369; Bath, with 1356; Canisteo, with 656; Danville, with 666; Painted-Peak, with 954; Pultney, with 1028; Reading, with 1310; Troupsburg, with 200; and Wayne, with 1025 inhabitants; amounting in the whole to 7246. This county is 203 miles N.W. from New York. Its surface is hilly, if not mountainous. Near the rivers its aspect is not inviting, except that the alluvial flats are in some parts very extensive and rich. The upland plains have a rich variety of deciduous trees, and extensive tracts of a rich and fertile soil, principally argillaceous or a warm mould. This county, the small town of Reading excepted, was included in the cession of New York to Massachusetts, and is principally peopled by farmers from the eastern states. The agriculture is improving; and the eastern people have brought hither their habits of houehold industry, from which the clothing is chiefly produced. The capital is Bath. This county has 445 electors, and sends one member to the house of representatives.

STEUBEN, formerly Naragaguus, a town of the district of Maine, in the county of Washington, at the S.W. corner of the county. Naragaguus river runs through its N.E. corner. It contains 552 inhabitants.--Alfo, a small fort in the Indiana territory, situated at the rapids of the Ohio, a little above Clarksville.--Alfo, a township of New York, in Oneida county, taken from Whitelawn, and incorporated in 1792. In 1796, the towns of Floyd and Rome were taken from this township. The western branch of Mohawk river rises here, and the centre of the town is about 13 miles N.E. of Fort Schuyler, and 32 N.W. of the mouth of Canada creek.

STEUBENVILLE, a post-town of Jefferson county, in the state of Ohio, situated on the W. bank of the Ohio, a few miles W. of the Pennsylvanian W. line, and containing 1617 inhabitants; 312 miles from Washington. N. lat. 40° 17'; W. long. 5° 30' from Philadelphia.

STEVE, a town of Sweden, in East Bothnia; 35 miles E.N.E. of Gamla Carleby.

STEVENS' Klint, a mountain of Denmark, in the island of Zealand, near Heddingen.

STEVENAGE, a village in the hundred of Broadwater, and county of Hertford, England, was anciently a market-town, and named Stigenaise, or Stingenhage. The manor was given by Edward the Confessor to Wulfminster Abbey, and was thereto annexed, till Henry VIII. converted the abbey to a bishop's see. After its dissolution by Edward VI., Stevenage, with Ashwell, and other manors in this county, became by grant the property of the see of London, to which they have ever since belonged, with the exception of a short period of possession by a convocation of queen Mary. It received, through the influence of Montaine, bishop of London in the time of James I., the grant of a weekly market, and three annual fairs. In the fifth year of William and Mary, a charter of confirmation was granted, with liberty to alter the market-day to Friday; but the contiguity of the towns of Baldock and Hitchin has greatly tended to the decay of this. Stevenage consists of one large, and several lesser streets, with a free school, and a small church, containing a nave, chancel, and aisles; a chapel on each side the chancel, with a tower at the west end. The population of this place, as returned in 1811, amounted to 1302, and the number of houses to 308. The petty feoffons for Stevenage division are held here. About three quarters of a mile southward from this place, on the east side of the high road, are six large barns, some of which have been superficially opened, but nothing of consequence has been discovered: they appear to be composed of gravel and fine clay; and have been thought, from the titles of Dane-end, Mundane, &c., which occur in this part of the country, to be of Danish origin. Stevenage is pleasantly situated on the high North road, 124 miles N.W. by N. from Hertford, and 514 miles N.N.W. from London. Beauties of England and Wales, vol. vii. by J. Britton and E.W. Brayley.

STEVEN'S, a short navigable river of America, which runs
rises in the district of Maine, within a mile of Merry Meeting bay, with which it is connected by a canal lately opened.

STEVENSBURG, a port-town of Virginia, in Culpepper county, on the road from Philadelphia to Staunton. It contains from 40 to 50 houses, and an academy. The inhabitants are mostly of Dutch extraction; 10 miles N. by E. from Strasburg, and 90 from Washington.

STEVENIA, in Botany, is said to have been so named by M. Poiteau, a French botanist, in compliment to Dr. Edward Stevens, American consul at Hispaniola, or St. Domingo, who had rendered many important services to the French in that island; but whether he composed any skill in botany does not appear; neither is he recorded to have afforded any particular patronage to this science. — "Poiteau Ann. du Mus. d'Hist. Nat. v. 4. 235." Poiret in LamarckDict. v. 7. 439. —Claro and order, Hempodina Monotypia. Nat. Ord. Rubiaceae, Juill. 

Gen. Ch. Cal. Perianth superior, of one leaf, in two deep, lanceolate, deciduous segments. Cor. of one petal, tubular, slightly silvery externally; tube cylindrical, the length of the calyx limb in six, sometimes seven, oblong, obtuse, spreading, somewhat reflexed segments. Stam. Filaments none; anthers inserted into the upper part of the tube of the corolla, and equal in number to the segments of its limb, oblong, straight, two-lobed, of two in each. Fil. Germ. globose, inferior; style erect, the length of the tube; stigmas two, spreading. Peric. Capsule globose, coated, of two cells and two valves, separating at the top, the partitions from the flexed margins of the valves, which at length split longitudinally into two parts. Seeds numerous, minute, oval, a little compressed; enucleated at the upper part with a membranous wing; tapering and pointed at the base. Receptacle central, hemispherical, forming the division between the two cells.

Eff. Ch. Calyx inferior, in two deciduous segments. Corolla tubular, with six or seven segments. Anther sessile in the mouth of the tube. Capsule of two cells, with many winged seeds.

1. S. bunifolia. Box-leaved Stevia. Poiteau Ann. du Mus. d'Hist. Nat. v. 4. 235. t. 60. —Native of the northern part of Hispaniola. An upright branching shrub, ten or twelve feet high; the wood very hard; bark ash-coloured, full of cracks. Young shoots covered with a viscid resin. Leaves opposite, flat, oblong, acute at each end, about an inch and half in length, rigid, smooth, shining above, pale and reticulated beneath. Footstalk short, connected by an undivided sheathing stipula. Flowers axillary, solitary, white, fragrant, on footstalks the length of the footstalks. Bracteae at the base of the calyx, in four divisions, two of which are short and obtuse, two the intermediate ones lanceolate and twice as large, sometimes leafy. We know this plant only from the descriptions of the authors above cited.

STEVENSWAERT, or Fort of St. Etienne, in Geography, a fortress of France, in the department of the Roer, situated on the E. side of the Meuse, built in the year 1653, besieged and taken by the allies in 1702; 50 miles N. of Liege.

STEVENTOWN, a township of New York, in Weftchester county, bounded W. by York town, and N. by Dutchess county, containing 1773 inhabitants.

STEWER, a river of the principality of Munster, which runs into the Luppe at Hattern.

STEVIA, in Botany, was named by Cavanilles in memory of Peter James Steive, or Elève, an eminent physician of Valencia, and professor of botany in that university, towards the middle of the 16th century. He is said to have published some valuable works, and to have left in manuscript a dictionary of the plants of the country where he resided. —Cavan. l.c. v. 4. 32. Wild. Sp. Pl. v. 3. 1774. Ait. Hort. Kew. v. 4. 510. —Claro and order, Hempodina Monotypia. Nat. Ord. Composita diffusa, Linn. Corymbifera, Juff.

Gen. Ch. Common Calyx simple, oblong, of several, nearly equal, leaves, in a simple row. Cor. compound, uniform, dicoid. Florets all uniform, perfect, fertile, funnel-shaped, with a five cleft spreading limb, not numerous. Stam. Filaments in each floret five, capillary; anthers united into a cylindrical tube. Fil. Germ. oblong; style thread-shaped; stigmas two, long and slender. Peric. none, except the permanent upright calyx. Seeds solitary to each floret, oblong; down chaffy, or partly bristly. Recept. small, naked.

Eff. Ch. Receptacle naked. Down chaffy. Calyx cylindrical, of a simple row of leaves. Obf. This genus is distinguished from Eupatorium and Ageratum, by its simple row of calyx-leaves. From the former, moreover, the chaffy feed-down keeps it clearly distinct.

1. S. linearis. Linear Stevia. Willd. n. 1. Cavan. l.c. v. 4. 32. (Ageratum lineare; ibid. v. 3. 3. t. 205.) Stem herbaceous. Leaves simple, linear to linear-lanceolate. Footstalks of five lanceolate scales, from the top. Native of New Spain, flowering in the garden at Madrid, from August to November, in the open ground. The stem is two feet high, branched, glaucous and smooth, like the rest of the plant. Leaves scattered, on short footstalks, entire, obtuse, narrow, an inch and half long, the lower ones often opposite. Flowers pale rose-coloured, terminal, corymbosse, not numerous. Bracteae solitary, at the base of each partial footstalk, linear-lanceolate. Calyx three-quarters of an inch long. Scales of the feed-down spreading, linear-lanceolate, acute, whitish, about the length of the downy feed.

2. S. Eupatoria. Three-ribbed Stevia. Willd. n. 2. Ait. n. 1. (Muffelia Eupatoria; Sprengel in Tr. Linneus. Soc. v. 6, 152. t. 13.) —Stem herbaceous. Leaves lanceolate, nearly entire, three-ribbed. Flowers crowded. Seed-down of short scales, with intermediate bristles. Native of Mexico. Brought from the Madrid garden, by the late marchioness of Bute, in 1798. A hardy perennial herb, flowering from July to September, but of no striking appearance. The stem is two feet high, inclined or spreading, round, leafy, its branches terminating in numerous small corymbosse flowers, of a reddish hue. Leaves rather above an inch long, shining, dotted, occasionally ferrated towards the point. Willdenow describes three obtuse scales, with as many intermediate bristles, in the crown of each seed; which answers to Sprengel's figure, but the latter describes five bristles.

3. S. follicifolia. Willow-leaved Stevia. Cavan. l.c. v. 4. 32. t. 554. Willd. n. 3. Ait. n. 2. —Leaves lanceolate, serrated, tapering and entire at each end. Seed-down of two awl-shaped bristles. Native of Mexico. Its seeds were sent to the writer of this, from the Madrid garden, in 1803. This is a greenhouse herbaceous plant, flowering in August and September, about two feet high. Leaves two or three inches long, smooth; glaucous beneath. Flowers corymbosse, more copious, but much smaller than in the first species; the florets flesh-coloured, with a red tube. Seeds slender, each crowned with two very narrow, rather spreading, bristles.

Jacq. Hort. Schoenbr. v. 3. 28. t. 300.)—Leaves linear-lanceolate, most ferrated towards the point. Seed-down of three short scales, with intermediate bristles.—Native of Mexico. We received it from the rich garden of the late Rev. Mr. Watts, of Aihill, Norfolk. It is a hardy perennial, flowering in autumn, about the size of the last, but its leaves are smaller and more abundant; flowers larger and white, in level-topped, corymbose panicles. The three long rough bristles which crown the seed are membranous at the edges, and connected by a membranous crown at the base, agreeing in structure, and, we doubt not, in number, with the same part in our second species.

5. S. pedata. Compound-leafed Stevia. Cavan. Ic. v. 4. 33. t. 356. Willd. n. 5. Ait. n. 4.—Leaves pedate, entire. Seed-down of several short equal scales.—Native of Mexico. Its seeds were received from Madrid, with those of the third species, in 1803. This proves a hardy annual in our gardens, flowering from July to September. The stem is two or three feet high, a little downy, fristated. Leaves seven, stalked, entire, elliptic-lanceolate, roughish; the middle one an inch and half long; the lateral ones gradually smaller. Flowers white, small, but of more numerous florets than of the same species, with violet anthers. Seed crowned with about ten, equal, short, obtuse scales.

STEVIN, SIMON, in Biography, was born at Bruges after the middle of the 16th century, but the year of his birth is not ascertained. He was held in great estimation by Maurice, prince of Orange, whose own taste led him to respect the mathematical and mechanical acquirements of Stevin, and he was employed in Holland as an inspector of the dykes. He seems to have been the first person who discovered the true proportion between the power and the weight on an inclined plane, which he accurately determined in all the different cases. In hydrostatics he was also no less an adept than in mechanics; and to him we owe the discovery of the famous paradox, that a fluid contained in a tube decreases its pressure, as with the same pressure on the base as if the tube were everywhere uniform. He was also the inventor of a sailing boat, which was moved entirely by the impulse of the wind, and with such velocity, that it conveyed passengers from Scheveling to Putten, through a distance of about forty miles, in the space of two hours. Although the exact form of this vessel is not much known, it excited general attention. Grotius, who was a passenger in it, wrote a poem in reference to it, intitled "Iter Currus Veliferi," and he has made it the subject of more than twenty epigrams, in one of which are the following lines:

"Ventivolium Tiphys deduxit in aqua naves;
Jupiter in felibus uterque anegdomus.
In terrisque folum virtus Stevina: nam nec
Tiphys tuum fuerat, nec Jovis ilud opus."

It is also ascertained by Swertius and Valerius Andreas, that Stevin could raise any weight with a small power, by a simple machine, called by the latter "pancraetor." Stevin died at Leyden, according to Weidler, in 1633. His works are: "A Book of Arithmetic in French," printed by Plantin at Antwerp in 1588; 2 vols., and reprinted with the whole Algebra in Flemish, in 1605: "Problematum Geometricorum, Lib. V." 4to; and various other treatises in Flemish, translated into Latin by Snellius, under the title of "Hypomnemata Mathematica," Lugd. Bat. 1608, 4 tom. fol. of which there is a French edition, with curious notes and additions by Albert Girard, 1634. 6 vols. fol. The first contains arithmetic and algebra, with tables of interest; the second, cosmography, that is, the doctrine of triangles, geography, and astronomy; the third, practical geometry; the fourth, statics; the fifth, optics; and the sixth, cafframetica, fortification by fluxes, and general fortification. One of his treatises relates to the finding of harbours, and is intitled in the French edition "Du Trouve-Port, ou la Maniere de trouver les Havres," which was translated by Grotius into Latin verse, 1599, 4to. Montucula says, that none of Stevin's works contain any new things, except his Mechanica; but Dr. Hutton informs us, that his improvements in algebra were many and ingenious. Hutton's Diäc. and Mathematical Tracts. Montucula. Weidler Hist. Ant. Wilkins's Math. and Phil. Works. Gen. Biog.

STEW, a small kind of fish-pond, the peculiar office of which is to maintain fish, and keep them in readiness for the daily uies of the family, &c.

The fish bred in the large ponds are drawn out, and put in here. For two large ponds of three or four acres a-piece, it is advisable to have four flews, each two rods wide, and three long. The flews are usually in gardens, or at least near the house, to be more handy, and the better looked to. See Fish-Pond.

In the construction of flews or ponds, the sides of them should be cut down sloping, carrying the bottom in a continual decline from end to end, so as to have a convenient mouth, as horse-ponds have, for taking out nets in drawing for fish: and if there be room enough, a mouth may be made at both ends, and the deeps part be in the middle, by which means the net may be drawn backwards and forwards, and the fish not have such shelter as is given by a depth under a head. And besides, the fish delight to come upon the shoals, and probably thrive better. These may chiefly be referred for carp, but not absolutely; and where tench and perch increase and prosper, smaller flews may be made to serve them apart, and take them when wanted, without disturbing the other fish. See Fish.

In general, the strongest and best fish, where it can be done, are faved and preferred for being put into the flews, in order to be brought forward, and got ready more quickly for the table.

In places near the sea, there are frequently salt-water flews formed for keeping various kinds of sea-fish. It is noticed in the account of the state of the agriculture of the county of Essex, that the flews for sea-fish in Foulness island, in that district, are extremely well contrived, and answer the purpose in a complete manner. The fish for them are, it is said, caught in weirs, on the extensive sands, which run out several miles on the coast there, and then, when plentiful, deposited in these flews, where they are afterwards dragged for, as wanted, with a small net, as in flews of the fresh-water kind. See Fish-Ponds, and Pond Fisheries.

It is material in all sorts of flews, that there be something of the house kind near to or connected with them, for the safety and securing of the fish, as well as for the purpose of ornament in some cases. Different flews may in this way be made to be partially covered and divided by them: and by having perforations opened through the dividing parts, the waters of the different ones may flow through and communicate with the whole. They may also have trap-doors, openings for each of the different flews, made to be so closed and fastened, as that no perfon, except the owner, can have the means of opening them, and getting at the fish, without being liable to detection.

These sorts of contrivances may be beneficially had recourse to in most cases, as preventing all risk of depredations being committed; and in some cases, where the flews are connected with the residencies of men of fortune, they may have such forms and shapes given them, as may render their
their effects highly ornamental; besides serving as habitations for old domestics.

Different sorts of fish, besides being preferred, are often raised and fed to very great sizes in tanks. Stews, or Stews, were also places anciently permitted in England, to women of professed incontinency, for the proffer of their beds to all comers. These were under particular rules and laws of discipline, appointed by the lord of the manor. See Southwark.

The word is probably borrowed from the French, effet, hot-baths, in regard profitantes are wont to prepare themselves for venereal acts by bathing.

STEWARD, or SERNESCHAL, an officer, of whom there are various kinds; thus called from the Saxen fles, fleas, place, or room; and ward, keeper, q. d. a deputy, or person appointed in the place of another. See Serneschal.

Steward of Great Britain, Lord High, is the first and highest officer of the crown; as having the power of what we call a vice-roy, the Danes, &c. feudalholder, and the Swedes, reichs drofett, q. d. vice rex. Chamberlayne.

Common lawyers call him magnus Angliae finem bellum.

His office, as expounded in an ancient record, is to supervise and regulate the whole kingdom, both in time of peace and war, immediately under the king, and after him, as authority in every part, that he has not been judged idle to trust it any longer in the hands of any subject.

The office was hereditary and permanent in the family of the dukes of Lancaster, till the time of Henry IV. since whom it has only been made pro hac vice, occasionally: as to officiate at a coronation; at the arraigning and trial of some noblemen for treason, or other great crime. And it hath been the constant practice (and therefore seems now to have become necessary) to grant it to a lord of parliament, else he is incapable of trying such delinquent persons.

During his stewardship he bears a white staff in his hand, and the trial, &c. ended, he breaks his staff, and with it his commission expires.

Steward, Court of the Lord High. See Court.

Steward of the House, Lord, is an officer, to whom the state of the king's house is committed, to be ruled and guided at his discretion. See Household and Lord Steward.

Steward, Court of Lord. See Court. See also Marquisate Court.

Steward of the Universities, Lord High. See University.

Steward of a Ship of War, an officer appointed by the purser to distribute the different kinds of provision to the officers and crew, for which purpose he is furnished with a mate and proper assistants.

He hath an apartment for himself in the hold, which is called the steward's-room, built on the larboard side of the after-platform, nearly aft.

STEWART, MATTHEW, D.D. In Biography, professor of mathematics in the university of Edinburgh, was the son of the Rev. Dugald Stewart, minister of Ruthfay, in the isle of Bute, where he was born in the year 1717. As soon as he left school in 1734, being intended for the church, he was entered at the university of Glasgow, where his application and proficiency engaged the peculiar notice and friendship of the two eminent professors, Dr. Hutcheson and Dr. Simfon. The latter especially, perceiving probably in young Stewart talents and propensities of study resembling his own, initiated him betimes in the sublime speculations of the ancient geometry, to which he afterwards manifested a very decided attachment. As his views required his attendance on the lectures at Edinburgh, in 1744, Dr. Simfon recommended his favourite pupil to the celebrated Maclaurin, whose lectures he attended, and by which he gained profit. At this time he kept up a regular correspondence with professor Simfon, communicating to him the progress of his studies, and his geometrical discoveries, which were even at this time various and important, and receiving in return interesting information with regard to the Locs Plani and Porismata of Euclid. Both the professor and the student prosecuted their investigations of these abstruse subjects in different directions, but with similar success. The result of Mr. Stewart's enquiries was the discovery of those curious propositions, which he published in 1746, under the title of "General Theorems," and which gave him high rank, at an early age, among eminent geometers. Whilst he was engaged in these speculations, he had entered into the church, and under the patronage of the earl of Bute and the duke of Argyle, he was presented with the living of Rosneath; and in this retired situation he had discovered the greater part of the fore-mentioned propositions. But the death of Maclaurin, in 1746, afforded an opportunity for his being advanced to the mathematical chair in the university of Edinburgh, for the very able and elegant work of that eminent mathematician and philosopher in September, 1747. His new professorship led to some change in the direction of his mathematical studies; and led him to make an application of geometry to those problems, for the solutions of which the algebraical calculus had been employed. The first specimen of his success in this way was the solutions of Kepler's problem, founded on a general property of curves, which, perhaps, had never been before observed. This was published in the second volume of the "Effays of the Philosophical Society of Edinburgh," for 1756. The first volume of the same magazine contains some curious speculations on the subject of porisms, and which are demonstrated with all the elegance and simplicity peculiar to the ancient analysts. Attached to the geometry of the ancients, Mr. Stewart had formed a plan of introducing its strict and simple mode of demonstration into the higher parts of the mixed mathematics; and in the prosecution of this plan he composed his "Tract Fisychial and Mathematical," which were published in 1761. Mr. Stewart, in the first of these tracts, lays down the doctrine of centripetal forces in a series of propositions demonstrated from the quadrature of curves being admitted, with the utmost rigour, and requiring no previous knowledge of mathematics, except the elements of plane geometry and of conic sections. Accordingly this tract may be regarded as the best elementary treatise of physical astronomy extant. In the three following tracts the author proposed, in the same method, to determine the effects of those forces which disturb the motions of a secondary planet; and from these it was his design to deduce, not only the theory of the moon, but the sun's distance from the earth. But his declining health did not allow him to pursue the arduous investigation of these subjects. In the year 1763, when the result of the observations of the transit of Venus had been unsatisfactory to astronomers, Dr. Stewart determined to apply the principles he had laid down to this subject; and accordingly in this year he published his "Effay on the Sun's Distancy," where, from actual computation, the parallax of the sun was found to be no more than 6.99, and consequently its distance nearly 29,875 semi-diameters of the earth, or about 1,155,414,428 English miles, a distance so much exceeding all former estimates as to excite surprise, and to produce a favorable examination of the principles on which the calculation was founded.
founded. This "Effay" was the last work which Dr. Stewart published; but he declined engaging in any controversy on the subject. Some months before he published his "Effay," he prented to the public another work adapted to promote the study of the ancient geometry, and entitled "Propositiones Geometricae, more Vetricum demonstratas." By his confluent use of the geometrical analysis he obtained many valuable propositions, several of which have found a place in the writings of Dr. Simson. Soon after the year 1765, the health of Dr. Stewart began to decline, and he was unable to encounter the fatigue of the duties of his office. He therefore retired to the country in the year 1772, and never resumed his labours in the university. In 1775 he had the satisfaction to see his son, Mr. Dugald Stewart, elected joint professor with him; and when mathematical studies ceased to be his business, they were still his amusement. Having at an early period of his life admired the analogy between the circle and hyperbola, his attention, during the leisure of his advanced life, was directed to this subject, and he left among his papers some curious approximations to the areas of both. At the length the state of his health would not allow him to prosecute this study even as an amusement; and he closed his honourable life in the month of January, 1785, at the age of 68 years. Dr. Stewart's application had been from his youth most intense and continued; his mental faculties preserved an extraordinary vigour; and his memory was so tenacious, that he retained his discoveries, and he rarely wrote out any of his investigations till it became necessary to do so for the purpose of publication. When he discovered a proposition, he put down the enunciation with great accuracy, and on the same piece of paper constructed very neatly the figure to which it referred; for every thing else he trusted to his memory. Although he was very judicious, he read few books. After the academical labours of the winter were concluded, he spent the summer at a delightful retreat in Airthire, where he found leisure to prosecute his favourite researches. "Transactions of the Royal Society of Edinburgh."

Stewart, in Geography, a county of the district of West Tennessee, in America, containing 4262 inhabitants, of whom 779 are slaves.

Stewart's Islands, a cluster of small islands in the South Pacific ocean, discovered by captain Hunter in the year 1791, and so named in honour of admiral Keith Stewart. S. lat. 8° 40'. E. long. 163° 18'.

Stewartia, or Stewart's town, in Geography, a town in the district of Cunningham, and county of Ayr, Scotland, is seated in a pleasant and fertile district, on the banks of the river Annach, at the distance of six miles N. from the town of Irvine. From a comparative view of the population reports of 1800 and 1811, it appears that Stewarton has greatly increased in houses and inhabitants during the intermediate eleven years, as at the former date, there were 447 houses, and 2657 inhabitants; and at the latter, the number of houses was 484, and that of inhabitants 1749.

The town and parish feoffed to have derived their name from the royal and unfortunate family of Stuart, who had a mansion here at a remote period, and part of it still remains. The principal trade of the town is the manufacture of bonnets, which has been continued for upwards of a century past to a great extent. A general post-office is here established. Here are a weekly market, and several well-attended fairs. The general appearance of the parish is flat, with a gentle descent towards the sea; and it is decorated with extensive plantations. The soil is chiefly strong clay; and lime-quiaries abound in great plenty; its extent is upwards of ten miles in length, and some places about four in breadth. — Carlile's Topographical Dictionary of Scotland, vol. ii. qto. 1813. Gazetteer of Scotland, 8vo. 1806. Sinclair's Statistical Account of Scotland, vol. ix.

Stewartstown, a post-town of the county of Tyrone, Ireland; 77 miles N. by W. from Dublin, and 5 miles N. from Dungannon.

Stewartstown, a town of America, in the county of Coos and state of New Hampshire, containing 186 inhabitants.

Stey Point, a cape on the coast of Labrador. N. lat. 56°. W. long. 61° 42'.

Steyenberg, a town of Germany, in the county of Hofa; 9 miles S.W. of Nienburg.

Steyll, a town of the duchy of Berg, lately belonging to the abbey of Essen; 2 miles S.E. of Essen. N. lat. 51° 22'. E. long. 9°.

Steyning, a borough-town in the hundred of Steyning, rape of Bramber, and county of Sussex, England, derives its name from the Steyne-stream, an ancient road, which passed through this part of the country. In the population return for 1800, it is stated to have contained 215 houses, and 1174 inhabitants; but in 1811, the houses only amounted to 187, and the inhabitants had increased to 1039. Here is a weekly market on Wednesday, a monthly one for cattle, and three annual fairs. It is seated at the foot of a lofty hill, near the river Adur, and is formed by four transverse streets.

Steyning is a borough by prescription, and returns two members to parliament, elected by the householders and inhabitants, who do not receive alms, within the borough, amounting to 80. The municipal government is vested in a confiable, who is on such occasions the returning officer; and is appointed at the court-leet of the lord of the manor. The town is connected with the town of Bramber, and is formed of Bramber, and is entitled to return two representatives, although one part of Bramber is in the centre of Steyning, and a part of Steyning intersects Bramber in a similar manner. See Bramber.

The church is an edifice of great antiquity, but of this building only the nave remains. It contains some very curious specimens of early Norman architecture. The tower is of flint and stone, with buttresses at the corners. About the middle of the 16th century, a free grammar-school was founded in this place, and endowed with lands to provide for the salary of the master. There have been also of late years extensive barracks erected here for infantry.

At a very remote period, a Benedictine priory for monks existed in this town, founded by Edward the Confessor; the church, which appertained to this establishment, and which is supposed to be that already noticed, contained the sacred relics of St. Cuthman, and of Ethelwulf, father of Alfred the Great. — Beauties of England and Wales, 8vo. 1814. By F. Shoberl, vol. iv. Carlile's Topographical Dictionary of England, vol. ii. Representative History of Great Britain, by T. H. B. Oldfield, vol. iii. 8vo. 1816.

Steyr, a town of Austria, situated on a small river near its conflux with the Enz, the inhabitants of which are mostly engaged in manufactures of iron and steel. It was formerly pre-eminent among the royal towns, but hardly a vestige of its reputation now remains. It was once the capital of a county belonging to Stiriia, but being separated...
Separated from Stiria, it was added to the country above the Enns, and hence deemed merely a feignory. It has often suffered much by fire; 80 miles W. of Vienna. N. lat. 48° 17'. E. long. 14° 23'.

STARYE, a town of Austria, on the N. side of the Danube; 84 miles W. of Vienna. N. lat. 48° 17'; E. long. 14° 25'.

STAYEB, a town of Austria; 5 miles E. of Glagnitz.

STAZZANO, a town of Italy, in the department of the Serio; 3 miles S. of Bergamo.

STAYANU, in Mythology, a name of the Hindoo god Siva, by which he is frequently designated in the celebrated poem the Purana. See Siva.

STHENIA, from sthénos, strength, a word of great import in the Brunnian theory of medicine, implying an inflammatory diathesis, and standing in opposition to asthenia, or debility, to one of which that ingenious but mistaken pathologist ascribed all disordered incidents to the living body. See Excitability.

STHENIA, σθενα, in Antiquity, a festival of Argos, supposed to be kept in honour of Minerva, furnished with sthenia, from σθένος, strength.

STHENIUS, in Mythology, denoting powerful or strong, one of the epithets of Jupiter; as Sthenius, or robust, was one of the epithets of Minerva.

STIL, a word used by some of the old authors for pebbles found on the sea-shore.

STIBAGION, among the Romans, a low kind of table-couch, or bed of a circular form, which succeeded to the triclinia, and was of different sizes, according to the number of guests they were designed for. They were held fixed, eight, or nine guests, and so of any other number.

STIBELAW, in Geography, a town of Pomerelia; 30 miles S.S.E. of Dantzig.

STIBILIA, a term used by some to express the antimonial medicines.

STIBING, in Geography, a town of the duchy of Stiria; 7 miles N.N.W. of Graz.

STIFINUS, a term used by St. Jerome, and others, to express the false black colour which the ancient Jews, and other eastern people, gave to their eyes-brows with stibium, or antimony.

STIBIUM, See Antimony.

STIBIUM Ceratun. See Vitrum Antimonii Ceratun.

STIBITITZ, in Geography, a town of Bohemia, in the circle of Koniggratz; 24 miles E. of Koniggratz.

STICA, a name given by some authors to all external astringents used in hemorrhages.

STICA, in our Old Writers, a copper or billon heptarchic coin, of the value of half a farthing, four of them making an eling. This small piece was only known in Northumbria, and in the later period of that kingdom. See Penny, and Serrata.

STICHOMANTIA, τίχομάντια, in Antiquity, a sort of divination by verbs (commonly those of the Sibylline oracles), which being wrote on little pieces of paper, and thrown into a silver vessel, the first drawn out was supposed to contain the will of the gods. See Sortes.

STICHEOMETRY, formed of τίχος, verse, and μέτρον, I measure, in Scripture History, a catalogue of books of sacred scripture, to which is added the number of the verses which each book contains.

STICHOS, a name given by the old writers to a pectoral confection, the principal ingredient of which was the herb marjoram, or horeshare.

Stick of Eels, a quantity or measure of twenty-five. A kind of eels contains ten flocks, and each flock twenty-five eels. Stat. Weights and Measures.

STICKS, a kind of straight sticks or poles, that is made of wood, to which is fastened by a cord or thong, a sharp point to be used in fencing, boxing, etc.

STICKADORE, in Botany. See Cassidony.

STICKELSTA, in Geography, a town of Norway, in the province of Drongheim; 46 miles E.N.E. of Drongheim.

STICKHAUSEN, a town and citadel of Eaft Friesland, founded by the Hamburghers about the year 1435, as a security against pirates, and afterwards still farther fortified; 18 miles E.S.E. of Emden. N. lat. 53° 14'. E. long. 7° 16'.

STICKLEBACK, in Ichthyology, a name given by us to that small fish called by authors by the several names of pimelis, pimam, and pungitius pimam; as also pimela villis, pimelis aculeatus, and the like; and finally, by Arcted, by the much more expressive name of gasteroboeus, expressing that great singularity it has in the bony structure of its belly.

The common stickleback, or gasteroboeus aculeatus of Linnaeus, is distinguished by Arcted by the name of the gasteroboeus with three spines on the back; and by this character it differs from the other species of this genus.

It is a very well-known fish, and is found everywhere in new-dug ditches, &c. where no body can perceive how it comes. Hence the vulgar have an opinion, that it breeds there equivocally and of itself, without the help of partners of its own kind, and that from it all other fishes are derived.

These are idle opinions: the smallest animalcule is not produced in putrid matter otherwise than by the egg of a parent animal; this origin will, therefore, hardly be believed of larger, and as they are called, more perfect animals. These small fish are so far from peopling ponds with other fish, that they are very great devourers of the spawn of larger fish, and do infinite mischief in ponds.

These are found no where in such great quantities as in the fens of Lincolnshire and Cambridgeshire, and some of the rivers flowing from them. At Spalding there are, once in seven or eight years, amazing shoals that appear in the Weald, and come up the river in the form of a vast column. These are supposed to be the multitudes that have been washed out of the fens by the floods of several years, and collected in some deep hole, till, overcharged with numbers, they are periodically obliged to attempt a change of place. The quantity is so great, that they are used to manure the land, and trials have been made to get oil from them. See Phil. Trans. No. 225. For the characters of this and the other species, see Gasteroboeus.

It is observed in the Norfolk Reports on Agriculture, that these little fish, which are caught in immense quantities in the Lynn rivers about once in seven years, have been bought as high as eight-pence a bushel. The favourite way of using them now, is by mixing them with mould, and carrying them on the land for turnips. Great quantities have been carried to Marham, Shouldham, and Beachwell. Mr. Fuller, there, is reported to have laid out 400l. for them in one year; they always answer exceedingly.

And Mr. Roger, of Narborough, has gone largely into this husbandry, laying out 300l. in one year, at 6d. to 8d. per bushel, besides carriage from Lynn: he formed them into composts with mould, mixed well by turning over, and carried them on for turnips: the success was very great. There can be no doubt but that these small fish afford a good animal manure.

Matters of this kind constantly afford a most efficacious manure, and should mostly be applied in the fresh state, though
though in limited proportions, according to the nature and condition of the land. When first mixed with good rich earthy substanaces, as above, they are probably in the best state of application for the promotion of arable crops. The operation of such filthy substanaces, as manure, is readily elucidated and explained. The fleshy parts of them, the writer of the work on "Agricultural Chemistry" considers as principally consisting of gelatine, which, from its slight state of cohesion, is quickly soluble in watery fluids; and, besides, the fatty matter which constitutes different internal parts of them, readily becomes useful in the same way. Their fibrous matter contains all the elementary matters of vegetable substanaces, that are particularly wanted for this use.

Little fish of the prickleback, thornback, and other similar kinds, may also probably be employed in the same way, with equal benefit and advantage, where they can be had in sufficient quantities.

STICKLER, in our Old Writers, an inferior officer, who cuts wood within the king's parks of Clarendon.

STICKNA, in Geography, a town of Bohemia, in the circle of Prachatitz; 5 miles S. of Strakonitz.

STICKS, Foot, in Printing, slips of wood that lie between the foot of the page and the chafe, to which they are wedged fast by the quoins, to keep the form firm, in conjunction with the side-ricks, which are placed at the side of the page, and fixed in the same manner by means of quoins. See REOLET.

STICTA, in Botany, from ektos, dotted, alluding to the minute impressions on the under side of the frond; a name given by Schreber to one of the sections into which he proposes to divide the Linnean genus of Lichen, which is now received as a genus by itself, like Stereocaulon, Spiroma, &c. (See those articles.)—Schreb. Gen. 768. Achar. Meth. 375. Lichenogr. 86. t. 8. f. 1.—8. Syn. 230. Cliffs and order, Cryptogamia Algæ. Nat. Ord. Lichens.

Eff. Ch. Shields orbicular, flat, felisile, with an elevated border of the substanace of the frond, scattered. Frond coriaceous; downy beneath, flammed with little bald pits. One of the most interesting of this natural order, found on old trees in various parts of the globe. The species in the Synoos of Acharius amount to twenty-two, of which seven are British; but the last in this list, S. Hyssastis, is not unattainted with doubt, and another is certainly misplaced, as we shall mention hereafter. We select a few of the most remarkable exotic, in addition to our native species.

—Found on trunks of trees in New Zealand, from whence Mr. Menzies brought our specimens. The fronds are three or four inches in length, or height, for we know not whether they grow erect or horizontally, and consist of numerous, very elegant, rounded, flattened, finely pinnatifid lobes, lying over each other. The upper surface is quite smooth, even, and veined, of a pale greenish-glaucous ash-colour, beprinkled with small, slightly elevated, flat fields, red when young, then chestnut-coloured; their border tawny, smooth, slightly crenate at the inner edge. The under side of the frond is yellowish or tawny, paler towards the extremities, and scarcely downy, except about the remarkably strong, brown, elevated, central rib, which run down into a sort of channelled common stalk. The pits, cyphelle, have an elevated polished border, raised above the smooth back of the frond, not funk, as usual in other species, amongst downy or pubescence.

S. comenita. Fringed Stichia. Ach. Syn. n. 2. Meth. 276. t. 5. f. 1. —Frond dilated, greenish-white, with wedge-shaped, somewhat forked lobes; pungent beneath, with cup-shaped pits. Shields tawny-red, fringed, like the frond, with radiating black hairs. —Gathered by Dombey on trees in Peru. One of his specimens was given us by M. L'Heritié, a remarkably handsome species, larger than the last, spreading in broad imbricated malles, and differing by the copious large red fields, bordered with black spreading hairs. The pits of the under surface are, in fact, pale brown-ovulate cups, imbedded in dense pungent pubescence of the same hue.

S. crocata. Yellow-veined Stichia. Ach. Syn. n. 6. (Lichen crocatus; Linn. Mant. 310. Dickf. H. Sicc. falc. 4. 84. Engl. Bot. t. 2110.) —Frond roundly lobed, dilated, cellular, glaucous-brown, with bright-yellow powdery cracks and margins; brown and pungent beneath, with minute bright-yellow pits. Shields dark-brown, with an entire border. Native of rocks, and trunks of old trees, in the Highlands of Scotland, as well as in the East and West Indies. The dark livid hue of the wrinkled cellular frond, strikingly contrasted with the lemon-coloured powder, which flours from all the cracks, edges, and walls. The pungent down of the under side is nearly as dark, though somewhat reddish; and the pits, though very minute, are rendered conspicuous by their bright lemon-colour. We never saw the shields. —Acharius misapplies to this the synonym of Dillemius that belongs to the following.

S. aurata. Golden-edged Stichia. Ach. Meth. 277. Syn. n. 7. (Lichen auratus; Engl. Bot. t. 2359. Platinum crocatum; Hoffm. Pl. Lich. v. 2. 52. t. 38. f. 1.—3. Lichenes lacunolus crotulum, marginibus flavis; Dill. Mufc. 549. t. 84. f. 12.) —Frond fringed, roundly lobed, nearly even, of a shining reddish-glaucous bright brown; the margin wavy, bearing golden-coloured powder; brown and downy beneath, with bright-yellow pits. Shields ...... Native of trees in St. Helena and the West Indies, possibly also of Devonshire; but the authority for the latter depends on unmarked specimens, found in Mr. Hudson's British herbarium. This was first distinguished from the last, by the writer of the present article, in Engl. Bot. v. 33. There can be no doubt of its being abundantly different, the paler redder colour of the upper side, and want of veins, wavy cracks, or cellular defformities, are sufficient characters.

The margin is more timid and wavy, with a rather more golden than lemon-coloured powder, which line also appears in the inner substanace of the frond, when broken, and in the minute pits of its brown under side. Nothing is known of the fields.

of the earlier botanists, and given rise to the name. The
colour of the upper surface, when fresh and moist, is a rich
bright green, verging towards olive, or brown by age or
drying. Its very prominent reticulations, usually smooth,
are occasionally rough with warts, or rather minute fibres.
The under side is downy, pale-brown; in an early flute
quite even, though marked with broad, oval, perfectly
smooth, and rather shining, spaces, apparently analogous
to the pits of other species, and therefore, in our opinion, justi-
fying the removal of this plant to the present genus, with
which it, no doubt, in every other respect, strictly accords.
These spaces become afterwards humid, and very prominent,
between the downy depressions, which answer to the ribs,
or reticulations, above. The shields are frequent, for the
most part seated on the margin, more rarely on the ribs of
the dill, flat, of a chefon-brown, with a narrow border
disappearing with age, when also the shields sometimes
become humid and convex. The resemblance of this plant
to the lungs, has caused it to be used, in a decoction with
milk, to cure coughs. It is bitter, astringent and mucil-
ginous, like the famous Iceland Mols, Lichen islandicus of
Linnæus, and may therefore agree with that species, in
whatever respects the latter may possess.

S. frorobiculata. Pitted Sticta. Ach. Syn. n. 13. (Par-
meia frorobiculata; Ach. Meth. 219. Liches frorobiculus;
L. verruculosus; Hudf. 545. Jacq. Coll. v. 4. 278. t. 18.
f. 17. Lichenes polunomen villum, superficie frorobi-
culata et peltata; Dill. Mufc. 216. f. 29. f. 114.)—Frond
dilated, rounded lobed, crinate, deeply cellular, obtusely
reticulated, glaucous, with grey mealy warts; brown
and villous beneath, with pale, ovate, smooth spaces. Shields
small, scattered, chefon, with a roughish border.—Found
in the mountainous parts of Europe, on trees and mossy
rocks, but rarely in fruticification. We met with it in this
state, but sparingly, near Lakes, on the beautiful shore of
Loch Lomond. This has much broader rounded lobes than
the foregoing, spreading loosely in large patches; the pale
yellowish, ferrugineous, and grey, if it is not covered with
a surface, though deeply cellular, is scarcely ribbed or reti-
culated. Grey mealy warts, looking like a fort of mould-
seal, occur towards the edges of old plants; and the shields,
when fresh, are feasted more towards the central part of
each lobe. The under side is clothed with dark-brown
spiny-downs, vanishing near the edge, and interperled with
oval, whitish, very smooth spots, evidently of the nature of
real cypella, though still so much resembling what we have
described in S. polunomus, as to confirm the genus
of that species.

Syn. n. 20. (Lichen limbatas; Engl. Bot. t. 1104.
Lichenes, Dill. Mufc. 108. t. 26. f. 100. varietas far-
ifolosa, B.C.)—Frond rounded lobed, glaucous-brown, smooth;
grey and powdery towards the margin; downy beneath,
with white cup-shaped pits. Shields brown, with a dark
border.—Native of shady mossy rocks, and about the roots
of trees, in Scotland, Wales, Oxfordshire, and, according
to Acharium, in Switzerland. We have a specimen with nu-
umerous shields, which are extremely rare, from Mr. Huddon's
herbarium, and another from Mr. Meunier. Much smaller
than the last, each plant rarely exceeding two inches
in diameter, and consisting of a few concentric, lax, rounded
lobes; whose upper surface is smooth and shining, emulating
brown fatti, with scarcely any depressions and reticulations;
the margin only, often tumid and repressed, being rugged,
and covered with grey mealy warts, proceeding from cracks
in the cuticle. The under side is even, of a nearly uniform
light brown, finely downy, besprinkled with small, white,
smooth, bordered pils, sunk in the down. Shields small,
seifile, with a broad base; their disk dark-brown, at first
concave, with an elevated, smooth, thick border, but soon
becoming flat, or slightly convex, almost black, the border
assuming the same hue. This border is not sufficiently ex-
dited in Engel. Bot. Neither Lichenus nor Acharium ever
saw the shields, and hence the former was led to look his
very distinct species to be the male, or "powder-bearing plant,"
of what we shall next describe, both having been for the
first time clearly determined in the Engl. Bot. from spec-
cimens collected and studied with no small care and at-
tention.

n. 21. (Lichen fuliginosus; Dickf. Crypt. facic. t. 13.
Engl. Bot. t. 1103. Lichenoides fuliginnosum et pulvu-
rentenium, frutellis rubiginosis; Dill. Mufc. 198. t. 26. f. 106.
116.)—Frond rounded lobed, dark greenish-grey, rough with
blackish granulations; downy beneath, with white cup-
shaped pits. Shields red-brown, with a pale border.—More
frequent than the last on rocks, as well as trees in old dark
woods, in the alpine countries of Europe. Acharius says
it grows also in France, America, and the isle of Bourbon.
We have it from Cornwall, Wales, and Wexford.
The size and habit of this plant agree with the last, but the
present species is distinguished by the innumerable dark
warty granulations of its upper surface, and the want of
those gray, dense, mealy warts, which distinguish S. limba-
as. The under sides of both species are similar. The shields
of the present, very rarely met with, are more elevated; at first
reddish, with a pale tumid border; and convex and dark
brown, their border disappearing. This has been very
erroneously confused as a variety of the following.

Pl. Lich. v. 21. t. 4. f. 2. Lichenes polychydes, villusum et scabrum, pelta parvis; Dill. Mufc. 195. t. 27.
46.)—Frond deeply lobed, dark greenish-brown, somewhat uneven and granulated; downy
beneath, with white pits. Shields marginal, vertical, con-
 vex, dark-brown.—Abundant in the mountainous woods of
most parts of Europe, clothing the ground in loose extensive
tuffs, intermixed with moss, under the shade of rocks or
old decaying trees; but the fruticification is among the
greatest botanical rarities. We have seen it however in
Dr. Hope's collection, who received his specimen from Dr.
Burges of Dumfriesshire: Dillenius and Hoffmann have
also delineated similar ones. The fronds spread much more
widely than those of S. limbatas or fuligina, and are longer,
though narrower and much more divided, with abrupt
divaricated segments. Their upper surface is usually
smooth and even, of a greenish-brown, scarcely so
green as in Hoffmann's plate. Sometimes it is obscurely
cellular, and besprinkled with dark granulations, like those of
fuligina; with which species likewise the under side
accords, the pits being those of a true Sittta. But the
fuligina, as represented by authors, appear very different
from all known species, being more like the male, and the
targets, of the genus Peltides, and treated, like most of them,
on marginal elongated portions of the frond. (See Pel-
tides.) Whether they are orbicular and bordered in a young state,
nobody has observed. If so, this ambiguous species would
prove a genuine Sittta; but otherwise it would, as a Pel-
tides, overturn the importance of the cypella for generic
distinction. Indeed this importance is much weakened
by
S. palumbosus and S. scrobiculata, in which these pits are so imperfectly defined; to say nothing of Parmelia glomulifera, Aech. Syn. 195. (Lichen glomulifera; Engli. Bot. t. 293) and other species, in which they distinctly, though but occasionally or sparingly, occur.

We beg leave, further, to observe that S. dissoluta, Aech. Syn. n. 19, has no character of the present genus, but, though.handle on both sides, seems naturally of the tribe called Cataria.

STIECHOWITZ, in Geography, a town of Bohemia, in the circle of Beraun, in the Muldau; 10 miles S.E. of Beraun.

STIEGE, or Stieg, in Commerce, a term of reckoning used in Germany, containing 20 pieces.

STIENNA, in Geography, a town of Italy, in the department of the Lower Po; 9 miles N. of Ferrara.

STIEPANOW, a town of Bohemia, in the circle of Kauzma; 15 miles S. of Kauzma.

STERNHELM, George, in Biography, a learned Swede, was born in Dalecarlia, in the year 1598. Enjoying the friendship of Burans, tutor to Gustavus Adolphus, he made great progress in literature and the sciences. Upon his return from a tour into foreign countries, he was appointed lecturer on morality in the gymnasium newly founded at Vetteros; but defined for a wider sphere of usefulness and reputation, he was appointed, in 1630, aforesaid in the court of justice at Dorpat; and in the following year he was ennobled. In 1654 he occupied an important office in Livonia, where it was his fate to be regarded by the ignorant and superfluous populace as a forerunner, because he employed microscopes, and other philosophical instruments, to aid him in the investigation of the secrets of nature. In 1648 he was advanced to the high station of vice-president of the court of justice of Dorpat; but being obliged to fly from the Ruffians, who threatened his person, the vessel in which he embarked was wrecked in its passage; and though he escaped himself, he lost all the property which he had preferred from the ravages of the Ruffians. When he arrived at the capital, he was penniless and almost naked; but he was soon relieved by the munificence of some fixed friends. Queen Christina treated him with respect; and nominated him antiquary of the kingdom; entrusting him also with the care of the public records, and conferring on him the title of "Custos Regni." In 1658 he was appointed by Charles X. provincial judge of Drontheim, in Norway; but when Drontheim was restored to Denmark, he became, in 1661, a member of the council of war; and when the college of antiquities was established at Upal, in 1665, he was appointed director. He died at Stockholm in 1673, at the age of 74. Sternhelm was a man of great learning, and excelled in an extensive knowledge of languages. All languages, in his opinion, were derived from the Scythian, which he maintained to be older than the Hebrew itself. By command of queen Christina, he was obliged, in her presence, and in the public hall of the academy of Upal, to hold a dispute on this subject with professor, afterwards bishop, Terlerus. His taste for poetry led him to an acquaintance with the principal compositions of the ancient poets; and his own verses are said to have been read with pleasure. In consequence of his extensive knowledge of mathematics and arithmetic, he was employed to regulate the Swedish weights and measures. Regardless of wealth, he was often reduced to such distresses as to be under a necessity of writing to the chancellor Oxenstierna, requesting public relief. When his friends regretted his poverty, they received for answer, "Bona mentis comes eft properas. Aut philosophum aut divitem oportet vivere." He preferred the former; and always seemed contented, cheerful, and happy. Being asked on his death-bed what epitaph should be inscribed on his tomb, he replied, "Vixit, dum Vixit, letus." Although he was a man of unquestionable virtue and integrity, he did not escape calumny. In matters of philosophy, he thought freely and boldly; but it does not appear that he ever wrote anything contrary to that respect which is due to the Supreme Being, or to the principles of true religion. Among his numerous works were, "Magog Aramaz Gothicus, five origines Vocabularum in Linguas pane omnibus, ex Lingua Svetica veteri"; a work printed at Upal in 410. but never completed; "Lugogo Veytrogthiche antiques, cum Prefatione et Indice Vocabularum obscuroserum," Stock. 1653, fol. ["Uphilas, iut Verfo quator Evangeliorum Gothica, Litteris Latinis quam Gothicas ediderat F. Junius, cum Ver Lombus parallela, Vexogthica, Illustris, et vulgata Latina," etc., 1617; ibid., 410.]; "Epilola ad Olaus Verelium de Origine Vocabularum Gothi et Srdi," pre-fixed to Hervara Saga; "Antiquiuerus, five de Originius Sveo-Gothicia," Holm. 1687, 8vo. The "Archiomph Reformatus" of Sternhelm, on trying metals by water; and his "Linea Carolina," are incontrovertible proofs of his deep knowledge in mathematics and natural philosophy. It appears that he had both microscopes and lenses, which were very rare in Sweden at this time. He was well versed in languages, history, and the northern antiquities. His memory was particularly cultivated on account of his being the father of true poetry in Sweden. He determined, as his biographer says, to throw aside that restraint which words of the same sound at the conclusion of the lines carry with them, and to try whether ingenious thoughts would not please as much in Swedish verse without rhyme, as in the poetry of the Greeks and the Romans. The attempt completely succeeded in hexameter or heroic verse, and Sternhelm's "Hercules" is and will continue to be a master-piece. Gen. Biog.

STIERNHOOK, Justus, a learned Swede, was born in 1576. After travelling in foreign countries from 1620 to 1624, he was appointed lecturer of jurisprudence and the political sciences at Vetteros; and in 1640 made professor of jurisprudence in the newly established academy at Abo. In 1658 his fight became bad, and he laboured under this infirmity until his death, which happened at Stockholm in 1675; and yet two years before this event he went to Holland, and visited the Hague, Leyden, Amsterdam, and several other parts, without any assistance. He was the author of various esteemed works, among which was "De Jure Syenum et Gothorum vetus Libri duo," Holm. 1672, 4to. Gen. Biog.

STIFF, the quality by which a ship is enabled to carry a sufficient quantity of sail without the danger of overfling. Vessels having this quality, arising from their construction, will certainly sail faster than others, which, in order to carry the same quantity of sail, require to be ballasted. The raffines of many ships, however perfect in their construction, may be materially injured by an injudicious mode of fowing; although, on the contrary, this excellence of the construction can be fet by rigid and rectified, to any considerable degree, by the fowing. See Ship-building, and Stowage.

STIFF JOINT, in neat cattle, a disease of these parts, which is often troublesome and very hurtful to them. It is most probably the rheumatic kind, and not unfrequently termed joint fallen by the country people.

It affects, for the most part, such old milk cows as are near calving, or such young cattle as are much exposed in the
the field in the spring of the year. It commonly arises from too great exposure to cold winds and moisture, and generally takes place in such animals as have been kept in a state of poverty and starvation for the winter fea¬son, on their being suddenly turned out in the early vernal months, and greatly exposed in low dews to situations to the severity of the north and easterly winds.

The appearances of it are, that the joints become particularly affected, and sometimes swelled; and there are great pain and weakness. For two or three days at first, the animals only appear stiff in the joints; which afterwards often begin to tumefy and enlarge, without any signs of an active inflammatory state; a cold inactive tumour consequent takes place about the articulations, which is attended with a great stiffness, that not unfrequently spreads and extends itself over the whole body, so that the beast is scarcely able to rise when laid down, without being in some measure afflicted. Such cattle as labour under this complaint often suffer greatly from the severity of the pain in the parts, and from the little leisure and incapability of stirring which attend it.

On the diseased first making its appearance, the beast should be removed, and be taken to some proper building of the cow-house kind, which is rather warmly situated, as moderate warmth is of much use in the removal of the complaint. Here proper remedies should be given, such as colostrum and gum guaiacum, in pretty full doses, as from half a drachm, to a whole drachm and upwards, of the former; and from half an ounce, to an ounce and more, of the latter, in powder, made up with the tincture of opium and balsam of copaiva into the form of a small ball. This may be given once or twice in the day, in a horrid or two of warm ale. And afterwards, recourse may be had to guaiacum, in combination with Peruvian or oak bark, camphor, and fomachic feeds, in the proportions of from one to two ounces of the gum, bark, and feeds; and from one and a half to two and three quarters of the cumin; the whole being formed into a fine powder, and given as above.

One or two ounces of the spirit of turpentine may also sometimes be given in a quart of thin oatmeal gruel with great benefit.

The use of strong stimulating applications rubbed externally on the swellings of the joints, which are so strongly recommended by some, are seldom probably to be had recourse to, as they may be attended with danger in many ways.

Where the diseased puts on an active state, and is accompanied with fever and much pain, as well as swelling in the joints, as occasionally is the case; it will be necessary and proper to have recourse to opening mild purgative remedies, as there may be occasion, with the balls and powders given in such a manner as may be suitable.

By the proper use of these means, the beasts will most likely soon get well of such stiffnesses in their joints.

But cows and other cattle sometimes have lamenesses and stiffnesses, which appear to be at one time in the fore-quarters, and at another in the hind ones; and which may be attended with considerable pain. These are often removed by hard driving, or other similar cau¬ses, and nut from the same causes as the above; but in these cases, too, the colostrum, as well as such remedies of the bark kind as have been advised above, will be found useful.

**Stiff Joints** in lambs, a diseased or afebrile in these parts of them, which mostly takes place during the hot summer season, as about the month of June, coming on with a stiffness in the different joints of the extremities, and sometimes seizing several lambs in the same flock at the same time. It is commonly supposed to be occasioned by the low state or condition of the eves to which they belong; but it is more probable that it arises from the sudden night colds and dampness which are liable to take place, and to which they are particularly exposed during this period of the year. At such times, however, the lambs are believed to be disposed to grow fast, and, for want of proper and sufficient nourishment, to become floured, and to have their joints stiff and swelling out; they, however, for the most part, recover of the complaint. It is most likely a disease of the rheumatic kind, which, when it does not readily go off, may give way to the use of calomel with a little opium in the form of a small ball, to the extent of from a scruple to half a drachm, once or twice in the day, or a small spoonful or two at a time of the spirit of turpentine.

**STIFLE, or STIFFLE.** The name of a diseased in the patella, or knee-pain, in a horse or other animal, which part it properly signifies. A lameness in the stiffle is caused by those accidents that produce it in all other joints. When a horse is lame in this part he generally treads upon his toe, and cannot feel that heel to the ground. Some strains in the stiffle are violent, and swell pretty much; but Gibson affirms, that he hardly ever knew any of them incurable, unless bad methods had been used in the beginning. They commonly may be cured by cooling fomentative applications, such as have already been prescribed for the above; but if the swelling be very large and puffy, which sometimes happens, recourse must be had to fomentations, to take off inflammation. Sometimes, however, imposthumations follow: in such cases, and when these break and run, there is commonly an end of danger.

**STIFT,** in Etching. See Etching.

**STIGLIANO,** in Geography, a town of Italy, in the Patrimonio; 9 miles E. of Civita Vecchia.—Also, a town of Naples, in Basilicata, celebrated for its baths; 24 miles S. E. of Acerenza.

**STIGMA,** in Medicine, a minute red speck in the skin, without any elevation of the cuticle, of the same nature as petechia, from which they differ only in magnitude.

**STIGMA,** in Botany and Vegetable Physiology, an essential part of the Pistillum (see that article) in flowers, being the organ defined to receive the Pollen, the action of which upon the stigma causes the fertility of the seeds. (See **FECULATION OF PLANTS**.) For the accomplishment of this important purpose, the part is situated so as to receive the pollen, and so formed as to retain it; whilst a peculiar moisture, secreted, more or less copiously, by the stigma, occasions the particles of the pollen, hitherto kept dry, to burst, and discharge their elastic contents, more immediately subservient to the end designed. When the pollen is of a glutinous quality, as in Orchis and Conotis, the same moisture must be supposed to act as a menstruum, performing the same thing in a slightly different mode.

The shape of the stigma is either simple, being little more than a mere point; or it is capitate, like a pin’s head, as in the Primrose. In the ringed flowers the two stigmas are typically simple, but of the most simple structure, devoid of all evident pubescence, so that it is hard to understand which is the efficient part; whilst in most gramineous the stigmas are amply branched or feathery, to detain the pollen. So in many of the mallow tribe, a great degree of pubescence, and abundance of viscid moisture, are evident in these organs; their rich purple or scarlet colour contrasting with the large yellow pollen, whole burring, or explosion, may almost be seen by the naked eye. The stigma of the Amsyllis formosa is furnished, as Linnéus observes in his
Differtation on the Sexes of Plants, with a large drop of clear fluid, which is protruded in the day time, fo as to seem in danger of falling to the ground. To this the pollen adheres, rendering it turbid or firefly, in which state it is re-absorbed towards evening into the style. The concave stigma of the Violet grapes to receive the pollen; that of the Marjoram is flatter to be insertible, clotting from the stimulus of the pollen, which by that means it more freely retains. That a vital principle is inherent in the stigma, at least till the ends of its formation are answered, we learn from an observation of Linnaeus, in the Differtation above alluded to. He found that this organ, in female plants of Hemp to which no pollen had access, remained for a long while green and vigorous, as not having had the vital principle exhausted; while the stigma of every blossom which had been impregnated, evinced the completion of that operation, by fading and withering away. Almost every flower, when carefully examined, confirms the truth of this remark. In those cases where the styles remain, to form a crown, or hooks, affixing in the dispersion of the seeds, the stigmas will generally be found decayed or separated. See GERMEN and STYLUS.

STIGMANTHUS, in Botany, a name of Loureiro’s, formed of *stigma*, the stigma, and *anthos*, a flower, in allusion to the unusually large size of that organ.—Loureiro, Cochin. 145. Clasts and *Pentandria Monogynia*, Nat. Ord. A. Rhamn. Juf. Gen. Ch. Cal. Perianth superior, of one leaf; tube short; limb in five deep, long, very slender, segments. Cor. funnel-shaped, with a long tube; limb in five deep, ovate-oblung, spreading segments. Stam. Filaments five, very short, inserted below the segments of the corolla; anthers oblong, reflexed (we presume between the segments). Fil. Gernen inferior, roundish; style thread-shaped, longer than the corolla; stigma ovate, furrowed, very large. Peric. Berry dry, compressed, tuberculated, of one cell. Seeds numerous, oblong, angular, bony. Eff. Ch. Corolla funnel-shaped. Stigma furrowed, very large. Berry dry, crowned by the calyx, of one cell, with many bony seeds.

1. *S. cyphiodes*. Cay buim of the Cochinchinae.—Native of woods and hills in Cochinchina.—A large, branching, climbing shrub, within tendrils or thorns. Leaves opposite, lanceolate, entire, smooth. Flowers white, in very large, axillary and terminal, cymes.

Loureiro hints the affinity of this plant to *Mussanda*, from which, he says, it differs chiefly in its seed-veil and stigma. We cannot refer it to any known genus, but it seems to range near the SOLERA of Willdenow. See that article.

STIGMAROTA, from *figma*, and *rota*, a wheel, alluding to the large, orbicular, toothed figma.—Loureiro. Cochin. 633.—Clasts and order, *Dicta Polyantria*. The name is bad, and of the genus itself we have not sufficient materials to form an opinion. Loureiro gives the following. Eff. Ch. Male, Calyx in four or five deep segements. Corolla none. Stamens thirty. Female, Calyx in five or five deep segments. Corolla none. Stigma wheel-shaped, five-lobed. Berry fleshy, with five seeds. The species are two.

1. *S. Jangomas*.—Stem arboreous, with branched spines. Stalks scattered, many-flowered.—Cultivated, and perhaps wild, in Cochinchina. This the author considers as *Jangomas*, Bont. Jay. 111, and *Spina Spinaria*, Rumph. Amboin. v. 7. 36. t. 19. f. 1, 2. He therefore rightly observes, that the latter synonym can have no reference to *Carissa Spinaria*, Linn. Mant. 559.

2. *S. africana*. Stem shrubby, with simple spines. Flowers solitary, terminal.

STIGMATA, in Natural History, the apertures in different parts of the bodies of insects communicating with the tracheae, or air-veils, and serving for the office of respiration. Nature has given to these minute animals a much larger number of tracheae and bronchia, than to us. We have the ramifications of the tracheae reaching no farther than into the breast, whereas, in the bodies of these insects, we find them extended through the whole, and finely and admirably interlaced with one another. We have but one mouth to expire by; and the organization of the parts, inertive to respiration, is very admirable in us; but in the insect class, the mouths or openings to breathe at, are much more numerous, and the organization much more complex.

All the two-winged and four-winged flies, which have a single or undivided corselet, to which their legs are all fixed, have also four figmata in that corselet, two on each side. They have them also on the rings of their body, but those on the corselet are the most considerable.

Of the four on the corselet, the two anterior ones are usually the largest. The bell way to find them, in the generality of flies, is to examine them first in the larger species of the libelle, where they are very distinct and plain, and after their situation is well known in that species, they will be found the more readily found in the rest.

These figmata of the corselet, as well the anterior, as the posterior, are oblong, and placed obliquely to the length of the body; that end of them next the head is more elevated than the other, and their size is sufficiently large to render them visible, especially the first pair. Each of these seems not a little to resemble a fasc-mucle with its shell a little open, or is somewhat like the opening of an eye. It is also surrounded by two eye-lds, proportionally thick; and beside these, which make its outer circumference, one may discover two others within, which are bordered with hair and which, when closed, often quite shut up the opening.

The colour of the figmata often is some help also to us for the discovery of them; they are very frequently different in colour from the corselet; some are yellowish, others of a coffee colour, or some degree of a yellow colour, in flies whose corselet is brown, or black, or blueish.

Flies have, beside these, several figmata also in the rings of their bodies, perhaps in every one of them, though commonly those in the two or three first are only to be distinguished; these are not like those of the corselet, but are round, usually a little eminent above the rest of the surface, and resembling pins’ heads; they are not easily discovered, because they are not only small, but usually hid by the folds, or convolutions of the rings. They are usually two on each ring, placed on the two opposite sides, and partly under the belly, Reaumur, Hist. In. vol. iv. p. 248.

Malpighi first discovered, that those eighteen openings, which are placed nine on each side of the caterpillar, and which are called by the name of figmata, serve to give respiration to this class of animals. M. Reaumur repeated his experiments, and made several new ones; and he concluded that these apertures served only for the inspiration of the air, which the caterpillar afterwards expired through the whole superficies of its body, because he could never observe that any bubbles of air were ever driven out of these figmata; but Mr. Bonnet, on the contrary, having seen bubbles of air coming out of these openings, was led to infer that the inspired air was also expired or discharged through these same orifices; and he is of opinion that no part
part of it is expired through the pores of the body. From several experiments he also inferred, that of the eighteen stigmata with which the caterpillar is furnished, the two anterior and the two posterior ones are of greater use for respiration than any of the others. Phil. Trans. vol. xlv. p. 300. &c.

STIGMATA, in Antiquity, certain marks impressed on the left shoulder of the soldiers when lifted. See STIGMATIZING.

STIGMATA is also a kind of notes, or abbreviations, consisting only of points, disposed various ways; as in triangles, squares, crosses, &c.

STIGMATA is also a term introduced by the Franciscans to express the manner or prints, of our Saviour's wounds, said to have been miraculously impressed by him on the body of their seraphic father, St. Francis.

A solemn feast was hereupon appointed to be annually celebrated in memory of the miracle, called "the feast of the stigmata of St. Francis!" and a peculiar mass or office was composed for the same.

An archi-confraternity was erected on the feast occasion, by Fr. F. Pizzetti, a Roman surgeon, in the year 1594.

STIGMATICI, among the Romans, were servitors marked for the crime of sacrilege.

STIGMATIZING, among the Ancients, was inflicted upon slaves as a punishment, but more frequently as a mark to know them by; in which case it was done by applying a red-hot iron, marked with certain letters, forming the name or some peculiar character belonging to their masters, to their foreheads till a fair impression was made, and then pouring ink into the furrows, that the inscription might be the more conspicuous.

Soldiers were branded in the hand with the name or character of their general.

After the same manner it was customary to stigmatize the worshipers and votaries of some of the gods. The marks used on these occasions were various; sometimes they contained the name of the god, sometimes his particular enigma, as the thunderbolt of Jupiter, the trident of Neptune, the Ivy of Bacchus, &c. or they marked themselves with some mythical number, by which the god's name was described. To these three ways of stigmatizing St. John is supposed to refer. (Rev. chap. xiii. ver. 16, 17.) Theodoret is of opinion, that the Jews were forbidden to brand themselves with the name of a god, for their being in a state of war; but it is certain, they used to consecrate themselves to their gods.

Among some nations, stigmatizing was considered as a distinguisughed mark of honour and nobility. In Thrace, as Herodotus tells us (lib. v.), it was practised both by perfons of credit, nor admitted by any but persons of the meanest rank.

The ancient Britons are also said to have impressed on the bodies of their infants the figures of animals, and other marks, with hot irons. Potter Arch. Grec. tom. i. p. 64, &c.

STIGSIO, in Geography, a town of Sweden, in Angermanland, seated on a river which runs into the gulf of Bethnia; 8 miles W. of Hernofand.

STIKKESHOLM, a place on the south coast of Iceland, situated at the extremity of a small peninsula, close to the sea, amidit abruptly precipitous rocks, some of which are columnar. Near the ilthmus, which is passed in entering this peninsula, is a hamlet, called "Heigæli," or the Holy Hill, from its situation on an eminence, with which certain superstitious ideas and usages were anceintly connected. On this spot was established one of the earliest of those settlements which the Norwegian emigrants made upon the coasts of Iceland. The access to Stikkeholm affords several fine views of the "Breidé-Fjord," which is here completely flooded with small rocky islands, amounting in number to about 150. Many of these islands contain the great numbers of eider-ducks. The houses are large, and, as well as the store-houses and cottages, belonged (in 1810) to Mr. Thorlacius, a native of the country, and reputed the richest man in Iceland. Before the war between England and Denmark, Stikkeholm was a place of considerable traffic. The fishery, which begins earlier than in the Faxé-Fjord, was very productive. During the early part of Sunday, the occupations of the people in this place were suspended, and many of them went to the neighbouring church at Hlegæli; but at six o'clock in the evening, the store-houses were again opened, and the inhabitants of the place, renewing their common drees, went to work as usual. This is also the case in every part of the country. The Sabbath of the Icelanders, according to the ecclesiastical law of the island, begins at six o'clock on Saturday evening, and terminates at the same hour on Sunday. The females of the family at Stikkeholm, as well as those of the higher classes of people in other places, did not sit at the table, when the travellers, to whose account we now refer, were eating with the men. The master of the house always served his lady when he rose from the table. Mackenzies Travels in Iceland in 1810.

STIL de Grain, in the Colour Trade, the name of a composition used for painting in oil or water, and is made of a decoction of the lycium, or Arvigion berry, in alum-water, which is mixed with whitening into a paste, and formed into twisted sticks. It ought to be chosen of a fine gold yellow, very fine, tender, and friable, and free from dirt.

STILAGO, in Botany, Linn. Mant. 16. Juff. 445. Stilago. Gen. 608. 836. Wildl. Sp. Pl. v. 4. 714. Mart. Mill. Dict. v. 4. Alt. Hort. Kew. v. 5. 367. was so called perhaps from the supjectory permanency of its stily. The name and the genus, however, require to be abolished, the characters, except that of the berry from Rumphius, having been taken from a specimen in the Linnean herbarium, which proves merely the male plant of Antidysma axilasteria. (See Antidysma.) Indeed the Stilago diantha, Roxb.Coromand. v. 2. t. 166, most evidently agrees in genus with his Antidysma polycarpa, t. 167. We cannot without rigour, for their being described by the learned author, who well knew what Stilago was. Still more wonderful is it that Norli tal, Rheede Hort. Malab. v. 4. t. 66, should be quoted by Willdenow, without any remark, for both Stilago Bunius and Antidysma axilasteria. We cannot deny the accidental propriety of this citation, they being, though the author did not know it, one and the same plant.

STILARO, in Geography, a river of Naples, which runs into the gulf of Squillace, N. lat. 38° 21'. E. long. 16° 50'.

Gen. Ch. Cal. Pernier inferior, double; the outer of three lanceolate, spreading, pointed leaves; inner of one leaf, tubular, five-toothed, at length hardened. Cor. of one petal, funnel-shaped; tube the length of the calyx; limb
limb in four or five linear-lanceolate, nearly equal, deep segments. Stem. Filaments four,awl-shaped, inserted into the throat of the tube, longer than the limb, somewhat unequal in length; anthers heart-shaped, obtuse. Fi Gill. German superior, ovate; style thread-shaped, the length of the filaments; stigma acute. Pedic. none, except the inner calyx become cartilaginous, inclining the leaf, and falling off with it. Seed solitary.

Some plants are said to bear only male flowers.

EFl. Ch. Calyx inferior, double; the outer of three leaves; inner five-toothed, cartilaginous. Corolla funnel-shaped. Capsule of one cell and one valve, separating entire from the base. Seed solitary.

1. S. piniflora. Fine-leaved Stilbe. Linn. Mant. 305. Wild. n. 1. Thunb. Prodr. 29. (S. verbita; Berg. Cap. 30. t. 4. f. 6. Selago piniflora; Linn. Sp. Pl. 876.)—Leaves lanceolate, pungent, revolute. Spikes erect. Limb of the corolla hairy.—Native of the banks of rivulets, at the Cape of Good Hope. It seems unknown in the gardens of Europe. Commelin's Veterinella, Hort. Amst. v. 2. t. 110, barely can have nothing to do with this plant. The flower is thin, with many bright round, small, white flowers, densely clothed with whorled, spreading, ascending, rigid, pale, lanceolate, revolute, entire, smooth leaves, half an inch or more in length; dotted above; on short broad stalks. Spikes terminal, sessile, solitary, erect, obtuse, long; with a bracteas under each flower, resembling the leaves, but shorter and broader. We have never seen the flowers in perfection, which Bergius describes as white. We are not without suspicion of his having, as well as Linnaeus, confounded two species, one with longer whitish hairs upon the corolla, and shorter less pungent leaves, than what his plate represents.

2. S. ervus. Drooping Stilbe. Linn. Suppl. 441. Wild. n. 2. Thunb. Prodr. 29.—Leaves prismatic, abrupt, with a small point. Spikes drooping. Limb of the corolla smooth.—Gathered by Thunberg, at the Cape of Good Hope. The leaves are only four in each whorl, not fix, as is the foregoing. Their form is triangular or prismatic, with a funk rib. Spikes shorter than the leaf, recurved, with much larger flowers, whose limb has only four segments, all smooth, lanceolate, and acute.

3. S. ericoides. Heath-leaved Stilbe. Linn. Mant. 305. Wild. n. 3. Thunb. Prodr. 29. (Selago ericoides; Linn. Mant. 87.)—Leaves ovate. Spikes erect. Limb of the corolla smooth.—Native of the Cape of Good Hope. A much smaller floribunda than either of the preceding, with small leaves, like some Heath or Thyme, imbricated in four rows, ovate, thick, smooth, with a fangular lanceolate keel, lodged in a furrow. Spike short and erect. Flowers apparently pubescent. Calyx fringed with white wool. No figure is extant of this or the last, nor have they appeared in any garden.

STILBITE, in Mineralogy. See ZEOLITE.

The French mineralogists, after Hally, have divided the mineral called zeolite into two species, mesotype and stilbite. The latter is often called nacreous zeolite, being distinguished by its nacre luster. The properties of this mineral will be described, with the other varieties of zeolite, under that article.

This cannot be seen a very doubtful genus of the vegetable kingdom, though not more obscure than the Chaos of Limnæus, or the Hydriid of Hunter, amongst animals. Perfoon remarks that there is no spérum, or capsule receptacle, as in Sphæxia (see that article); and that a compound microscope is necessary for the determination of the different shapes of those minute granular bodies, which he knew not whether to call seel-vèrtje, or seeds, or perhaps but, all forming, to the naked eye, one uniform black mass. He defines six species.

1. S. afterdeoerm. (S. afterdeoerm; Hoffm. Germ. v. 2. t. 13. f. 3.)—Capes fillet.—This appears in the form of variously-shaped black spots, under the cuticle of trees, and is found, under a high magnifier, to contain numerous, compact, radiated bodies, composed of oblong pods, croffing each other, and divided internally into three or four cells.

3. S. ovata. Perf. Obs. Mycol. falc. 1. 31. t. 2. f. 2. (S. pyriform; Hoffm. Germ. v. 2. t. 13. f. 2.)—Capes? or seeds? ovate.—On the trunks of beech. The shape is exactly oval, but no distinct partitions, or cells, are discernible, according to Perfoon, though Hoffman's figure seems to express them.

4. S. angulata. Perf. Syn. n. 4.—Seeds minute, ovate, inclining to cylindrical. Intermediate between the leaf and the following, nearly agreeing in minuteneas with the latter.

5. S. microserm. Perf. Obs. Mycol. falc. 1. 31. t. 2. f. 3.—Seeds minute, unequally ovate, rather acute at each end.—On branches of beech, or the bark of Betula alba, &c. Various in form, roundish, ovate, or oblong, defficate of partitions.

6. S. sphéroerm. Perf. Obs. Mycol. falc. 1. 31. t. 1. f. 6.—Seeds minute, globoso.—Found on the stems of the Common Reed, Arundo phragmites, appearing to have run out of figurers in the straw, and sometimes collected into round spots.

STILBUM, from stilbe, shining, a genus of fungi, which Perfoon in his Synopt., p. 68c, thus defines. Efl. Ch. Little, talled, mucker-like fungi; with a roundish solid head, at first watersy or gelatinous, becoming generally opaque, or turbid, and it ripens.

He defines sixteen forms, distinguished on rotten wood, of which the most conspicuous and remarkable is the first.

S. birautom. Perf. Dipl. Meth. Fung. 30. Hoffm. Germ. t. 10. f. 2.—Permanent. Stalk yellowish, rough with straight upright hairs.—A pretty species, found rarely on rotten trunks of trees. This is among the largest of its genus, and may even be dried and preserved. The blisftly aspect of the field, one or two lines in height, readily distinguishes it.

We cannot perceive why this genus may not be comprehended under Micorum. See that article.

STILE, and STILES. See STYLE.

STILE, in Rural Economy, the name of a well-known contrivance for the admission of foot-passengers, without permitting the stock of the inclosures to get through. Stiles are made in very different forms and manners, in different districts, according to the nature of the materials, situations, and purposes for which they are intended. But they may be more clearly understood, by a short description of them. Where stones are in use, a file of a very simple construction is formed, by having at the bottom a thin flat stone set up edge-ways, to prevent sheep, and other small animals, getting out; and above there is a long cross stone or bar fixed, to prevent hores or cattle jumping over. Another file of a simple construction, and which is well calculated
STIL

STIL

calculated for situations where the traffic is not great, is
formed by having stepping-roads fixed in the sides of the wall.
In the Cornish style, the foundation is a stone-wall, in
which a gap is left, and stones are laid across a ditch of
some depth, made lengthways in the gap; the foot-pa-
sengers step on the stones, but four-footed animals miss
them, and fall into the ditch.
Wherever employed in forming files, they have many
different forms, according to the nature of the situ-
tions, and the ingenuity of the workmen who construct
them. Common files of this sort are made with two framed
pieces of timber set upright, part of them parallel to each
other, leaving sufficient space for a passage to pass between
them; and by a fort of upright railing set firmly into the
ground, with steps fixed through it towards the bottom
part, by means of which the passageways are enabled to get
over. There is likewise the wall file, which has some-
what the form of a small gate, swinging between two other
similar frames, which are let fall into the ground in an
angular manner; and the regular step-form, with a rail.
It is probable, too, that there are other different kinds
and forms in use in different places.

STILES, in Carpentry, denote also the upright pieces
which go from the bottom to the top in, any window or,
the like.

STIFREIRED, in Geography, a town of Austria; 7 miles N.E. of Weikendorf.

STILL, an island in the Grecian Archipelago. N. lat. 36° 37' E. long. 27° 40'.

STILICHO, in Biography, a commander who disillu-
ished himself in the decline of the Roman empire, was
of Vandal origin, and the son of an officer of cavalry in the
service of the emperor Valens. Brought up to arms, he
rose rapidly through various gradations to the post of ma-
ner-general of the cavalry and infantry of the Roman,
or at least of the Western empire. He accompanied Theodosius
in all his wars, and maintained the Roman dignity in ratifying
a treaty with the king of Persia. On his return, he married
Serena, the niece and adopted daughter of Theodosius.
Although Rufinus, who was the confidential minister of
Theodosius, was jealous of Stilicho, and wished to deprive
him in the estimation of the emperor, he was counteracted
by the influence of Stilicho's wife; so that he was
with the emperor at the time of his death in 395, and en-
trusted him with the guardianship of his two sons, Ar-
cadius and Honorius. The latter, who had the Western
empire for his share, appointed Stilicho for his prime mi-
nister; and he began his administration by renewing the
ancient alliances of the Romans with the German nations,
and establishing peace. In 398, Stilicho returned to the succour
of Greece, which was ravaged by Alaric. Having either
neglected or betrayed his trust, by suffering Alaric to
escape, he was obliged to withdraw from Greece, and was
declared at Constantinople a public enemy, with confron-
tation of all his estates in the East. Stilicho exerted himself
with vigour in recovering Africa, which had revolted from
the Western empire; and acquired new influence by the
marriage of his daughter, Maria, to the young emperor,
Honorius,—an union elegantly celebrated by Claudian, the
perpetual panegyrist of Stilicho. When the timid Honorius
was alarmed by the irruption of Alaric into Italy in the
year 403, and was disposed to quit Milan, the seat of his
government, and to retire to one of the Gallic provinci-
es, Stilicho opposed this disgraceful measure, and collecting
a powerful force, vanquished the Goths at Pollentia, and
obliged them to retreat: nevertheless Alaric, breaking
through the passage of the Apennines with his cavalry,
spread an alarm that reached even Rome, so that Stilicho
advised the purchase of his retreat from Italy with a sum of
money. When Alaric had finally departed, the policy of
Stilicho was publicly arraigned for suffering him to escape.
In 406, Italy was again invaded by a vast multitude of bar-
barians, who penetrated as far as Florence, laid siege to the
city, and reduced it to great distress. Stilicho hastened to
the relief of the beleaguered, dispersing the barbarians, forced
them to surrender, and put to death their commander,
Radagaisus, who had been taken prisoner. Although
Italy was again delivered by Stilicho, Alaric still remained
at the head of new levies of Goths, and other barbarian
warriors. Stilicho, either from motives of personal aim-
bition, or of state necessity, entered into a negotiation with
Alaric, by virtue of which he was declared master-general
of the Roman armies in Illyricum. While Stilicho was
forming a purpose to lead an army of Romans and Goths
to Constantinople, and conciliating with Alaric in making
an extravagant demand upon Ravenna, the feeble-minded
Honorius was connecting himself with a new favourite,
who succeeded in impressing the mind of the emperor with
alarms of the treacherous intentions of Stilicho. Honorius
determined to visit the camp at Pavia; and soon after his
arrival at it, a pretext was formed for massacring all the
friends of Stilicho, who occupied disdained posts in the
army and state. Stilicho received intelligence of this mea-
sure at Bologna; and a council, which he summoned, ad-
sired him to march immediately, and revenge the deaths
of his friends. Whilst he was hesitating, a Gothic chief
rushed into his camp, killed his guard, and penetrated
into his tent, whence he had but just time enough to escape.
Flying to Ravenna, he took sanctuary in a Christian
church; but being deceived by count Heraclien, who
appeared at the gates with a body of troops, and confiding
in his oath that he meant only to secure him, surrendered
himself into their hands. Upon this the treacherous count
produced an order for his immediate execution, to which
he was submitted with a firmness becoming the military charac-
ter which he had acquired. His son Eucherius was taken, after
apprehended, and put to death; and his daughter Thermi-
antia, who had succeeded her father in the imperial bed,
was divorced. Stilicho's surviving friends were cruelly tort-
ured, in order to procure the confession of a supposed con-
spiracy against the emperor; but they suffered in silence.
This catastrophe occurred in the year 408. The apparent
piety of Olympius, the new favourite of Honorius, has in-
duced the ecclesiastical historians to treat the memory of
Stilicho with great severity; but Zosimus, though upon
the whole not favourable to him, acquits him of the treason
laid to his charge; and the poetry of Claudian eulogizes
Hist.

STILL, the name of an apparatus used in distillation.
See Distillation and Laboratory. See also Alwm,
Etort, Worm, &c.

Dr. Lewis has contrived a still, adapted to his portable
furnaces, which is sufficient for the purposes of an experi-
mental laboratory. The body of the still is a wide copper
pan; and, for distillation in a water-bath, another veiled
of the samefigure is received into it almost to the top of
the space between them being nearly filled with water. Both
these vessels are of the same width at the mouth, and either
may be used as a still equally with the other: either of them
serves also, on other occasions, as an evaporating pan, a
boiler for experiments in dyeing, and other like purpo-
ses.

All the parts are made of thin copper plate, and well
tinned on the inside with pure tin. In consequence of their
thinness,
thinness, they admit of some alteration of their figure about the edges, so that though they should not be perfectly round, they are readily accommodated to one another, and fit cloze; the junction is easily made perfectly tight, by applying ordinary melt, and if required, the refined bladder, which are more convenient than luting, as being readily stripped off when the operation is finished. A short pewter pipe, with a pewter stopper fitted to it, for returning the distilled liquor, or pouring fresh liquor occasionally into the still, without the trouble of unluting and separating the vejiets, is folded into the top of the head, which, in these kinds of instruments, is the most convenient place for it. For separating, by distillation, spirituous from watery liquors, or the rectification of spirit of wine, the head is raised, by inferring between it and the breast, a thin copper pipe about two feet long. A warm and refrigeratory are necessary, as for the common still; and a glas head is requisite for some uxes, particularly for the distillation of vinegar, and such other liquors as would corrode a copper one, and impregnate themselves with the metal; in which case, the uxe of the metallic worn allo is to be avoided, and the glas or rose-ware receiver joined to the pipe of the head. Lewis’s Com. of Arts, p. 9, 10.

Still-Bottoms, in the Distillery, a name given by the traders to what remains in the still, after the working of the waff into low wines.

These bottoms are procured in the greatest quantity from the malt waff, and are of so much value to the distiller in the fattening of hogs, &c. that he often finds them one of the most valuable articles of the distillery. They might also be put to other uxes, such as the affording of a large proportion of an acid spirit, an oil, a fuel, and a fixed salt; and with some address, and good management, a vinegar and a tartar. Another very advantageous use of them, is the adding of them to the next brewing of the malt for more spirit: the increas of the produce from this is more than could easily be conceived. It also more readily dipoles the new waff to ferment, and gives the spirit a visosity that it cannot have without it; the proportion, in this case, can never exceed that of a fifth or sixth part of the whole quantity of the liquor employed. The liquor left behind in the still, after the rectifying of the low wines into proof-spirit, is also called by some by the name of still-bottoms; but this is little more than mere phlegm, or water impregnated with a few acid, and some oily parts, not worth separating, unless for curiosity. The liquor left in the still, after the rectifying of the proof-spirit into alcohol, is also of the same kind.

The bottoms of molasses spirits seem calculated for many uxes. It is very probable that the vinegar-makers would find their account in trying them, and the strong and lasting yellow colour with which they tinge the hands may recommend them to the dyers. A small proportion of them, added to the new treacle to be fermented, greatly promotes the operation, and increases the quantity of spirit.

The bottoms of the wine spirit, that is, the remainder after distilling the spirituous part from damaged wines, or wine-kegs, may be brought to afford Mr. Boyle’s acid spirit of wine, and that substance, called by Becher the medus fuscans vinii. A parcel of tartar may also be procured in very great perfection; and the lait remainder may be converted into excellent and genuine salt of tartar. The liquor may otherwise be serviceable in making vinegar and white lead. Shille’s Essay on Distillery.

Still-House. The Dutch have much the advantage of us in the structure of their still-houses, and have every thing in great readiness and neatness. The general rules in building these houses should be these:

The first caution is to lay the floor a slop, not flat, where any wet work is to be performed; it should also be well flagged with broad stones, so that no wet be detained in the crevices, but all may run off, and be let out at the drains made at the bottom and sides.

The stills should be placed abreast on that side of the still-house to which the floor has its current. The largest stills in Holland, for their greatest works, are never of that monstrous size which are constructed in England, but much more manageable and convenient, as seldom containing more than for or eight bogheads; and with such stills a single hand will perform more business than with one of a much larger size. Fronting the stills, and adjoining to the back wall, should be a stage for holding the fermenting backs, and these being placed at a proper height, may empty themselves, by means of a cock and a canal, into the stills, which are thus charged with very little trouble.

Near this set of fermenting backs should be placed a pump or two, that may readily supply them with water by means of a trunk or canal, leading to each back. Under the pavement adjoining to the stills should be a kind of cellar, wherein to lodge the receivers, each of which should be furnished with its pump, to raise the low wines into the still for rectification; and through this cellar the refined waff, or still-bottoms, should be discharged by means of a hose, or other contrivance. These are the principal things to be regarded in the erecting of a still-house for the original production of spirits; and if these rules are well observed, multifluid will be made with little more trouble than molasses; for by this means the bushes of brewing and cooling the waff, which, according to the method generally practised in England, takes up so much time and trouble, is entirely saved. Fermentation is carried on to a much greater advantage, and the quantity of spirit increased. Shaw’s Essay on Distillery.

Stillatious Oils, are such as are procured by distillation, in opposition to those got by infusion, expression, &c.

Stillingleet, Edward, in Biography, a learned prelate of the English church, was born at Cranbourn, in Dorsetshire, in the year 1635; and after preparatory education in the grammar-schools of Cranbourn and Ringdell, was elected in 1646, to be a fellow of St. John’s college, Cambridge. Of this college he was chosen fellow in 1653, and presented to the rectorcy of Sutton, in Bedforshire, in 1657, having previously received episcopal ordination from Dr. Browning, the deprived bishop of Exeter. In 1659 he published his ‘‘Irenicus, or the Divine Right of particular Forms of Church Government examined,’’ hoping, by this publication, to remove the prejudices, and consoliate the attachment of those who were alienated from the church of England. In this treatise he maintains, that Christ did not determine the form of the government of his church by any laws; that the church has adapted it to the various circumstances of time, place, and persons; that episcopacy is lawful; that in the primitive church no invariable form of church government was adopted; and that the most eminent divines, at the Reformation, did not conceive any one particular form to be necessary. In a new edition of this work, in 1662, he annexed an appendix, concerning the power of excommunication in a Christian church. The Irenicus was highly commended for its learning and moderation; but the author himself, as bishop Burnet says, deplores of avoiding the imputations of hostility to the church
which it occasioned, retracted the book, and gave way to the humours of a high fort of people, beyond what became him, perhaps beyond his own fene of things. Whilst he was employed in performing the functions of a country parson, he pretent to the public a second work, of exten-
vive learning and pertipicus style, which has been always esteemed one of the best defences of the Christian religion; and which was intitled "Origines Sacrae; or a rational Ac
count of the Christian Faith, as to the Truth and divine Au-
thority of the Scriptures, and the Matters therein con-
tained;" 4to. This work established his reputation as a
writer, so that he had a commination from Dr. Henchman, 
bishop of London, to draw up a vindication of archbishop
Laund's conference with Fisler the Jesuit; and the title of
his work was, "A rational Account of the Grounds of the
Protestant Religion;" 1664, folio, in which Dr. Tillotson
affords to be fully answerable to this appellation. Soon after,
he was elected preacher at the Rolls chapel, and in 1665
prevented by the earl of Southampton to the living of St.
Andrew's, Holborn, and appointed likewise lecturer at the
Temple. In 1668 he took his degree of doctor in divin-
ity, distinguiting himself on the occasion by keeping an
act in which he displayed great fluency in the Latin lan-
guage, and logical acuteness. At the nomination of
Charles II., to whom he was chaplain, he was nominated
archdeacon of St. Paul's, a work, which preferred him
above the archdeaconry of London, and in 1678 the
deanery of St. Paul's, which was his highest promotion
during that reign. Whilc Dr. Stillingfleet was thus ad-

dvancing from one dignity to another in the church, he was
occupied in a variety of compositions on doctrinal and con-
 tradorfer subjedec, more particularly directed against the So-
ciniens. He also published a number of tracts against the
Roman Catholics; one of the first was "A Discourse con-
cerning the Idolatry practised in the Church of Rome, and
the Hazard of Salvation in the Communion of it," 1671 ;
which provoked a great number of answers and replies.
Although much of his time must have been occupied in
controversial writings, he found leisure to present to the public
"A Letter of Resolution to a Person unsatisfied
about the Truth and Authority of the Scriptures;" which
was considered as an excellent piece of reasoning. He also
preached a sermon about the time of the Popish plot, the
design of which was to unite the Diffenters in the common
cause, and to induce them to abandon their separation from the
established church, which involved him in a contro-
versy with Baxter, Owen, and others, who were not likely to
acquiesce in his fundamental position; that, "since, ac-

cording to the judgment of divers among themselves, a con-
formity to our church's worship was not unlawful, by con-
sequence their separation must be sinful and dangerous." To
their strictures on his fermen he published a reply.

Dr. Stillingfleet extended his investigations far beyond the
limits of theological and ecclesiastical subjects; and on
occasion of the impeachment of the earl of Danby, he vindic-
tated the right of bishops to vote in criminal cases, in a trea-
tise entitled "The Jurisdiction of Bishops in capital Causes," which
proved his extensive acquaintance with parliamentary his-
tory, as well as statute and common law. A second work,
published in 1689, and entitled "Origines Britannice, or
the Antiquities of the British Churches," gave an ample view of
the origin and progress of Christian churches in Britain, since
the first introduction of Christianity in the island to the con-
version of the Saxons. In this research, Stillingfleet had
been preceded by the learned archbishop Usher, in his work
"De Ecclesiis Britannicarum Primordiis." King James
having instituted an ecclesiastical commission, summoned

STILLINGFLEET.

Stillingfleet, who had long been prolocutor of the Lower
House of Convocation, to appear before it; on which occa-
sion he drew up a "Discourse concerning the Illegality of
the Ecclesiastical Commission, in answer to the Indictment
and Defence of it," which was not published till the year
1689.

At the Revolution, the services rendered by Dr. Stilling-

fleeting the established church were recompensed by the
bishopric of Worcester, to which see he was consecrated in
October 1689; in which high station he was sedulous in the
discharge of the duties of his office, and in defending the
rights of his order by his speeches in parliament. On
the death of archbishop Tillotson, in 1664, the queen is said
to have wished for the advancement of Stillingfleet to the see
of Canterbury, but the Whigs opposed it, from an appreci-
ation "that both his notions and his temper were too
high." The bishop again engaged in controversial divinity
against the Socinians and Unitarians: and in a treatise in-
titled "A Vindication of the Trinity, with an Answer to
the late Objections against it from Scripture, Antiquity, and
Reason," he introduced some animadversions on Locke's
Essay on the Human Understanding, under an appre-
henion that the definition of subsistence, and the account
of ideas contained in that work, were unfavourable to the doc-
trine of the Trinity. The philosopher replied to the pre-

land, who is thought on this occasion to have sustained a defec-
An edition of his 50 sermons appeared in 1707,
folio.

Dr. Stillingfleet injured his constitution, which was natu-
rally strong, by his studious and fedentary life; so that repeated
attacks of the gout terminated his life on March 27th,
1699, after he had nearly completed his 64th year. He had
been twice married, and had several children, three of whom
survived him. His remains were interred in the cathedral of
Worcester, where a monument was erected to his mem-
ory, with a Latin inscription by his chaplain, the cele-
brated Dr. Bentley, in the high style of panegyric, part of
which has been thought to exceed even the just encomiums
to which this prelate was intitled. The bishop, who had a
good portion, and a lofty temper, somewhat moderated by
good sense and a knowledge of the world, had collected a
noble library, which was purchased, after his death, by
Dr. Marth, archbishop of Armagh, as the foundation of

STILLINGFLEET, BENJAMIN, grandson of the bishop of
the same name, and son of Edward Stillingfleet, M. D., who
left his father's favour by marriage, and afterwards taking
orders, settled upon a living in Norfolk. Benjamin was born
about the year 1702, and after a previous education at Nor-
wich school, was entered, in 1720, at Trinity college, Cam-
bridge, of which Dr. Bentley was then master; who, forgetting
his obligations to the family, procured the rejection of
young Stillingfleet, when candidate for a fellowship. We
may naturally imagine that the disappointed candidate should
feel resentment at such conduct, for which it is difficult to
devise a sufficient apology. The subject of our memoir
left college, and travelled to the continent; and upon his
return, passed an unambitious life, which was chiefly devoted
to the study of books and nature. Under the patronage
of lord Barrington, he obtained the post of barrack-maier
at Kennington. To Mr. Windham, of Felbrig, Norfolk,
he was more substantially indebted, being often refedent
at his house, and receiving from him an annuity, which
was considerably augmented when he became Mr. Wind-
ham's executor. He is well known as the author of several
pieces in prose and verse, particularly for "Everyday on
Conversation," which was published in the first volume of
Vol. XXXIV.

C'o

Doddley's
STILLINGFLEET.

Doddley’s Collection of Poems; and also from a volume of "Miscellaneous Tracts," printed in 1759, and containing chiefly of translations from Linnaeus’s Amphioxides Academicae. To this work were annexed valuable "Observations on Graecia," and also a "Calendar of Flora," formed upon a suggestion of the Swedish naturalist, and adapted to this climate. The poet Gray, with whom he became acquainted, mentions him in one of his letters, dated in 1761, in the following terms: "I have lately made an acquaintance with this philosopher, who lives in a garret in the winter, that he may support some near relations who depend upon him. He is always employed, consequently, according to my old maxim, always happy, always cheerful, and seems to me a worthy honest man. His present scheme is to fend some persons, properly qualified, to reside in Attica, to make themselves acquainted with the climate, productions, and natural history of the country, that we may understand Aristotle, Theophrastus, &c. who have been heathen Greek to us for so many ages." It is observed, that the term garret used by Gray is rather a disparagement of Stillingfleet’s town-lodgings at a stranger’s in Piccadilly, where he died in 1771, at the age of 60. He ordered all his papers to be destroyed at his decease. Gen. Biog.

This ingenious, learned, and worthy man, was well acquainted with the theory of music by reading and meditation; and with the practice by hearing all the best performers, and by frequenting their rambles and interchanges with Mr. Price of Foxley, Mr. Tate of Mitcham, and Mr. Smith, the disciple and successor of Handel in carrying on the oratorio, for whom Mr. Stillingfleet wrote new sacred dramas, which he set and had performed in turn with those of Handel.

His work, intitled "Principles and Power of Harmony," the most clear, agreeable, and interesting treatise on a dark, obscure, and speculative subject that we know, is nothing more than a commentary on the theoretical writings of the celebrated Tartini. It has been often observed with truth, that theory and practice are more frequently at strife in music than in any other art. Those who treat music merely as a science, without possefing the practical part, are naturally contracted in their ideas, and ufeles to professors: and, on the contrary, mere practical musicians, who have seldom had either education or leisuare to qualify themselves on the side of learning, produce nothing but crude and indigested reversion, which a man of taste in literature dildains to read. That this has been the case with some of the most able practical musicians, we can, from our own knowledge, assert. They have the ambition of puffing for men of science; they speak of Greek writers without Greek; of arithmetical proportions without figures; of ratios without geometry; and equations without algebra. The late Dr. Pepusch, a man of great learning, and of universal reading in musical compositions, attempted to explain the Greek systems; but abstruse calculations being necessary in the business, he had recourse to his friend De Motve, who was no musician, and understood the doctor as little as the doctor understood Euclid: they never met without a quarrel; for as each would talk abstruse and the other moderate, each must by turns have been abjured. The same thing happened in France between the famous Rameau and d’Alembert: at Padua, between Tartini and Padre Colombi, his friend, the professor of mathematics in that university. The work of which we are now speaking, however, seems free from such objections; as it was written by no half scholar or shallow musician; but by one possefl of all the requites for such a task.

In the author’s commentary on Tartini’s first chapter, he explains clearly the now well-known phenomenon of a single string or sound producing its own harmony, upon which Rameau has built his system of a fundamental base. (See BASS FUNDAMENTALS.) The author, in the history of this discovery, traces it no farther than the time of Mercurius, with whom he leaves it; but it seems to have been long known before his time, as the organ is constructed upon the same principle; the stops of that instrument being proportioned to each other in the same manner as the sounds above-mentioned, which are generated by a single string or tone: when the stops, known by the names of the diapason, principal, 12th, 15th, and tierce, are drawn out, every single key of an organ gives the complete chord, as, when G only is struck, and it is imagined that no other sounds are mixed with it, wind is conveyed to the pipes G, g, d, g, b, &c.

But the principal phenomenon upon which Tartini builds his system, was quite new, and discovered by himself. It is that of the third found produced in the medium by the concurrence of two sounds that can be sustained for any time upon one or two instruments, as trumpets, horns, flutes, hautbois, two violins, or one in double stops, two sounds on the organ, with only the open diapason out, &c. a third sound will be heard, which is its true fundamental base. See Terzo Suono, where thefe invisible bases will be specified to every interval, but chiefly those that are consonant. Every chord is characterized by this circle; its nature and signification in harmonies, Mr. Stillingfleet examines with great candour, and some pleasantry.

It is in the third chapter that Tartini unfolds his musical system, and treats of concords and dissonances, their nature and definition. The commentator’s remarks on this chapter are very solid and luminous.

The fourth chapter of Tartini gives the origin of the musical scale and genera, their use and consequences. In our author’s commentary upon this important chapter, he acquaints himself with great dexterity, and proves that he is not only profound in the theory of sounds, but endowed with nice feelings, and of great experience and observation, with respect to practical music.

But though we admire the ingenuity of Tartini in tracing the origin of the octave in modern music, and think, with his commentator, that it is not implanted in our nature, as it is never sung by any people out of Europe (nor would it seem so easy and natural there, if it were not for the bells and church singing in almost every Christian town and village, which indefinably teach intervals and the scale to every one that has a voice and an ear from early childhood); we regard the gamut, and its octaves and scales, as the musical alphabet; and nature never teaches an alphabet to the natives of the most civilized and polished country any more than to savages.

Our author’s praise of the harp, and wishes that there were better music for it than old and vulgar Welsh tunes, would have been highly gratified, had he lived a few years longer; for in 1771, when his book was published, a short time before his decease, the pedal harp had not been introduced or heard of in England. And it seems as if Madame Crumblitz was not only the first great performer upon that instrument in our country, but the first who had good music to perform, to shew its powers; with which she had been furnished by her husband and master.

The commentator joins with Tartini in thinking more favourably of the ancient Greek music and modes than late writers have done; and concerning Italian recitative, he gives from Tartini a curious account of its surprising effects, with no other accomplishment than a base.
In the year 1714, if I am not mistaken, in an opera performed at Ancona, there was, in the beginning of the third act, a passage of recitative, unaccompanied by any other instrument but the bafe; which raised, both in the profef{ion} and in the ref of the audience, such and fo great a commotion of mind, that we could not help staring at one another, on account of the visible change of colour that was caused in every one's countenance. The effect was not of the plaintive kind: I remember well that the words expressed indignation; but of fo harsh and chilling a nature, that the mind was disordered by it. Thirteen times this drama was performed, and the same effect always followed, and that too universally; of which the remarkable previous silence of the audience, to prepare themselves for the enjoyment of the effect, was an undoubted figure. This almost equals the miraculous powers related of the ancient Greek music. But this can never happen where the Italian language is not universally known to the whole audience.

A period of Tartini in favour of simple music, has suggested to his commentator a reflection which we cannot pass over in silence; as we are unable, implicitly, to subscribe to his opinion, that the tunes in the Beggar's Opera should be the standard of good melody, modulation, and harmony. It is true, that many of them are the tunes of our nurses, to which our ears have been accustomed from our infancy; for this reason, perhaps, ninety-nine out of a hundred of the playhouse, will prefer them to any other music. In fo mixed and popular an assembly as the audience of an English theatre, are not the majority ignorant of other music, and as likely to be prejudiced in favour of bad, as more refined ears in favour of a more polished and artificial kind of music; but would it not be the same thing with painting, poetry, and sculpture? Would not a sign-poll, highly coloured, be preferred by the ignorant to a picture of Raphael; or a jovial and balderdash song to the Essay on Man, or Milton's Paradise Lost? Simplicity almost equals the excellent and desirable thing in all the arts; but let it be an elegant simplicity, free from vulgarity and barbarism.

Why should people of refined ideas, and, if you will, delicate tastes, be governed by the ignorant and unpolished, any more than those last mentioned by the former? It has been well said, that authors and artists are the only people in this country who are not tried by their peers.

What Tartini says in favour of simplicity could never extend to such a medley of tunes of all nations being introduced into the Beggar's Opera, which are made up of Scotch, French, Italian, Irish, and English; and is a lover of music to be thought affectedly refined, who wishes for something less hackneyed and vulgar? The music in the pope's chapel, with which our author was so enchanted, could never remind him of that in the Beggar's Opera. But the moderns, and modern music, are always to be abused; it was in Plato's time; the custom has been continued by every writer on the subject; and every musician, who, like Timothens, adds a new firing to his lyre, will be found to endanger the flame; but about taste and prejudice, it has long been agreed, that there is no disputing; our habits and our feelings will ever be uppermost.

STILLINGIA, in Botany, was sent under that name to Linnaeus, by the celebrated Dr. Alexander Garden, of whom a biographical account may be found in its proper place. This genus is dedicated to Mr. Benjamin Stillingfleet, of whom we have made some mention in our account of Mr. William Hudson, and who is well known as the author of a popular book of "Tracts," relating to natural history, &c. partly translated from the writings of Linnaeus. He was an elegant scholar, an enthusiastic admirer of virtuous liberty, and a philosophical naturalist, intimately attached to the Price, Barrington, and Littleton families, as well as to some men of talents and cultivation in Norfolk. A M.S. volume of his advice to the late distinguished politician Mr. Windham, we have seen in the Felbrigg library.—(See the preceding article.)—Linn. Mant. 19. Schreb. Gen. 698. Willd. Sp. Pl. v. 4. 598. Mart. Mill. Dict. v. 4. Ait. Hort. Kew. v. 5. 537. Walt. Carol. 259. Pursh 609. Juss. 590.—Claris and order, Monocotyledones. Nat. Ord. Tricoce, Linn. Euphorbiae. Jull.

Gen. Ch. Male, Cal. Perianth leon-flowered, coriaceous, hemispherical; petal-shaped, entire. Cor. of one petal, tubular, funnel-shaped, gradually dilated upwards, much narrower than the calyx; its margin undivided, but fringed in a jagged manner. Stamina. Filaments two, thread-shaped, twice as long as the corolla, spreading at the summit, very slightly connected at the base; anthers kidney-shaped, of two round lobes.

Female, at the base of the same spike, Cal. Perianth as in the male, but single-flowered. Cor. superior, shaped as in the male. Ptil. German roundish, between the calyx and corolla; stigmas three, dilated, recurved. Peric. Capsule somewhat turbinated, bluntly triangular, three-lobed, of three cells, surrounded at the base by the enlarged calyx, sessile, oblong, obtusely triangular, marked on the inner side with a transverse scar.

Ob. The "two cup-shaped glands," which Schreber, after Walter, describes in the male flowers of the original species, appear to be either a bract, or abortive calyx. These perhaps contain some fruit.

3. S. fischeri. Poplar-leaved Stilligina, or Chineese Tall-tree. Michaux, ibid. Willd. n. 3. Pursh n. 3. Ait. n. 3. (Croton fischeri; Linn. Sp. Pl. 1434. Richius chinense fischeri, polupi nigree folio; Pati. Ger. Sp. 34 f. 5. Euonymus affinis Sinarum, polupi nigree folio, &c.; Pluk. Amath. t. 7. f. 500. f. 2.)—Stem arborescent. Leaves rhomboid, pointed, entire. Native of China, in moist situations. Now said to be naturalized on the sea-coast of South Carolina, flowering in July and August. It has been known more than a century in our florists, or rather greenhouses. The habit is that of a Poplar, with smooth leaves, on long slender flanks. Spikes terminal, dense, cylindrical. Male flowers with a roundish scale or gland at each side of the calyx, analogous to what we have mentioned after the Eff.
STILO, Ital. Style, in Mufa, a peculiar manner of fingering, playing, or composing. In ancient ecclesiastical music, the stiles of Palestrina, Tallis, and Bird, are venerable, and highly esteemed by masters, and all good judges of that species of composition. In oratorios, the stiles of Handel, Leo, and Jommelli, are marked with an original spirit of excellence; the opera stiles of Pergolesi, Halé, Piccini, Sacchini, and Paisiello; in symphonies, the elder Stamitz, the Manheim school, Haydn, Mozart, and Vanhal at the Vienna school, are original; as are the quartets of Haydn; the quintets of Boccherini and Mozart; the harpischord pieces of Domenico Scarlatti, Alberti, Schober; the piano forte pieces of Emanuel Bach, Haydn, and Mozart; but the comic operas of this last must be enrolled among the first for genius, originality, and good composition, that modern times have produced.

The town of Naples, in Calabria Ultra, 17 miles N.N.E. of Gerase. — Alto, a town of European Turkey, on the E. coast of Morea. N. lat. 36° 55′ E. long. 23° 4′.

STILBOTATUM, in Architectura, denotes the body of the pedestal of any column.

STILPO, in Biography, a Grecian philosopher, who was a native of Megara, flourished in the third and fourth centuries B.C., and is said to have died after the year 294 B.C. He is considered as belonging to the Megarian sect, and to have been a disciple of one of the successful of Euclid of Megara. In his youth he is represented as having been licentious; but having corrected his natural propensities by the moral precepts of philosophy, he acquired reputation among philosophers, and became distinguished for his sobriety and moderation; and also for his eloquence and skill in dialectics. When Ptolemy Soter captured Megara, he presented Stilpo with a large sum of money, and invited him to his court; but the philosopher returned the greater part of this money to the people of Megara, and chose to retire during Ptolemy's stay at Megara to the island of Egina. When Demetrius, son of Antigonus, took Megara, the folders were ordered to spare the house of Stilpo, and to return any thing that might have been precipitately taken from him. The philosopher being required to give an account of those effects which he had lost, replied, "that he had lost nothing; for no one could take from him his learning and eloquence." To the conqueror he recommended himself by the pathetic manner in which he incited upon him the exercise of humanity. So great indeed was his fame, that when he visited Athens, the people ran out of their shops to see him; and even the most eminent philosophers of Athens took pleasure in attending upon his discourses. Nevertheless, he excited prejudices by not paying respect to the Athenian superstitions, of which an infatuation or two occurred during his abode at Athens. Having asked a person, if Minerva, the daughter of Jove, was a deity? and being assured that she was, he rejoined, "but this before us (referring to the statue) is not the Minerva of Jove, but of Phidias, and therefore no deity." For this speech he was carried to the court of Areopagus, and ordered immediately to leave the city.
When Crates put the question to him, whether the gods took pleasure in prayers and adorations? experience having taught him caution, he replied, "you fool, do not question me on this subject in the public street, but when we are alone." But there is no proof of Stilpo's infidelity with respect to the existence of a supreme divinity. Some of his peculiar doctrines were, that species, or universal, have no real existence, and that one thing cannot be predicated, or affirmed, of another; and that in using the word "man" as an universal term, we speak of nothing; for the term signifies neither this man, nor that man, nor applies to any one man more than another. In order to prove that one thing cannot be predicated of another, he said, that "goodness" and "man," for instance, are different things, which cannot be confounded by asserting the one to be the other: he farther argued, that good-ness is an universal, and universal have no real existence; consequently, since nothing cannot be predicated of any thing, good-ness cannot be predicated of man. Some have supposed that Stilpo was not serious in this kind of reasoning, and that it was his intention merely to tetch the sophistry of the schools. If he be serious, it could not be wholly without reason that Glycera, a celebrated courtezan, when she was reproved by Stilpo as a corruptor of youth, retorted the charge upon him by saying, that he spent his time in filling their heads with sophistical quibbles and useless subtleties. On moral topics, Stilpo is said to have taught, that the highest felicity consists in a mind free from the dominion of passion, a doctrine similar to that of the Stoics. He lived to a great age, and is said to have hastened his final departure by a draught of wine. 

STILTON, in Geography, a village and parish in the hundred of Norman-Cros, and county of Huntingdon, England. The houses are situated on the sides of the high North road, in a flat country. The population of this place is 1800, and in the succeeding 11 years which occurred before the next report, it appears to have increased to 663 inhabitants and 107 houses. This village is chiefly noted for a peculiar species of cheese, which obtained the name of Stilton from having been first fold here; but it is manufactured mostly in certain districts out of Leicestershire. In a fortnight part of this cake is generally consumed, and is in a cheaper price. The usual retail charge is now 12. 6d. per pound. Each cheese is made of about 12 lbs. weight, and is formed in a deep round vat.

The great Roman road, called Ermine-street, intersected this parish from N. to S. between the two flations at Godmanchester, called Durobridge, and at Caistor, called Durolin-ponte. About one mile N. of Stilton is Norman-Cros, where very extensive barracks and a prison were erected during the late wars. The latter was appropriated to French prisoners, and several thousands were confined here at the time of ratifying peace.

South-west of Stilton, about one mile and a half, is Denton, the seat of the Cotton family, and the birth-place of the celebrated antiquary Sir Robert Cotton. (See Cotton.) This family, who retained large possessions in the north of Huntingdonshire, had formerly another estate, designated Connington, at a short distance south of Denton, and many of the descendents of the Cottons are buried in Connington church. Some fragments of the old manor are remaining. It is now the seat of the family of Heathcote. — Beauties of England and Wales, vol. vii. Huntingdonshire, by E. W. Brayley.
STI

kingdoms; among which may be enumerated all the aromatic plants, with their seeds, bark, and roots, the balsams, gums, and essental oils, procured from them; ammoniac, &c.

However these stimulant substancess may have contributed to the sensual gratifications of mankind, there cannot be a doubt that they, especially the various amnestic matters, have contributed quite as largely to their pains, difeases, and vices. The derangements of the functions, and ultimately of the structure, of some of the most important organs of the body, which continued or excessive stimilation induces, are well known, as well as the disorder of intellect, and the distortion of the moral principle, which so frequently refult from it. But upon these topics it were useless to enlarge. With respect to the medicinal employment of stimulants much might be said; for although the rational and observant part of the profession make a very sparing use of them in practice, they experience much difficulty in counteracting the mischiefs which popular and vulgar medical prejudices are constantly inflicting by cordials, and corrosives, and by the use of heating and irritating diet. There are few morbid conditions in which the constitution is benefitted by stimulants. In all difeases that are called nervouss, some organ or other is deranged in its structure or functions, most commonly the stomach, bowels, liver, or uterus; and he who attempts to remove the lowness and languor by stimulants, while the function or structure continues disturbed, will only make the patient worse. The Bustainable sytem, whose founder was practically too fond of the diffusible stimulants to fee clearly upon the subject, contributed to prolong the reign of stimulation in medicine, longer than unbiased reason and experience would have maintained it.

Gentle stimulants, employed with proper caution and regulation, are chiefly valuable under those circumstances of debility, which succeed fevers, hemorrhages, and other violent difeases, when the morbid action has ceased, and no organic disorder remains. The powers of the constitution often languish under such circumstances; the circulation is feeble, and the digestive functions weak; and the muscles, therefore, very slowly recruit their vigour and stimulat. Under such a condition of tardy convalescence, these functions are materially assisted by a supply of gentle stimulation; and it is then principally that stimulants are useful and safe.

STINCHER, in Geography, a river of Scotland, which runs into the sea at Ballantrae, in the county of Ayr.

STING, AEDULUS, an apparatus in the body of certain insects, in form of a little spear, serving them as a weapon of offence.

The sting of a bee, or wasp, is a curious piece of mechanism; it consists of a hollow tube, at the root of which is a bag full of sharp penetrating juice, which, in stingling, is injected into the flesh through the tube.

Within the tube, Dr. Derham has observed, there lie two small sharp bearded spears; in the sting of a wasp, he told eight beards on the side of each spear, somewhat like the beards of fish-hooks.

STI

One of these spears in the sting, or sheath, lies with its point a little before the other, to be ready, as should seem, to be first darted into the flesh, which once fixed, by means of its foremoat beard, the other then strives in too; and so they alternately pierce deeper and deeper, their beards taking more and more hold in the flesh: after which the sheath, or sting follows, to convey the poison into the wound, which, that it may pierce the better, is drawn into a point, with a small slit below that point, for the spears to come out at.

By means of these beards it is, that the animal is forced to leave its sting behind it, when disturbed, before it can have time to withdraw the spears into its scabbard. See Anatomy, &c. of Bees.

STING, or STITCH, a disagreeable smell exhalating from a corrupted or other body, and which is prejudicial to the nose and brain. A stinking breath is usually the result either of diseased lungs, or else of scorbative gums, &c.

A stinking nose, feter maris, is the result of a deep ulcer within the nose, whence arise fetid fæces, &c. Its cause, according to Galen, is a sharp putrid humour falling from the brain, on the processus mammillares. This is reckoned, by the civilians, one of the legal causes of annulling marriage.

STINK-HORN, in Botany. See PHALLUS.

STINK-POSS, an earthen swell charged with powder, and, other inflammable and suffocating materials, with a lighted fuse at the aperture, thrown on board an enemy's ship in the action of boarding.

STINKING HOUND, in Agriculture, a common weed in hedges and rubbishy places, of the more troublesome perennial kind. By the Swedes it is considered as an universal remedy in the diseases of cattle. See BALLOTA NIGRA.

STINKING-ILIS, a name sometimes provisionally applied to a disease of the brisky kind, often met with among sheep in some situations. See STOMACH-ILL.

STINKING ISLAND, in Geography, a cluster of islands near the E. coast of Newfoundland. N. lat. 40° 28'. W. long. 52° 30'.

STINOS, an island in the Grecian Archipelago, about six miles in circumference; 6 miles S. of Naxia. N. lat. 46° 52'. E. long. 25° 33'.

STINT, Tringa Cinclus of Linneus, in Ornithology, the name of a small bird common about the sea-floors in many counties of England, and seeming to be the same as the Cinclus Prior of Aldrovand, and the scianios, or junco of Bellonius, called by the French avocet de mer, the sea-lark; and by Pennant, purre.

It is somewhat smaller than the common lark, and in shape resembles the smaller rime. Its beak is black, slender, and straight; its legs of a dusky green, the toes being divided to their origin; the head and hind part of the neck are ash-coloured, marked with dusky lines; a white streak divides the bill and eyes; the chin white; under side of the neck mottled with brown; the back of a brownish ash-colour; the breast and belly white; the coverts of the wing and tail of dark brown, edged with light ash-colour or white; the greater coverts dusky, tinged with white; the upper part of the quill-feathers dusky, the lower white; the two middle feathers of the tail dusky, the rest of a pale ash-colour, edged with white.

These birds come in prodigious flocks to our coasts during the winter: in their flight they perform their evolutions with great regularity; appearing like a white or dusky cloud, as they turn their breasts or backs towards you.
you. They leave our flowers in spring, and retire to some unknown place to breed. They were formerly a well-known dish at our tables, under the name of flints.

Pennant.

STINTER, in Geography, a river of Switzerland, which runs into the Thur, near Bifchoff-Zell.

STTO, a town of Naples, in Principato Citra; 16 miles S.W. of Cangiano.

STIP, in Ichthyology, a name given by the Dutch in the East Indies to a fish of the class of our European ones which has a two-back-fins, the anterior of which is prickly, the hinder not so. Its face is spotted, and its fish very delicate, and well tafted. It is generally caught by hooks.

Ray.

Gen. Ch. Cal. Glume single-flowered, of two valves, pointed valves. Cor. of two valves; the outermost terminated at the tip by a very long, twisted, erect awn, pointed at the base; inner valve long the outer, awnless, linear. Nectary of two linear-lanceolate, membranous scales, gibbous at their base. Stam. Filaments three, capillary; anthers linear. Pila. Germen oblong; styles two, hairy, united at the base; stigmas two, linear, linear. Peric. none, except the glume adhering to the seed. Seta solitary, oblong, covered by the corolla.

Obl. Linnaeus remarks that the genus is distinguished by the awn of the corolla being connected by a joint to the extremity of the glume.

Eff. Ch. Calyx of two valves, single-flowered. Outer valve of the corolla terminated by a very long awn, pointed at the base.

1. S. penna. Soft Feather-grasses. Linn. Sp. Pl. 115. Engl. Bot. t. 1356. Knapp. t. 38. —Awns feathered. Native of many parts of Europe, and admitted into the British Flora on the authority of Dillenius, to whom specimens were sent from Wettmoreland, said to be gathered on lime–stone rocks. The plant has, however, never been detected since in this country. It flowers in June. Root perennial, fibrous, tufted. Stems a foot high, leafy, smooth, fimbriated, jointed. Leaves upright, long, slender, acute, rough-his, their sheaths very long, dilated, embracing the stem, fimbriated, smooth, shining on the upper side. Stipa lanceolate, adhering to the leaf. Flowers in a simple panicle, rising from the sheath. The valve of the corolla, being very sharp and barbed, works its way into the ground, and the awn then separates from it by means of the brittle joint.

"In curious gardens this elegant plant is cultivated for the sake of its plump awns, which are sometimes worn by ladies as feathers, or used to decorate the chimney-piece in winter, the air of a room keeping them in continual motion."

STIPA.

branched, spreading *panicle*. **Corolla** rough at the top. *Cavanilles* rightly determined the plant of Vahl.

10. **S. ovata**. Oat-Feather-gras. Linn. Sp. Pl. 116. (Andropogon folio superiori fpathaceo; Gron. Virg. 153.)—Awns naked. Calyx equal to the seed in length.—Native of Virginia. **Stems** slender. Upper leaf ventricose, the length of the **panicle**, which is composed of conjunctive, single-flowered *flasks*. **Leaves** frayed, smooth. This **grass** resembles *Avena fatua* in habit, but is smaller.

11. **S. membranacea**. Membranaceous Feather-gras. Linn. Sp. Pl. 116. Wildl. n. 11.—Flower-flasks dilated, membranaceous.—Native of Spain. This species is also like an *Avena* in habit, and is scarcely a foot in height. **Stem** smooth, thread-like. **Panicles** simple, scarcely subdivided, loose, feathery. **Flowerv-flasks** convoluted, bluish. **Awns** of the calyx the length of the **glume** of the corolla. **Linnaeus** in his *Mannta* calls the *panicle* a racemus, and observes that the upper flower but one is sessile. This is mentioned in Fl. Brit. 119, as certainly a *Festuca*, very near to *uniglumis*, if not the very same.

12. **S. barbata**. Bearded Feather-gras. Mart. n. 12. Desfont. Atlant. t. 27.—Leaves rigid, frayed on one side. **Panicle** lax, elongated. Awns very long, bearded from the base to the tip.—Native of uncultivated hills in Barbary. Very like *S. ovata*, but differs in having rigid, glaucous, flatish leaves, frayed on one side, wider, tereated, with a very long awn, hairy all over.

15. **S. canadensis**. Canadian Feather-gras. Lamarck n. 12. Pursh n. 2. (S. juncea; Michaux Boreal-Amer. v. 1. 1803.)—Leaves thread-shaped, very long. **Panicle** spreading. Calyx one-third the length of the corolla. **Awns** straight, naked.—In sandy fields, from New Jersey to Carolina, flowering from June to August. The silky purple *panicles* exceed in beauty every other **grass**. Pursh.

17. **S. exsativa**. Spreading-flowered Feather-gras. Lamarck n. 18. Pursh n. 6.—Leaves frayed, smooth, rather glaucous. Spikes alternate, panicled, spreading. Flowers distantly, sessile. **Calyx** longer than the corolla. **Awn** very short, naked.—Found in Carolina, by M. Bofc. **Panicle** lax, eight or ten inches long, of whole very long capillary branches supports a slender spike of alternate very small flowers.

18. **S. panicoides**. Panic Feather-gras. Lamarck n. 19.—Leaves leaticose, smooth. **Panicle** contracted, of few flowers. **Awn** naked, thrice as long as the calyx. **Seeds** lenticular.—Gathered by Commerson at Monte Video. This has rather the habit of a *Panicum*, with straight, smooth **leaves**, and long very slender **flanks**.

19. **S. fria**. Clove-branched Feather-gras. Lamarck n. 20. Pursh n. 17.—Leaves lanceolate. **Panicle** elongated, with jointed very close branches. **Awn** naked, somewhat zigzag.—Gathered in Carolina, by the late Mr. Frazer. A tall plant, with reed-like **leaves**, and the **inflorescence** of an *Andropogon*.* Purpure.*

20. **S. mollis**. Downy-flowered Feather-gras. Brown n. 1.—Leaves involute, with downy sheaths. **Corolla** finely. **Awn** feathery from the base, beyond the joint; naked at the end.—Found by Mr. Brown near Port Jackson, New South Wales.

21. **S. sumbharbata**. Half-bearded Feather-gras. Br. n. 2.—**Awn** feathery from the base to the joint; naked beyond. **Corolla** finely. **Calyx** coloured, roughish.—Native of Van Diemen’s land.

22. **S. pubescens**. Downy-jointed Feather-gras. Br. n. 3.—Leaves involute, with a short stipula. Joints of the **stem** downy. **Awn** very finely downy below its joint. **Corolla** finely. **Calyx** abrupt, somewhat jagged.—Gathered near Port Jackson, by Mr. Brown.

23. **S. ferruginea**. Joints-feathered Feather-gras. Br. n. 4.—Leaves involute, smooth like their sheaths. **Stipula** elongated, undivided, naked. Joints of the **stem** smooth. **Panicle** lax. **Awn** naked, bent. **Corolla** downy. **Calyx** smooth, with long tapering points.—Native of New South Wales, and Van Diemen’s land. **Brown**.

24. **S. elegans**. Elegant Feather-gras. Labill. Nov. Holl. v. 1. 23. t. 29. Br. n. 5.—**Awn** naked. Branches of the **panicle** compound, feathery.—Gathered by Labillardiere at Cape Van Diemen. A yard or more in height, branched, with a solid, rather woody, **stem**. **Leaves** involute, with tumid sheaths. **Panicle** ample, rather spreading; its branches slender, once or twice forked, finely feathery throughout. **Calyx** longer than the **corolla**, downy. **Awn** long, tapering, smooth; spiral at the bottom.

26. **S. arvensis**. Joints-feathered Feather-gras. Br. n. 7.—**Stem** compressed, smooth and even like the sheaths. **Leaves** involute. **Stipula** elongated, naked, somewhat notched. **Awn** naked, very long, nearly straight. **Corolla** finely.—Gathered by Mr. Menzies, on the south-west coast of New Holland.

27. **S. micrantha**. Minute-flowered Feather-gras. Br. n. 8. Cavan. Bev. v. 5. 42. t. 457. f. 2?—**Stem** branched, smooth as well as the sheaths. **Leaves** nearly flat, rough. **Awn** naked. **Corolla** smooth, nearly feathery. **Calyx** pointed.—**Gathered near Port Jackson, by Mr. Brown**, who has some doubt respecting *Cavanilles*’ synonym. The latter describes his as a New Holland plant likewise, flowering in April. The **stem** is slender, a foot and half high, erect, with three or four reddish-brown joints. **Leaves** rather short, with long sheaths. **Panicle** four inches long, dense, with short branches like a spike. **Flowers** very small, smooth, each with a bent **awn**, not an inch in length.

28. **S. eminens**. Tall Feather-gras. Cavan. Bev. v. 5. 42. t. 457. f. 1.—Lamarck n. 27.—**Stem** and sheaths very smooth, frayed. **Leaves** flat. **Awn** naked. **Corolla** downy.
downy, Calyx pointed.—Native of Mexico, near the town of Chalma, flowering in August. The stem, three feet or more in height, is nearly covered by the long sheaths of the still longer leaves. Panicule lax, compound, a foot in length. Outer valve of the corolla very downy all over. Awn an inch and half long, bent towards the middle.

29. S. humilis. Dwarf Feather-gras. Cav. 1c. v. 5. 41. t. 466. f. 1. Lamarck n. 3.—Leaves convolute; the floral one with an inflated sheath, and taller than the panicule. Awn naked at the base; feathery below the joint.—Native of South America, near Port Delire, in a barren soil, flowering in December. Stems several, from four to six inches high, slender, smooth, hairless. Lower leaves slender, involute, awl-shaped; the upper one with a long swelling sheath, embracing the panicule, which does not rise so high as the leaf itself, and is scarcely branched, consisting of but eight or nine flowers, on short smooth stalks. Calyx whitish, very acute, more than thrice as long as the corolla. Awn with a series of long white feathery hairs, below its joint.

30. S. ukranensis. Tartarian Feather-grass. Lamarck n. 22. III. Gen. v. 1. 157.—"Tifia; Gueudard. Mem. v. 1. t. 19. c. 1. 23."—Leaves channelled, keeled. Awn naked at the base, very acute, more than thrice as long as the corolla. Native of the Ukraine. The radical leaves are copious, forming dense tufts. Stem two feet high. Panicule eight inches long, a little drooping, with almost setaceous branches. Calyx reddish, with pale papery points. Corolla downy at the base, with a straight, naked, capillary awn, four or five inches long. Horsetails are said to be very fond of the feeds.

STIPEL, in Geography, a town of Prussia, in Oberland; 9 miles N.N.W. of Soldan.—Alfo, a town of Germany, in the county of Mark; 3 miles S. of Bockum.

STIPEND, Stipendium, among the Romans, signified the name with tribute; and hence stipendarii were the name with tributarii.

STIPES, in Botany and Vegetable Physiology, an old Latin word for a flake, or the trunk of a tree, is technically used for the flake of a FROND; see that article. Thus the flake of a fern is a true Stipes. The same term is also used in fungi, for the flake of an agamic, &c.; but never for any thing except cryptogamous plants.

STIPES, Stipite, Stipitum. See NATIVI.

STIPPING, in engraving on copper by means of dots; and is contradistinct from this word flippeting, from that mode of art which consists of courses of continued lines. The dots in flipped engravings are either round, that is to say, each dot forms a small cone in the copper, whose apex is downward; or they are angular, each dot forming a peak, or small isosceles triangle, on the surface of the plate; or, when the dot conists of more than one of these peaks, (as is commonly the case in engraving in the chalk manner,) its form is of course multangular.

The round dots in flippeting are performed by means of a dry needle, or an etching-point; and the angular dots by means of that well-known steel instrument which is termed a graver. Stippeting with the graver is also much used in the art of engraving on wood.

It has happened unfortunately for the public and for this branch of engraving, that some thirty or forty years ago, while it was imperfectly known and practised, it was much sought after by the English traders in art, on account of its cheapness, and the novelty which then rendered it attractive; and that now,—so fickle is taste or fashion, and such its unhappy influence on art; so crafty are the majority of dealers, and so heedless the majority of the public;—now

STI

chall-engraving is improved, it is neglected. In the hands of the elder Schiavonetti, Cardon and Holl, it acquired a variety, a rich and harmonious copiousness, and an energy it had not before disdained; of which "The Landing of General Abercrombie's Army in Egypt," after De Loutherbourg, and "The Woman taken in Adultery," after Rubens, are feliciteous examples.

In the former of these, the water, lily, smoke, broken ground, and other passages of the landscape part of the performance (which had hitherto opposed so many difficulties to the progress of chalk-engraving), are scarcely less happily discriminated than they would probably have been, had Schiavonetti employed the line-engraver's art, in which he was so great a proficient: but it is observable, that the clearness of the water, the crumbliness of the ground, &c. are in a great degree owing to the flipping being wrought into lines, such as are usually hatched in drawing with chalks.

The best line-engravers have always, from the very infancy of the art, intermingled with their work a large portion of flipping. The works of the celebrated portrait engravers of France more especially abound with it. And the best line-engravers have either mixed positive lines with their flipped work, or wrought their flipping into courses of chalky lines, and disdained the work above-mentioned by Schiavonetti, and in the draperies of Cardon's print of "The Woman taken in Adultery."

In our account of the ENGLISH School of Engraving, we have asserted that the modern improvements in chalk-engraving have been effected chiefly by living professors; but Schiavonetti and Cardon are now no more.

STIPPING is a term also used by miniature painters, to express the minute touches of colour laid on with the points of hair-pencils, with which their works on ivory for the most part consist, and which give that mottled or granulated surface to miniature pictures which is more or less obvious, and in which the granulation is larger or smaller in the different works of this species; serving to discriminate the style of execution of one artist from that of another.

STIPULA, in Botany and Vegetable Physiology, an ancient Latin word for a flower, as well as for the flowers remaining upon straw or reeds. Linnæus has adopted it for those appendages to the herbage of plants, which are so many inflorescences, though not presint in all. See fulcra.

STIPULATION, in the civil Law, the act of stipulating, that is, of treating, and concluding terms and conditions to be inferred in a contract.

Stipulations were ancienly performed at Rome with abundance of ceremonies, the form of which was that, one party should interrogate, and the other answer, to give his content, and oblige himself.

By the ancient Roman law, nobody could stipulate but for himself; but as the tabellones were public servants, they were allowed to stipulate for their masters; and the notaries, succeeding the tabellones, have inherited the same privilege. The stipulation had its origin in the lex Aquilia, and another law of the emperor Augustus. See Satisdictio.

The word is formed from the Latin stipula, a straw, because in making a faic, a straw was given to the purchaser, in sign of a real delivery; which custom is still retained in some parts of France, particularly at Verdun. The custom always has been on this occasion, for the two parties to break a straw between them, and each take his moiety, which they afterwards joined again, to recognize their promise.

STIPULICIDA, in Botany, from stipulae, the appendix.
ages of the leaves, and cedo, to cut, because the stipulae are divided into many fine segments, a supposed genus of Michaux, Fl. Boreal.-Amer. v. 1, t. 26. t. 6, of which he there describes and delineates one species, S. fetacea. This is Polycarpum stipulifidum. Pursh 90, after Peron. It occurs in barren gravelly soil of Lower Carolina, flowering in May and June. The root is annual. Stem erect, very slender, a foot high, repeatedly subdivided in a foxtail manner, with a pair of small feather stipulae under each joint. Leaves all radical, small, ovate, ifalked. Flowers minute, three or five together in each little terminal tuft.

STIRI, in Geography, a town of European Turkey, in the province of Livadia; 9 miles south of Livadia.

STIRIA, in Ancient Geography, a small island near the isle of Cyprus, on the northern coast, towards the west, in a small gulf, between the promontory of Acadus to the N.W. and the town of Atnaonoe to the S.E.

STIRIA, or STIRIA, in Geography, a duchy in the empire of Austria, bounded on the north by the archduchy of Austria, on the east by Hungary, on the south by Carniola, and on the west by Carinthia. It is divided into Upper and Lower. Upper Stiria is bounded on the north by Austria, on the east by Hungary, on the south by Lower Stiria and Carinthia, and on the west by the archbishopric of Salzburg; and is about 110 miles in length from east to west, and from 25 to 45 in breadth from north to south. Lower Stiria is bounded on the north by Upper Stiria, on the east by Hungary and Croatia, on the south by Carniola, and on the west by Carinthia; its extent from north to south is about 80 miles, and about 48 from east to west. Upper Stiria contains many lofty mountains, but, by the industry of the inhabitants, the whole country is pretty well cultivated; inasmuch that, in many places, the very highest tops of the mountains are inhabited. The people who dwell in these parts in winter, when large quantities of snow fall, are for several months kept as it were prisoners; and even in general seldom come down from their heights. By continual colds too they are habituated to the cold. It is very astonishing, that amidst these mountains and steep heights they are able to succeed with the plough, and that the eminences themselves are likewise fertile. They cultivate a fine sort of wheat, which is sufficient not only for the supply of their own necessaries, but in some measure also for sale. They have, in particular, large breeds of cattle, wild fowl, game, and chamois: the brooks and lakes, of which there are many situated between the high rocks, are rich in fish. In some places too are small vales; and the inhabitants endeavour to avail themselves of every spot of earth. The mountains contain silver, lead, copper, and, in particular, iron. The iron-mines have been already worked above one thousand years, and still continue rich. The Stirian steel is highly valued. The forests with which the ridges of the mountains here are covered, yield in sufficient quantity the wood necessary for the smelting-huts. Silver was formerly dug; but ever since the year 1588, the mines have been filled with water. In the mountains, likewise, are hot-baths and medicinal springs. At Aussee are some good salt-works. The principal rivers which run through this country are the Muehr and Ena. Judenburg is the capital. Lower Stiria contains fewer mountains, and more champaign: the soil is generally fertile, and on the hills is produced some good wine. In it are hot-baths and medicinal springs. This part of the country is watered not only by the Muehr, but also by the Drave and Save. Grat is the capital. In the whole duchy are nearly 120 towns, and 500 citadels: many of the last stand on the highest summits of the rocks. The highways are good, notwithstanding the country is mountainous. The language is very rough. The inhabitants of the quarter of Cilley are Winds or Wends, and speak the Wendish language, which is in use even among the common people, for some miles from Grat. Those who are but a small degree removed from the common rank speak Wendish, German, and Italian, and the principal inhabitants also French. No other doctrine, or worship, was till lately permitted in all this country, excepting that of the Roman Catholic. At Seckau is a bishop, who bears the title of a prince of the holy Roman empire; he is subject to the archbishop of Salzburg, whose general vicar he also is through the greatest part of Stiria. The most important manufactures in the country are the iron and steel works, the produce of which is exported in great quantities. Stiria was formerly a part of Carinthia, but in the eleventh century was separated from it, and made a peculiar mark. The number of inhabitants, as stated by M. Marcel-de-Serres, (Voyage en Autriche, &c. published at Paris in 1814,) was 800,000.

STIRIS, in Ancient Geography, a town of the Phocide, situated in the environs of the frontiers of Boeotia. Here was a temple dedicated to Ceres Stiritis: the statue of the goddess was of fine marble, holding a flame in each hand. Ceres was highly honoured in this place. Pausanias.

STIRK, or STUK, a term used among country people for a young ox or heifer.

STIRLING, formerly Stirling, in Geography, an ancient town, and capital of the county of Stirling, Scotland, is noted, in the annals of Scottish history and topography, for many important events connected with its castle, and for the peculiar situation of that and its other buildings. Like the castle of Edinburgh, that of Stirling is erected on the summit of a craggy precipice; and the town is built and disposed along the ridge of a hill, which slopes to the north and south, and is very abruptly terminated at the west. The origin of this fortress is not recorded, but it is evidently of remote date. Border wars generally occupied its inhabitants till the accession of the Stuart family to the throne of Scotland; whence the ancient name of Strirling arose, it is thought, from the frequency of strifes in its vicinity. The ready communications between the northern and southern parts of Scotland, by means of the bridges and fords in this neighbourhood, rendered the possession of Stirling castle always an object of great importance. From its hill may be viewed two of the most celebrated scenes of Scottish triumph, the fields of Falkirk and of Bannockburn.

The history with respect to the incorporation of the town is wholly unknown: the earliest charter which is extant bears the name of Alexander I.; but as this only confers some additional privileges, it is supposed that the town existed at a much earlier period. About the middle of the twelfth century, Stirling was honoured as a royal residence, for David I. kept his court here, to be near the abbey of Cambuskenneth, which he founded in 1147. Some marks of regal magnificence yet remain about the castle.

James III. afterwards raised Stirling higher into notice, by making it the principal place of his habitation. He adorned it with a magnificent hall for parliamentary meetings, of which the walls alone remain. Pope Alexander VI. when it became a kingly residence, added a royal chapel adjoining the former building. Within the towers of Stirling, several of the Scottish monarchs were either born, or underwent the ceremonials of coronation; and it became a place of retirement for the unhappy Mary, and for the minority of James VI. under his tutor Buchanan. In the north-west part of this edifice, James II., about the middle of the
15th century, shuttered William, earl of Douglas; and the cloist is still designated by the name of the Douglas room.

Near the castle is a flat piece of inclosed ground, once appropriated for tournaments, and a rock, whence the female spectators used to behold the valour of the knightly champions, now called "The Ladies Rock." On the south side of this fortress, surrounded by a stone wall, is the park; at the east end of which, vestiges of the royal garden, and a mount of earth, the frequent scene of the amusements of James IV, are yet visible. This park, with several other neighbouring pieces of land, form the custumary of the castle.

Since the reign of queen Anne, when this building was enlarged, and a battery erected, and called by her name, no material alterations have taken place: it is now commonly commanded by the usual routine of military officers, and garrisoned by 100 men.

The houses and public buildings which constitute the town are chiefly of an ancient style; particularly that begun by the earl of Marr, when regent of Scotland, in 1570, yet unfinished, and entitled Marr's work; and one known by the name of Grey's lodging, some time possessed by that family, but originally erected by Alexander, vicount of Stirling. Two churches, denominated from their situations the east and west kirks, have also a claim to antiquity: they constituted, it is supposed, at the period in which they were built, but one edifice, and were connected with the monastery of the Franciscans. They are thought to have been erected by James IV. in 1494; and from the circumstance of the eastern end having received some additions from cardinal Beaton, is the reign of Mary, they are sometimes described as having been built by different founders, and at different times. At the reformation, a partition wall was added, which now forms them into two extensive and convenient churches. James VI. was crowned here in 1567, and general Monk raiied his batteries in this church-yard in 1651, when the castle was besieged. The flece and roof yet retain the marks of having been violently battered by the shot from the garrison.

The town-house is a large building, with apartments for the town and county courts: in the council chamber is kept the heraldic records of the county. Stirling contains three hospitals, six, one, endowed by Robert Spittal in 1530, for poor tradesmen; a second, founded by John Spittal in 1659, for decayed brethren of the guild; and a third, instituted by John Allen in 1725, for the education and maintenance of the children of poor tradesmen. Beside these charitable institutions, the merchant company, the kirk fellowship, the kirk fellowship of theburgh feecers, the town funds, and those of each particular incorporation, in addition to large voluntary contributions, are all employed to relieve the wants of the poorer inhabitants.

In this town is the only prison in the county. Here are a weekly market on Friday, and six annual fairs. The population of Stirling, till the manufactures caused the erection of many new buildings, has undergone but very little alteration for the last 600 years; but of late, as the comparative reports of 1800 and 1811 prove, it has considerably increased: in the former year it amounted to 5271 inhabitants, with 620 houses; and at the latter period, to 8280 inhabitants, and 749 houses. The manufactures which are carried on here are those of carpets and cotton, which have been introduced from Glasgow: formerly, sloaons were made in Stirling to a considerable extent; but though in some degree still carried on, the manufacture has greatly declined from its first commercial greatness. There is a valuable salmon fishery on the Forth, which forms a part of the corporate revenue. (See Forth.) In this borough, the municipal government is vested in a provost, four bailies, a deacon guild, a treasurers, seven merchant-counsellors, and seven deacons of trade; it has also the privilege, in conjunction with some other places, of returning one member to parliament.

To the north-east of Stirling, a small village, called the abbey, marks places where that of Cambellkenneth formerly stood. The abbots of this place was originally denominated abbots of Stirling. This was founded, as already noticed, by David I. in 1147, and supplied with inhabitants from Arosie, near Arbroath, in Scotland. For about 200 years after its erection, it rapidly increased in ecclesiastical power and splendour. In the reign of David Bruce it was despoiled of its most costly furniture, and in consequence of this, the vicarage of Clackmannan was presented to it by the bishop of St. Andrews. In 1559 the monastery was again despoiled, and the reformed religion received by many of its former inmates. In the commotions attending the reformation, its benefices were seized, its revenues forcibly diverted of, and its very stones were carried by the earl of Marr for the construction of the building entitled Marr's work. The extent of the whole parish does not exceed 200 acres.

STIRLINGSHIRE, one of the counties of Scotland, situated nearly in the centre of the southern portion of that country, and occupying a narrow tract of land; bounded on the east and part of the north by the Frith of Forth, on the west by Loch Lomond, on the north-west by Perthshire, and on the south by Dunbartonshire. This area of land measures about 49 miles from east to west, and on an average nearly 16 miles from north to south. The boundary line is however very irregular, and is formed in a great measure by the natural demarcation of rivers and lakes: on its southern side was a famous Roman wall. From the peculiar natural features and situation of this district, it appears to have been a repeated scene of hostilities in former ages, when political jealousies and animosities impelled the Scots, Picts, Britons and Roman mercenaries of these islands, to wage continual wars with each other. Hence this country is particularly noted in the annals of Scotland.

The Romans erected one of their celebrated barriers on the edge of this district; and the most famous of the Scotch battles have taken place at Falkirk and Bannockburn, within this county. The lawless Highland chief, Rob-Roy, at one time held the lands along the eastern shore of Loch Lomond, and levied black mail, or money for protection, to the south-east of this district. Several of his caverns are yet remaining. The parish of Killearn is noted for the birthplace of the poet and historian, George Buchanan, Kilkenny for the greatest victory James, marquis of Montrose, gained in behalf of Charles I. The topographical antiquities of the county are, the northern front of the Roman wall; two large cairns, wherein human bones and funeral urns have been discovered: a singular Druidic monument of three large stones, denominated "the auld wife's lif;" and remains of early fortifications along the course of the Forth. The embalmed bodies of lady Kilflyth, with her Joan, may be also regarded as a singular though not a remote piece of antiquity, they having been preserved in a most surprizing manner after death, for many years. A rude circular building was formerly standing on the banks of the Carron, and entitled by the neighbouring inhabitants "Arthur's oven." It was supposed to have been a temple to the god Terminus, the protector of land-marks, erected by Agricola, when he fixed the boundaries of the Roman empire. The parish of Dunipace is also supposed to have derived its name from the two
two artificial mounts near the church, thought to have been reared at the conclusion of some important treaty. The remains of a religious house, founded by king Malcolm IV., about the year 1156, for nuns of the Bernardine order, called Emanuel nunnery, are situated on the west bank of the water of Avon.

Mountains.—The most hilly parts of this county are in the neighbourhood of loch Lomond to the north, and those of the southern division are in the parishes of Kilpatrick, Balderock, Campie, Killyfirth, and Denny. The northern ranges of the latter are denominated the Lennox hills. The more southern branches receive the names of the parishes in which they are, and are called Campie fells, Killyfirth or Kilpatrick hills.

The principal northern mountain is Ben Lomond, which rises from loch Lomond. (See Ben Lomond.) The highest in the southern division of those denominated the Campie fells, is about 1500 feet above the level of the sea; and nearly 1200 from the base of the ridge. Although the activity of the hills is generally very rapid, they possess more of the character of the Lowland than of the Highland mountains, for their surfaces are either verdant, or covered with mossy pasture, and they do not present terrific and precipitous naked peaks. In the parishes of Killyfirth, these mountains never exceed in their elevation 1000 feet from the valley, or 1508 from the level of the sea: the view from the highest of these is one of the most extensive, beautiful, and variegated in all Scotland, and commands nearly one half of that delightful kingdom, the prospect being suppos'd, at a moderate computation, to embrace an area of 15,000 square miles.

Mineralogy and Mineral Products.—The minerals of Stirlingshire consist chiefly of coal, iron-flints, and lime-flints. The vicinity of the Grampian hills appears to cut off all secondary strata to the north-west; and towards loch Lomond the country is destitute of any valuable mineral. Ben Lomond is composed of granite, interpenetrated with quartz, which is found near the top in such masses as to weigh several tons. The shores of the loch beneath are covered with rounded pebbles, composed of quartz, granite, and micaceous schistus, with coarse red jasper, similar to the composition of the adjoining hills, from which they have been washed by rivulets, and polished by the waves of the lake. Upon the Enrick, and the upper part of the Forth towards the centre of the county, peat is the ordinary fuel; but in Campie, Killyfirth, and towards the east, large strata of coal run within the bowels of the mountains. In various parts of the hills, passing from Dumbarton to Stirling, are subterraneous piles of basaltic rocks; and a grand colonnade of basaltic columns rises in a hill called Dun or Down, in the parish of Fintry. This consists of twenty pillars in front, of a gigantic stature, some appearing to be separated in loofe blocks, and the shafts of others seeming entire through the whole extent: they stand perpendicular to the horizon, and rise to the height of fifty feet. They consist of various shapes, being square, pentagonal, and hexagonal. On the eastern side of this range the pillars are parted by the distance of three or four inches. This gradually lefens towards the west side, till nothing more than a mark is to be deciphered, and which soon disappears in one solid mass of rock, very much honeycombed, and which has the appearance of having been ignited. The mountain on which they stand consists of extensive beds of red ochre. The frost of the precipitation in the parish of Strathblane, for the space of a fortnight, is laced with flatly columns of the same kind. They consist of four, five, and six files, from two to three feet in diameter, and thirty feet high. They rise from the horizon with a little inclination from the perpendicular, and some of them are apparently bent in the segment of a curved line. In the latter mentioned parish, at the water-fall called the Spout of Ballagan, a very remarkable section of the hill is presented. The side of it, being perpendicularly cut by the water, discloses two alternate strata of earth and limestone; but towards the bottom of the section are several thin strata of the purest alabaster. Near the same place, in a late inundation of the river, some fragments of antimony were thrown up, which on trial were found to be of the finest quality. The vein, however, from which they were torn, has not been discovered. In what are filled the secondary hills, coal is very abundant. The strata of these mountains, immediately succeeding the vein of coal, consist of limy-flint mixed with clay, here denominated cannel-flint, and which breaks into a heavy lime, but requires to be flaked while hot. Above this mixture of lime and clay, are several strata of excellent iron-flint, of different degrees of thickness, with a soft flake, which interposes between the layers. The summit of the mountains is formed of layers of rock, called moor-flint. In the inferior hills, about the Glasart, is a large field of coal on both sides of the stream, at the depth, on the north side, of from two to fifteen fathoms, and on the south side, of twenty-two fathoms. The coal is, at an average, from forty-two inches to four feet in thickness. The adjoining parishes of Balderock, and the Kelvin, contain like abundance of coal and limestone. The coal resembles that of Newcastle, caking together, and giving out a strong heat when allowed to rest for some hours undisturbed.

The parish of Killyfirth contains also very valuable minerals in great abundance; and iron-flint, which was wrought by the Carron company upwards of thirty years since, still continues to be worked to a great extent. (See Carron and Iron.) In the westem part of the above parish are found great quantities of ball iron-flint, and considerable beds of limestone. In the Carron Glen is a large quarry of free-flint, soft and easily wrought when first drawn from the quarry. The bed whence it is taken is generally from ten to fifteen feet, and is placed upon a seam of coal about as many inches thick. There is a variety of slates arising, from thin slates like trees, from the surface of the earth. Some of them are fix, ten, or twenty feet long, in proportion to the depth of the free-flint; and they differ as much in diameter as in length, being of all sizes, from an inch to two feet. These are esteemed as considerable curiosities, and have furnished much matter for speculation. They exceedingly resemble a petrifaction, and yet the substance is not calcareous earth, but solid free-flint, of a similar texture with the circumjacent rock. One of the largest of them is described as being nearly sixteen inches in diameter, and about six feet nine inches in length.

Rivers.—Of the rivers in this county, the Forth is the chief, and though not the largest, has always been considered the most distinguished of the Scottish rivers. (See Forth.) The Carron river rises in the centre of the county, and running southwest, enters the Firth of Forth about three miles from Falkirk. (See Carron.) Bannockburn is more celebrated for the historical events that are connected with it, than for any importance it possesses as a river, being only a small stream. (See Bannockburn.) The lesser rivers in this county are the Avon, which rises in the south-eastern parts; the Enrick; and the Kelvin, which descends from the west and flows to the south-east; and the Blane, which gives its name to the parish of Strathblane, springs from a high hill called the Earl's feat, amid the Lennox hills. In a short course this river forms several water-falls, one of which, called
called the Spout of Ballagan, forms a cascade 70 feet in height, confined to a narrow channel, with lofty mountains on each side. This stream is sometimes increased to a torrent by violent storms of rain, which occasionally pour down like water-spouts. At such times, very considerable injury is done by the rapidity of the torrents, in overwhelming the low grounds.

Lakes.—This county contains no lakes of importance, unless Loch Monond be considered as partially belonging to it. In the parish of Buchanan, near Loch Monond, there are three small lakes, Dulochlan, Lochlarclaret, and Lochmanercarn. In the parish of Strathblane are six lakes; the largest of them, however, does not exceed half a mile in length, and a quarter of a mile in breadth; but they serve to feed a degree of liveliness upon a desolate region. In the parish of Kilcreith, the great reservoir for the canal between the Forth and Clyde, though artificially formed, may be considered as a lake. See Forth and Clyde Canal.

Soil, Climate, and Agriculture.—The soil of this county is extremely various, as may be expected in a territory so much diversified by hills and dales. In the western parishes, it generally contains a considerable portion of clay, that renders it cold, retentive of water, and productive of mosses and coarse grasses. The subsoil is mostly a hard till, impregnated by water, and an argillaceous kind of grit, of a reddish colour, blotted and streaked with white, grey, and yellow. The cafe lands consist of one of the most remarkable soils in the county. They lie in a low situation on the banks of the Forth, and extend from the river Avon on the east, to Kelly-water on the west; at an averaged space of about 30 miles in length and 2 in breadth. They are elevated from 10 to 20 feet above high-water mark, and a small portion of them is in some places overflowed at times by the river. The soil is universally allowed to be the alluvial deposited by the Forth and its tributary streams, and consequently to be the spoils of the higher grounds through which the river takes its course. It chiefly consists of a high-coloured clay, a small quantity of sand, and a pretty large mixture of once organized matter. In some places, there are patches of till of various colours; but not a stone so large as to obstruct the plough is to be found. The soil of the better quality, when dug fresh from the natural bed, is of a bright-blue colour, and of a substance resembling the richest soap, and sometimes even serves as a substitute for fuller’s-earth. In many places, the clay is excellently suited for the wares of the village, and forms the basis of stone-ware. The depths are from five to fifty feet; the subsoils are flint clay, hard till, and sea-shells in a natural state. The beds of shells are from a few inches to four yards in thickness; they are chiefly large oysters, with a mixture of cockles, whilkas, and some other shells at present found in the Firth. Patches of rich and fertile loamy soils are intermixed in different parts of the shire. Light gravelly soils are chiefly on the banks of the Enrick, Carron, Blane, and other rivers in the western and midland parts of the county.

The highest parts of Stirlingshire, as in other parts of Scotland, consist of a moor, extremely lofty when dry; but when wet, retentive of moisture. Of the many pastures in this county, some have been formed upon the kerse or low grounds adjoining the principal river, by the Romans having cut down the trees, which formerly grew here, and which formed the most formidable retreats of the natives. Where the moor is removed, these trees are found lying in all directions before their roots, which still continue firm in the ground in their natural position; and from impressions still visible, it is evident that they have been cut with an axe, or some similar instrument. That they were cut down by the Romans, is not only probable from the accounts which the historians of that people have given of their operations, but is confirmed by a circumstance that occurred in May 1768, when a large round vessel of this barks, and of curious workmanship, 25 inches in diameter and 16 inches in height, was discovered upon the surface of the clay, buried under the moor. It was denominated by the Edinburgh Society of Antiquaries, a Roman camp-battle.

The agriculture of this county is very varied. In the parish of Gargunnock, and elsewhere upon the Carse or Kerie, all estates consist of moor, dry field, and kerie farms. The dry fields occupy the space between the hills or moor and kerie grounds; and upon these, great improvements have of late been effected. The carse lands, which are all arable, are subdivided into farms from about 15 to 100 acres each; but those of 30 and 40 are most common. Farms in the higher part of the county are from 20 to 1000 acres, of which there is commonly a mixture of rough wet land, that is pastured only. Almost universally the farms are occupied by the persons who rent them. Small poifesions, from 2 to 30 acres, are to be met with in several parts, and in the old language of the country are still denominated gateis. These are generally occupied by day-labourers, who gain their livelihood by working on the high roads, or for the neighbouring farmers. Many of them are also in the possession of manufacturers or mechanics, for the accommodation of their families. Around the villages there are some considerable numbers of small properties held in feu.

In the Kerie, wheat is usually preceded by flummer-fallow; and much barley is reared. The cultivation of wheat is become very general. Peas and beans are little cultivated in the high parts of the county, but very generally in the Kerie as a mixed crop. Turnips, in the county, are extensively carried on towards the eastern part of the county. It appears from a memoir presented to the Board of Agriculture by William Wright, M.D. F.R.S. that potatoes were not planted in the open fields in this county, or any where else in Scotland, till about the year 1728, when Thomas Prentice, a day-labourer, first cultivated them in this mode in the parth of Kilcreith. About 13 or 15 years after this introduction, a Mr. Graham of that place cultivated them in great quantities for sale. He was the first who supplied the market of Glasgow with potatoes. Being very successful, his example in raising the large, round, reddish-coloured potatoe in the open field for the market was soon followed by many farmers; and the practice is now so universal, that they are even planted in strong clay land.

On some estates, the farm-buildings are substantial and well arranged, and a good situation is generally chosen. Dwelling-houses on many estates are two stories high, and are usually covered with slate or tile. About two-thirds of this county, exclusive of the moors, are supposed to be inclosed; and every description of fences, from high walls of stone and lime to neglected quickest hedges, are to be seen. One proprietor in the neighbourhood of Falkirk, has inclosed within eight years no less than 7000 Scottish acres. The fences are mostly of white-thorn, with double ditches, between which a mound or dyke of earth is raised. The ditch next the hedge is commonly five feet wide at the top, and three feet deep; the other is three feet wide. The dyke or bank between them is four or five feet broad at the base, and as much in height above the surface. The lines of the inclosures are all straight, at right angles with
one another, and many of them run in the same direction for several miles. The ridges follow the same course as the fences, for which the situation and the ground correspond remarkably well. Wet ditches alone are in some parts of the country supposed to be sufficient fences; several of them are ten feet wide, and of considerableness depth. It is believed, that the extraordinary dimension of these excavations has been owing to the long continued practice of procuring from them clay for various purposes.

The cattle of Stirlingshire are few; the inhabitants being supplied by the Highland dealers. A considerable part of the moors is patured with sheep, which are almost universally of the black-faced kind, and are called here the Linton breed, from the name of the village in Tweeddale whence they originally came. It appears, from the valuation of lands in the middle of the 17th century, that Ben Lomond, with the whole of the upper part of the parish of Buchanan, was almost entirely stocked with goats. A considerable portion of the rents, in those days, consisted of kid’s and goat’s milk cheese. Very few of that species of flock are now kept in the county.

Woods and Plantations. — Stirlingshire contains many coppices, that have been used as such from time immemorial. Torwood, in the parish of Dunipace, and the wood of the town of Falkirk, are generally believed to be the remains of the Caledonian Forest, with which the greatest part of this county, when the Romans invaded Scotland, seems to have been covered. The trees are principally oak, beech, hazel, and birch. Some of the oaks, when allowed to remain, grow to a great size. Of this, the county affords several examples. The most noted tree in the whole district was Wallace’s oak, in the midst of the famous Torwood. This tree, which, when entire, measured 12 feet in diameter, afforded in its trunk, hollowed by age, a shelter in the house of danger to that order who bears, and a part of his followers. The oak, the althorn, and the beech, are the most valuable trees in this county. Great attention has been paid, especially during the last 35 years, to rearing timber of all kinds. Plantations for shelter, ornament, and profit, form a considerable part of the improvement of the many estates which have been inclosed and improved since that period. The ground on which these plantations occupy, amounting to 2000 and 3000 acres. The trees generally planted are those best suited with various pines, especially the larch, which at the seven years old raises its head nearly double the height of any other tree of the pine genus.—Beauties of Scotland, vol. iii. Chalmers’s Caledonia, vol. i.

STIRPFING, a town of Austria; 4 miles N.E. of Weikendorf.

STIRRUP, or STIRROP, in the Manage, a reft or support for the horfemen’s foot, serving to keep him firm in his seat, and to enable him to mount.

The great art of a cavalier in the ancient tournaments was to make his antagonist lose his stirrup. For combating, it is a rule to have the right-foot stirrup somewhat shorter than the other.

Stirrups are allowed to be a modern invention; no mention being made of them in any ancient Latin or Greek author; no figure of them to be seen in any statue or monument; nor any word expressive of them to be met with in classical antiquity.

Menage observes, that St. Jerom is the first author who mentions them. This passage, however, is not to be found in his epistles; and if it were there, it would prove nothing, because St. Jerom lived at a time when stirrups are supposed to have been invented, and after the use of saddles. Montfaucon denies the authenticity of this passage; and, in order to account for the ignorance of the ancients with regard to an instrument so useful and so easy of invention, he observes, that while cloths and housings only were laid upon the horses’ backs, on which the riders were to stand, the stirrups could not have been used, because they could not have been fastened with the same security as upon a saddle. But it is more probable, that in this instance, as in many others, the progress of human genius and invention is uncertain and slow, depending frequently upon accidental causes. Berenger’s Hist. and Art of Horsemanship, vol. i. p. 65, &c.

To lose one’s stirrups, is to suffer them to slip from the foot.

Stirrup-foot is the near or left foot before.

Stirrup-leather is a thong of leather descending from the faddle down by the horse’s ribs, upon which the stirrups hang.

Stirrup-bearer, called in French porte étrier, is an end of leather made fast to the end of the faddle, to truss up the stirrup when the rider is alighted, and the horse sent to the stable.

Stirrup, in Ship-building, an iron or copper strap or plate, that turns upwards on each side of a ship’s keel and dead-wood, close forward or aft, and bolts through all. Stirrups are only used to British ships, when the after-piece of the keel is carried away by accident, and is replaced without the dead-wood bolts being driven through. See Rudder.

STISSIC MOUNTAIN, in Geography, a mountain of America, that lies between Connecticut and Hudson river, near which the Mahikander Indians formerly resided.

STITCH, in Agriculture, a term which in some districts signifies a ridge or but in a field which is under the plough. The forms and breadths of stitches are liable to vary according to the nature and uses of the land in different districts and places. In the county of Essex, their variation is said not to be considerable. In the most part of the western portion of it, the more wet land is laid out on two-bout ridges, or four-furrowed work; and a scattering of these is every where, it is laid to, to be seen: but on the strong land in the sea-districts, eight, as they are termed, or stitches of eight furrows, are more common. And towards the north of the county, ten-furrow work is rather more general. These form the chief varieties in respect to this matter. But there is a matter of forming the stitches in some instances, where they are laid by the plough in an admirable way. In particular cases, not one falf furrow can be seen, nor any form of tendency to any thing of the hog-trough kind, upon the whole extent of stitches on the farms: the form of the lands is perfectly correct, and so regularly and gently rounded, that not a drop of water can any where lodge upon them. It is difficult, it is thought, to plough lands of so fift a quality so thoroughly well. They are all ten-furrow lands or stitches, and the harrows and other tools for them are made for the breadth in a suitable manner.

Some farmers are particularly cautious in ploughing down old stitches or ridges, especially where the land is of the cold clayey kind, though others bring them down, without much hesitation or caution, in a gradual manner. Some have ploughed down high old stitches for the purpose of forming grazing-land, but have repeated it ever afterwards, considering that the staple of land is the artificial child of cultivation; and if it should be buried, and the under soil be brought up by such levelling, is injured for an age, or
for ever afterwards. They are consequently decidedly of opinion, that high lands or fitches should on no account whatever be ploughed down. They have often seen them laid to grass in their old form with great success, but scarcely ever when ploughed down. In such cases, if brought to good, paturage, it has been, it is thought, by force of manuring or top-dressing.

There can, however, be no fort of doubt, but that high and bad-landed formed lands or fitches in grounds may be brought down and reduced, in many cases, with considerable advantages in different respects, though it should always be done with a good deal of care and caution, as well as mooily, perhaps, in a regular and gradual manner.

STITCHEL, in Rural Economy, a term applied to a kind of hairy wool met with on some forts of sheep. See Sheep and Wool.

STITCHING, in Agriculture, a term applied to the forming of ridges in land, the same as ridging.

STITCHWORT, a name sometimes given to the alfine, or stiffularia of botanists, otherwise called chickweed. See Stellaria.

STITHY, or Stuthy, is used either for a smith's anvil, or a device in oxen, causing their skin to tick fo close to the ribs, that they cannot swin.

STIVA. See Thebes.

STIVER, in Commerce, a money of account and copper coin in Holland and Flanders. The gilders or florins of account contain 20 flivers, each of which is divided into 16 pennings. A fliver contains 2 groots Flemish, and 8 duyt; and a duyt, 2 pennings; a gold gilder, with which accounts are kept in the corn-trade, is worth 28 flivers. In flivers, there are pieces of 1 fliver; and in copper, duyts which are the 8th part of a fliver. At Antwerp, and the whole of Brabant and Flanders, accounts are kept mostly in florins and gilders of 20 fluivers, or flivers, formerly called Patars, which were formerly subdivided into 16 pennings, but for a long time have been divided into 12 parts or deniers. The smaller silver coins are the new pieces of 5 and 2½ flivers, and plaquettes of 5½ florins current. A piece of 5 florins is valued at 4½d., and a plaquette at 3d. See Coin.

STIVING, in Sea Language. See Steving.

STIX NEYSILD, in Geography, a town of Austria; 3 miles N.W. of Brugg.

Loueiru toppolos the Atinus, Rumph. Amboin. v. 1. 171. t. 66, to belong to the same genus. But that is an upright tree, with polyandrous or icofandrous flowers. If, indeed, there be no mistake in the author's account of the flamens in his Stich, it cannot belong to the natural order we have guessed, nor are we able to form any further conjecture on the subject.

ST. LAWRENCE COUNTY, in Geography, a county of New York, erected in March 1802; bounded on the N.W. by the river St. Lawrence, and the British possessions in Canada; E. by Franklin county; S. by Montgomery and Herkimer counties; S.W. by a small corner of Herkimer county, and by Lewis and Jefferson counties. Its extent on the St. Lawrence is 654 miles, in a right line; the E. line is 61 miles, the S. line 26, and the S.W. 43 miles; so that it has an area of about 2000 square miles. It is situated between 44° 5′ and 45° N. lat., and 70° and 1° 50′ W. long. from New York. Its number of towns is 12, the capital being Oswego, 212 miles from Albany; its population consists of 7894 persons. The soil is principally land or loam, thickly wooded with maple, beech, ash, tilia or bals wood, butternut, elm, and groves of white and yellow pines: it is not mountainous nor steep hilly; it is well watered by springs and streams, washed on the N.W. for an extent of 75 miles by the St. Lawrence, and penetrated by many navigable rivers. In the southern part are small lakes. This county sends one member to the house of assembly.

STOE, room, in Antiquity, the porticos at Athens. These were full of exedrae, cibae, and fide buildings, furnished with seats fit for fluidy or discourse. Here it is probable philosophers and their scholars used to meet. See Exedra.

STOAKED, in a Ship. When the water in the bottom cannot come to the well of the pump, they say, the ship is afloat, or floaked: so they say also, the timber-hales are floaked, when the water cannot pass through them; and that the pump is floaked, when something is got into it which chocks it up, so that it will not work.

STOAT, in Zoology, the name used by many for the animal whose skin is the ermine. See Ermineum Animal.

This genus consists of nine species, all natives of the Cape of Good Hope, only one of which had previously been described by Linneus. With this original species, Carlina atrafiloides of the Amanitaceae, v. 6. 96, the younger Linnaeus confounded two other very distinct plants, which are perhaps the S. glabra and rigida of Thunberg. The specific characters of this writer are too short and incomplete to determine the point; and we must content ourselves with giving all the information he has afforded.

1. S. glabra. Thunb. Prodr. 141. Wildl. n. 1.— "Leaves heart-shaped, clasping the stem, oblong, smooth".—We should rather have said "leaves oblong, smooth; clasping the stem with their heart-shaped base," which is the case with both the uncertain species alluded to above.

2. S. carthamioides. Thunb. ib. Wildl. n. 2.— "Leaves heart-shaped-oblong, smooth, with runcinate spinous teeth."

STOBER, a river of Silesia, which runs into the Elbe; 6 miles below Brieg.

STOBERA, in Ancient Geography, a town of India, which belonged to the people called Ichthyophagi.

STOBI, a town of Macedonia Salutaris, which succeeded that of Pelagonia, as the metropolis of this province. It was colonized by the Romans. Play.

STOBORHILL, or Stiborum Promontarium, (Marsel-Berber) in Ancient Geography, a promontory of Africa Propria, upon the coast of the gulf of Numidia, between the promontory Hippus and the town of Aphrodium.

STOBREZ, in Geography, a small sea-port of Dalmatia, near the coast of the Adriatic, on the site of the ancient Epetium, a colony of the Iliri; the ruins are still visible; 4 miles E. of Spalatro.

STOC and STOVEL, in our Old Writers, a forrestroute where any one is taken carrying signes and sublum out of the woods; for signes signes signifies signs, and sublum, sublum.

STOCK, in Commerce, a fund raised by a commercial company; or a principal sum of property employed in trade.

STOCK, in Book-keeping, denotes the owner or owners of the books.

STOCKS, or Public Funds, are the loans advanced to government, for which interest is regularly paid, from revenues set apart for the purpose. This mode of raising supplies by levying taxes for the payment of interest, is called the "funding system," and the loans thus raised constitute the "national debt." (See Public Funds and National Debt.) The debts of government differ from other contracts in this, that the public creditor can claim only his interest; he may, however, sell his stock, that is, he may transfer his claim, and thus obtain his capital, more or less, according to the price of stock, which fluctuates from various causes. The different funds or stocks are variously denominated, according to the terms on which they were established. Thus, fome are called the 3 per cent., fome the 4 per cent., others the 5 per cent., &c. And the manner of buying stock is to give a specific sum for a nominal hundred: e.g., if the price of the 3 per cent. be 60l., the sum is paid for 100l. stock, which yields a dividend of 3l. a year, that is 3 per cent. per annum; for at the same rate of 3l. for 60l., 100l. would yield 5l. When stocks are low, the interest is high; and vice versa. In some funds there is a higher interest than in others, and this is chiefly owing to the preference given to that stock which is most marketable, or the least likely to be redeemed; for government has an option to pay off or redeem certain loans, when an advantage may be made by such redemption. New loans are paid by infallments of 10 or 15 per cent. at stated periods, and they generally comprehend different kinds of stock, which together are called "omnium." If these be disposed of separately, before all the infallments are paid, the different articles are called "scrip." an abbreviation for subscription. In raising loans, a douceur is sometimes given by government of an anuity for a limited time: such are called "terminable annuities," and "irredeemable;" but the regular stocks, on which the common interest is paid, are called "perpetual annuities," and also "redeemable." Loans are called "funded debt," when taxes are appropriated for paying the interest; but sums raised for which no such provision is yet made, are called the "unfunded debt." Of this latter description are exchequer, navy, victualling, and ordnance bills, which are fills by these different offices, and bear an interest until they
they are paid off. The interest is mostly 3d. or 3½d. per day for every 100l.
Stock-Brokers. See Brokers.
Stock-Exchange Funds, an institution formed in the year 1801, for the relief of the decaying members of the Stock-exchange and their unprotected families. The annual subscription is one guinea, and that for life is 10 guineas. The annual relief does not exceed 40l. to any applicant; donations are restricted to 200l. Persons receiving any annual allowance are ineligible; and the allowance may be withdrawn if the party is no longer deserving, or if his circumstances have improved so that he ceases to be an object of charity.

Stock-Jobbing denotes the practice of trafficking in the public funds, or of buying and selling stock with a view to its rise and fall. The term is commonly applied to the illegal practice of buying and selling stock for time, or of accounting for the differences in the rise or fall of any particular stock for a stipulated time, whether the buyer or seller be possessed of any such real stock or not. This is that gambling at the Stock-exchange, which ruins numbers of people every year, and which is injurious, in a variety of respects, to individuals and the public. Transactions of this kind are declared to be illegal by an act of parliament “to prevent the iniquitous practice of stock-jobbing;” and no debt accruing from stock-jobbing accounts is recoverable at law.

Stock-Jobbing is a “lame duck,” so that he can no longer frequent the house, nor do any more business on credit, with his brethren. A stock-jobber, who has bought stock for time, which he never intended to take, is called at the Stock-exchange a “bull” laden with a burden which he wishes to shake off. On the contrary, he who has sold, upon speculation, what he does not possess, and consequently cannot transfer, is called a “bear.” Eager and hungry, and trying to devour the property of others. The first of these parties wants the fund he has bought to rise, that he may sell the same sum at an advanced price, and receive a profit, which is called the “difference.” It is his man’s interest to propagate false intelligence in time of war, of victories, negotiations for peace, &c. The bear, on the contrary, will endeavour to obtain false news of defeats by sea and land, in order to lower the price of the fund he has sold on speculation, that he may have an opportunity of buying the same sum at a lower price, and thereby receiving a profit. Thus by the various arts of the stock-jobbers, real property is affected, and the rise or fall of the funds is regulated by the jobbing accounts at the Stock-exchange. The greatest part of the national debt, consisting of 3 per cent. conf. annuities, in which most business is daily transacted, the greatest jobbing, and the most frequent variations, happen in that fund. All ranks of people, and persons of both sexes, engage more or less in stock-jobbing, often through the persuasion of their brokers; especially if they are known by transferring, or by purchasing, to have considerable property of their own. But persons of the most particular characters, and persons connected with them, have the best opportunities of playing a sure game, by means of early intelligence; and so they generally carry their gains out of the country: this is a great evil. Commerce likewise suffers considerably by stock-jobbing, for tradesmen are tempted, by the hope of more rapid profits than any they can make in the ordinary way of business, to frequent the Stock-exchange; and not being in the secret of obtaining true intelligencc respecting public affairs, they lose instead of gaining, and too often become fraudulent bankrupts. See Stock-Broker.

Stock, in Agriculture, a term signifying any sort of crop, or other kind of farm property. All kinds of stock of this nature should constantly be well fattened and adapted to the size, quality, and nature of the farms, so far especially as relates to tools, machinery, crops, and the different sorts of animals which are to be kept and employed upon them, whatever this fort may be; as, upon this being nicely and properly adjusted, a great deal in their economy and utility depends. It has now been long well known that very great advantages result to the farmer, from his thus accurately fitting his crops and live-stock of different kinds, as well as other things, to the estate, qualities, and circumstances of his lands; as they are found to be greatly influenced by them, and of course to be much benefited, where such a correct attention is had to the matter.

This has sometimes the terms of farm and farming stock applied to it, by different writers on husbandry.

Stock, Live, that kind which comprehends all sorts of domestic animals. See Live-Stock.

Stock, Live, Choice of Food for, the particular selection or choice of that fort to which they are attached, as being the most agreeable to them. The attachment or dislike to a particular kind of food, as shown by animals, however, it is said, affords no sort of proof of its nutritive properties in general; as different sorts of meat, fish, and other animals, at first refuse linseed cake, which is well known to be one of the most nourishing and fattening substances on which they can be fed; and the same is probably the case with some other matters used as food of animals.

The writer of the late work on “Agricultural Chemistry” has given the following remarks on the selection or choice of different kinds of common food, by sheep and cattle, on the authority of Mr. G. Sinclair, the gardener to his grace the duke of Bedford, at Woburn Abbey. With respect to rye-grass (leukium perenne), sheep, it is said, eat this grass, when it is in the early stage of its growth, in preference to most others; but after the seed approaches towards perfection, they leave it for almost any other kind. A field in the park at the above place was laid down in two equal parts, one part with the above grass and white clover, and the other with cock’s-foot and red clover. From the spring till midsummer, the sheep kept almost constantly on the rye-grass part; but after that time they left it, and adhered with equal constancy to the cock’s-foot part, during the remainder of the season. In regard to the cock’s-foot grass (daucus glomerata), oxen, horses, and sheep, are stated to eat this grass readily. The oxen continue to eat the straws and flowers, from the time of flowering until the time of perfecting the feed. This was exemplified in a remarkable and striking manner, in the field just alluded to. The oxen generally kept to the cock’s-foot and red clover, and the sheep to the rye-grass and white clover. In the experiments published in the “Amenitates Academicum,” by the pupils of Linnaeus, it is stated, it is said, that this grass is rejected by oxen. The above facts, however, is in contradiction with the results which is usually known by the title of meadow fox-tail grass (alopecurus pratensis), sheep and horses seem, it is said, to have a greater relish for it than oxen. It delights in a soil of intermediate quality as to moisture and dryness, and is very productive. In the water meadow at Priefley, near the above place, it constitutes, it is remarked, a considerable part of the produce of that excellent meadow. It there, it is said, invariably keeps possession of the top of the
the ridges, extending generally about six feet from each side of the water-course; the space below that, where the ridge ends, is filled with cob's-foot, the rough-flaked meadow-graft, the meadow fescue, the hard fescue, the agrostis foliifera and palustris, with the sweet-pectorated vernal grafs, and a small admixture of some other kinds. In speaking of the nature of the meadow cast-tail grafs (poe pratensis), it is noticed that it is certain that it is a grafs which is eaten without reserve by oxen, sheep, and hores. It is noticed, that it has been fayed by doctor Pulteney, that it is disliked by sheep; but that in pastures where it abounds, it does not appear to be rejected by these animals, but to be eaten by them in common with such others as are growing with it. In respect to the floren grafs (agrostis foliifera), in the experiments detailed in the Amencitats Academice, it is said that hores, sheep, and oxen, eat it greedily. On the duke of Bedford's farm at Maulden, floren hay was placed in the racks before hores, in small distinct quantities, alternately with common hay; but no decided preference for either was, it is said, manifested by the hores in this trial. But that cows and hores prefer it to hay, when in a green state, seems fully proved, it is thought, by Dr. Richardson, in his several publications on floren; and of its productive power in England, which has been doubted by some, there are satisfactory proofs. Lady Hardwicke has given an account of a trial of this grafs, it is observed, wherein twenty-three milch-cows, and one young hor, besides a number of pigs, were kept a fortnight on the produce of one acre of ground. In regard to the rough-flaked meadow-grafts (poe pratensis), oxen, hores, and sheep, eat it, it is said, with avidity. Hares also eat it; but they give a decided preference to the smooth-flaked kind, to which it is, in many respects, nearly allied. Respecting the smooth-flaked meadow-grafts (poe pratensis), oxen and hores are, it is said, observed to eat it in common with others; but sheep rather prefer the hard fescue, and sheep's fescue, which affect a similar soil. This, it is noticed, is a species of grafs that exhausts the soil in a greater degree than almost any other; the roots being numerous, and powerfully creeping, become, in two or three years, completely matted together; the produce diminishes, as this takes place. It grows common in some meadows, on dry banks, and even on walls. With respect to the crested dog's-tail grafs (cyonurus crifatus), the South-Down sheep and deer appear, it is said, to be remarkably fond of it. In some parts of Woburn park, it forms the principal part of the herbage on which these animals chiefly browse; while another part of the same park, that contains the agrostis capillaris and pneumus, flegia ovina, drumulius, and cambria, is seldom touched by them. But the Welsh breed of sheep almost constantly browse upon these, and neglect the crested dog's-tail, the rye-grafts, and the rough-flaked meadow-grafts. The fine, or common bent grafs, (agrostis vulgaris or capillaris), is noticed to be a very common grafs on all poor, dry, sandy soils. It is not palatable to cattle, as they never eat it readily, if any other kinds be within their reach. The Welsh sheep, however, prefer it, as has been just observed; and it is singular that these sheep, being bred in the park, where some of the best grafs are equally within their reach, should prefer these grafs which naturally grow on the Welsh mountains; it would seem to argue, it is thought, that such a preference is the effect of some other cause than that of habit. As to the sheep's fescue grafs (flegia ovina), all kinds of cattle are said to relish, and perhaps to have a sort of preference for it; but it is thought that it appears, from the trial which has been made with it on clayey soils, that it continues but a short time in possession of such kinds, being soon overpowered by the most luxuriant forta. It is suggested, that on dry shallow soils, which are incapable of producing the larger kinds, this should form the principal crop, or rather the whole; for if it is feld or ever, in its natural state, found intimately mixed with others, but by itself. Regarding the hard fescue grafs (flegia durifcula), it is noticed that it is certain that it is a grafs which is eaten without reserve by oxen, sheep, and hores. It is noticed, that it has been fayed by doctor Pulteney, that it is disliked by sheep; but that in pastures where it abounds, it does not appear to be rejected by these animals, but to be eaten by them in common with such others as are growing with it. In respect to the floren grafs (agrostis foliifera), in the experiments detailed in the Amencitats Academice, it is said that hores, sheep, and oxen, eat it greedily. On the duke of Bedford's farm at Maulden, floren hay was placed in the racks before hores, in small distinct quantities, alternately with common hay; but no decided preference for either was, it is said, manifested by the hores in this trial. But that cows and hores prefer it to hay, when in a green state, seems fully proved, it is thought, by Dr. Richardson, in his several publications on floren; and of its productive power in England, which has been doubted by some, there are satisfactory proofs. Lady Hardwicke has given an account of a trial of this grafs, it is observed, wherein twenty-three milch-cows, and one young hor, besides a number of pigs, were kept a fortnight on the produce of one acre of ground. In regard to the rough-flaked meadow-grafts (poe pratensis), oxen, hores, and sheep, eat it, it is said, with avidity. Hares also eat it; but they give a decided preference to the smooth-flaked kind, to which it is, in many respects, nearly allied. Respecting the smooth-flaked meadow-grafts (poe pratensis), oxen and hores are, it is said, observed to eat it in common with others; but sheep rather prefer the hard fescue, and sheep's fescue, which affect a similar soil. This, it is noticed, is a species of grafs that exhausts the soil in a greater degree than almost any other; the roots being numerous, and powerfully creeping, become, in two or three years, completely matted together; the produce diminishes, as this takes place. It grows common in some meadows, on dry banks, and even on walls. With respect to the crested dog's-tail grafs (cyonurus crifatus), the South-Down sheep and deer appear, it is said, to be remarkably fond of it. In some parts of Woburn park, it forms the principal part of the herbage on which these animals chiefly browse; while another part of the same park, that contains the agrostis capillaris and pneumus, flegia ovina, drumulius, and cambria, is seldom touched by them. But the Welsh breed of sheep almost constantly browse upon these, and neglect the crested dog's-tail, the rye-grafts, and the rough-flaked meadow-grafts. The fine, or common bent grafs, (agrostis vulgaris or capillaris), is noticed to be a very common grafs on all poor, dry, sandy soils. It is not palatable to cattle, as they never eat it readily, if any other kinds be within their reach. The Welsh sheep, however, prefer it, as has been just observed; and it is singular that those sheep, being bred in the park, where some of the best grafs are equally within their reach, should prefer those grafs which naturally grow on the Welsh mountains; it would seem to argue, it is thought, that such a preference is the effect of some other cause than that of habit. As to the sheep's fescue grafs (flegia ovina), all kinds of cattle are said to relish, and perhaps to have a sort of preference for it; but it is thought that it appears, from the trial which has been made with it on clayey soils, that it continues but
kind, it may serve to direct the proper and most useful means of preparing and laying down lands, for the purpose of pasturing and feeding fitch and flock in the best and most beneficial manner and succession as to the use and consumption of the food, as well as probably be of utility and advantage in some other ways.

For the nature, qualities, and properties, of the different forts of domestic animals which constitute the living flock of the farm, see Live-Stock.

Stock Account, that sort of account which is kept of the flock of a farm. It is of much utility and advantage to the farmer, in many different ways, that a correct account of the different sorts of flock on the farm be kept in a perfectly accurate and proper manner; as it not only shows how he stands in respect to profit and loss, but, in some measure, directs the management which is the best and most proper, as well as the most beneficial to be followed in different cases.

In order to accomplish the business in the most proper manner, a general flock-book should be kept; in which, at the close of every year, or at any other more suitable period, should be entered the result of a full and careful examination and estimate of the state, condition, and worth of the whole of the flock and property of every kind, as well as of the debts and credits which are existing. Such a book will at all times, and on all occasions, be of great value and utility for the purpose of referring to, and for affording the necessary satisfaction how every thing on the farm is going on, whether properly or improperly. In this intention, in the first place, all the different trackage, accounts and charges are to be got in, and the state and worth of the household property taken, but without any great degree of minuteness in this particular; then that all particular accounts made out for the hores, the rest cattle, the sheep, and other sorts of live-flock, with those for grain in the straw and threshed out, for hay and fodder of other kinds, for manure, for growing crops, for fallows, for timber-wood and woods, for ploughs, harrows, carts, wagons, harnesses, traces, stocks, and small implements of all sorts; concluding with the situation and state of the fences of all kinds, the gates, the drains, and water-courses, &c.; with estimates of the necessary repairs which they may stand in need of, on the side of the proprietor, as well as the tenant. Such memoranda being at first made out upon wise paper, the particulars of them may afterwards be copied and entered into the flock-book, in such a manner as may be considered necessary in regard to minuteness.

After the whole of this sort of work has been completed and properly adjusted, a debtor and creditor account may be made out in the manner of Stock Dr., and Centra Cr.; the balance of which will shew, in an exact and certain manner, the present state and worth of the farmer’s estate and property.

On the debtor side of this account is to be entered or put down all the farmer owes, beginning with rent, tythe, and taxes, and proceeding with other items; and on the contra, or contrary side, all he is possessive of every kind, and all which is owing to him. Everything is to be rated at what is thought to be the fair and just worth or value of it at the time: manure, and tillage-work which has been performed, are to be valued at what is considered the value of the particular district; and the corn which is not threshed out, and other similar articles, are to be taken by estimation at the fair rate which is then to be had for them. All other things are to be valued in the same manner.

There are several different modes and forms provided for keeping accounts of the farm kind; but for common farmers, the ordinary method is probably the most suitable, and may most be made fully sufficient for the purpose. Instead of the puzzling, though beautiful and correct, philosophical Italian mode, a sort of half that method has been advised, as both useful and unattended with either intricacy or trouble. It is merely that of creating or entering what are called flock accounts, in a ledger, without any of the connections by reference, common in that method. Thus, it is said, if a farmer wishes to be very correct in his accounts of the profit or loss, upon a lot of stalled oxen, for instance, or on the crop of any particular field, his book and readiest method is to make out an account, either for the one or the other, in his ledger, debtor and creditor. On the debtor side let him place the cost or expense, including every minute particular; on the creditor, the returns: in course, on the vale of the articles, the account is closed, and the balance demonstrates the profit or loss.

The keeping of both a day-book and ledger becomes necessary for the farmer; the first, in order to serve the purpose of affording necessary memoranda, as guides in the conducting of his business; and the latter, for shewing the general state of his affairs. But he need not be over nice or fudicious of forms, but enter down in the former whatever he may think needful, with the date; as, besides other things, the times when the males were put to the females of different sorts of domestic animals, as accidents are liable to frequently happen, for want of timely notice and care about the period of their bringing forth. It is also of vast use to keep correct accounts of the dates of different sowings, as well as of the various transplantations of the tillage and other kinds on the farm.

In fact, the regular taking of the flock of farms annually, at some certain period of the year, and of keeping fair and exact accounts, is, on the whole, when well and perfectly considered, attended with far less trouble and inconvenience, than the everlastling puzzle, confusion, uncertainty, and loss, of heedless negligence in this respect, but which is a great deal too common among farmers. Regular accounts and annual valuation will it is said, not only afford the farmer an exact knowledge of his real situation, but wonderfully sharpen and improve his judgment on the real worth and value of all those articles in which he deals, or has any concern; and in the necessary contemplation of the final event, he will have the satisfaction of reflecting that all stands fair for the benefit of his family, and as little liable as possible to loss or dispute in any way.

In a situation like that of a farm, where the whole homestead or residence is necessarily surrounded with different sorts of combustible matter, the insurance against accidents by fire should never, on any account, be neglected, or put off for even the shortest space of time. The accidents and deaths of different sorts of live-flock may likewise be probably insured against, both of which should, of course, form accounts in the flock-book.

Stock, in Gardening. See Stocks.

Stock, in Block-making, a wooden instrument used for boring holes, by fixing a bit in the lower end, and a pin with a round head in the other end; the pin and the bit serving as an axis upon which to turn it.

Stock of an Anchor, is composed of two long pieces of oak, tapering from the middle, fastened together with iron hoops and tree-nails, and fixed on the shank transversely to the arms. Some anchors have iron stocks.

Stock-Show, in Block-making, a large sharp-edged cutting-knife, with a handle at one end, and a hook at the other, by which it hooks in an iron-flaple, that is driven into
STOCKFIELD, a town of Sweden, in the province of Smalnad; 54 miles N.W. of Calmar.

STOK, a town of France, in the department of the Lower Meuse, situated on the W. side of the Meuse; 12 miles N. of Maestricht. N. lat. 51° 91'. E. long. 5° 45'.

STÖCKER, in Ichthyology, a name given by the Germans to the Salmo of the ancients, the trachurus of the later writers. It is a species of the tructor, known among us under the name of the brook-trout.

STOKE, in Geography, a town of Austria, on the left bank of the Danube; 12 miles S. of Sonneberg.

STOCKTON, a town of Sweden, the county seat of the province of Smalnad; 28 miles N.N.W. of Wexio.

STOKKEBY, a town of Sweden, the county seat of the province of Smalnad; 5 miles S.E. of Bareuth.

STOCKBRIDGE, a borough in Hampshire, England, is a small market-town on the eastern side of the Teff, and on the road from Winchester to Salisbury. The population, according to the report of 1811, amounted to 663 inhabitants, occupying 145 houses. A new bridge was erected here over the river Teff a few years since; about two miles to the westward, on Houghton-down, is a great race-course. Stockbridge is a borough by prescription, and its government is vested in a bailiff, who is the returning officer, a constable, and a sergeant at arms. This place sends two members to parliament, which privilege was first possessed at the commencement of the reign of queen Elizabeth; since which time, the members and voters have frequently been cited before the house of commons for corruption and bribery. This, indeed, is one of those boroughs which has brought the English representative system into frequent and severe reproach. The ingenious and learned sir Richard Steele was elected one of the members for this borough in the time of queen Anne; and obtained his election by flocking a large flock full of guineas, and declaring it should be the prize of that man whose wife should first be brought to bed after that day nine months. The two members are now elected by 57 voters, who receive, according to Oldfield, 6d. a man. (See a particular account in the Representative. Hift. vol. i. part ii. p. 507.) The right of election is in the inhabitants paying the church and poor rates. A weekly market is held here on Thursday; and there are three annual fairs. It is 66 miles W.S.W. from London, and 15 E. from Salisbury. The parishes of Stockbridge contain the borough, and Stockbridge-street, alias White-street.—Numerous journeys and travels. Hift. vol. iv. by J. Britton and E.W. Brayley. Oldfield's Representative History, vol. i. part ii.

STORK, a township of America, in Windor county, and state of Vermont, situated on White river, and containing 700 inhabitants. Also a post-town in the state of Massachusetts, and county of Berkshire. 44 miles W. by N. from Springfield. This is the chief township of the county, incorporated in 1739, and containing 1737 inhabitants.

STOTON, a town of Massachusetts, in Berkshire county, containing 1049 inhabitants.

STOWN, a tract of land, six miles square, in the S.E. part of Onondaga Reservatio, in the state of New York, inhabited by about 300 Indians, who some years ago removed from Stockbridge, in Massachusetts, and from this circumstance are called the "Stockbridge Indians." They are an industrious people, and are employed in agriculture, and in breeding of cattle and swine.

STOCKTON, a town of the Duchy of Wurzburg; 2 miles N. of Neustadt.

STOCKHEIM, a town of the district of Wurzburg; 4 miles E. of Kitzingen.

STOCKHEIM, Kasten, a town of the district of Wurzburg; 2 miles N. of Gerolzhofen.

STOCKHEIM, Tiefen, a town of the district of Wurzburg; 6 miles E.E.S. of Kitzingen.

STOCKHOLM, the capital of Sweden, is said to have been founded by Birger Jarl, regent of the kingdom, about the middle of the 13th century, during the minority of his son Waldemar, who had been raised to the throne by the states of the kingdom; but the court and royal residence were not removed hither from Uspal before the 17th century. The situation of this city is singularly distinguished by its romantic scenery. This capital, which is long and irregular, occupies, besides two peninsulas, even small rocky islets, scattered in the Mosel, in the streams which issue from that lake, and in a bay of the Baltic. The harbour is an inlet of the Baltic; the water of which is so deep, that ships of the largest burthen can approach the quay, which is of considerable breadth, and lined with spacious buildings and warehouses. At the extremity of the harbour, several streets rise one above another, in the form of an amphitheatre; and the palace, which is a magnificent building, crowns the summit. Towards the sea, about two or three miles from the town, the harbour is contracted into a narrow strait, and winding among high rocks, disappears from the sight; the prospect is terminated by distant hills, overspread with forests. The central islet, from which the town derives its name, and the Niddarholm, are the handomest parts of the town. Excepting the suburbs, where several houtis are constructed of wood, painted red, the buildings are generally of stone, or brick stuccoed white, mostly erected on piles. The palace, situated in the centre of Stockholm, and on the highest spot of ground, was begun by Charles XI., and the large principal stone walk of the façade of the palace are both elegant and magnificent. From an eminence in the south suburbs, called the "Mount of Moses," the spectator commands a bird's-eye view, almost unparalleled in its kind, of the city and various isles, of the harbour, the channel, and the lake Mäler, forming an assemblage of rocks, houfes, wood, ships, and water, in all the variety of rugged, beautiful, and romantic scenery. The several parts of Stockholm communicate with one another by 18 bridges.
bridges. The arsenal of Stockholm contains an immense number of standards and trophies, chiefly taken from the Imperialists, Poles, Russians, and Danes. The manufactures of this city are of glass, china, wool, silk, linen, &c; and the number of its inhabitants is estimated, by the latest accounts, at about 80,000. For an account of its academies, see Academy; and of its bank, see Bank. For other particulars, see Sweden. N. lat. 59° 20'. E. long. 17° 40'.

Stockhorn, a mountain of Switzerland, in the canton of Berne, the height of which is estimated at 7218 English feet.

Stocking, in Rural Economy, an improper practice with cow-jobbers, or dealers, consisting in obliging the cows to suffer the pangs of retention twenty-four, or sometimes forty-eight hours previous to sale, in order that they may have a great flow of milk in the udder. Such buyers, however, as know any thing of cattle, are fully aware of the custom, and consequently avoid the deception. The idea of any knowledge of the animal being more favourable for the purpose of milking, when obtained in this state, is highly ridiculous; as there are other better rules of judging, and which are familiar to every experienced stock-farmer. Many cows get inflamed and even indurated udders by such means. This unnatural practice ought of course to be generally reprobated and put an end to, as being productive of much mischief to these animals.

Stocking of farms, &c. In Agriculture, the means of first furnishing and providing them with all the different sorts or appropriate stock, according to their several natures and kinds, both of the living and dead forts, and of afterwards keeping them properly up, so as that all the necessary operations and management of the whole may be carried on in the most full, proper, suitable, and advantageous manner. It comprehends the providing of all the various descriptions of domestic animals for carrying on the work, as well as for keeping, feeding, or feeding off in the view of profit; and of the numerous tools, implements, machinery and carriages, as well as all other contrivances and things, which are requisite and proper in the husbandry. It is that matter which the farmer should next attend to, and which, much depends upon the several different kinds of stock being well fitted, suited, and adapted to the nature, size, state, situation, kind, and quality of the farms, whatever they may be, otherwise great inconveniences, losses, and disappointment, may be experienced.

In addition to what has been said on hiring and stocking of farms, under the proper head Farm, in speaking of and considering their general nature and management in these and different other respects, it will only be necessary to observe, that the farmer should seldom or never, on any account whatever, engage for more land as a farm, than what he has capital fully at command for stocking, managing, and carrying on with proper spirit, and in the best, most proper, and most beneficial manner; that he should, as seldom as possible, divert any of such capital from these its proper objects, to speculations of other kinds; and that he should never, in any material way, neglect the supplying of the different necessary sorts of stock, as they may become wanted on the farm, in the most suitable and appropriate kinds and quantities, as to their nature and extent, as well as the time of providing them. The improved methods of cultivation and farming in general, and the increased expenses of it, as well as the higher prices of tools, labour, and wages, and the vastly augmented state of taxation, render the charge of stocking in different kinds of farms, with all the different kinds of stock, mostly double, often treble, and in some cases nearly quadruple as much as it was twenty-five or thirty years ago. This should, of course, be constantly well considered and attended to by the farmer, before hiring and stocking any farm which he may be about to enter upon. See Farm.

In regard to stocking different sorts and qualities of land with different kinds of live-stock, in the view of keeping them merely, or those of feeding and fattening the animals, or in any other intention, it may just be noticed, that, for the most part, probably the best method is to run them neither too thickly nor too thinly upon the lands, but so as to have them constantly, without being either too full or too destitute of keep, no food being wasted or stock injured in either case, as there may be impropriety and loss in having the grounds too closely, heavily, or hard stocked, as well as in having them too thinly or lightly supplied with animals; though hard or heavy stocking may be necessary and useful in particular cases, circumstances, and situations, and with some particular kinds of stock. In the difference, however, between these two modes of stocking, it has not yet been well decided upon: for though some farmers are of opinion, and strongly contend, that light stocking is less hurtful to the land than close feeding, which renders it not so productive, by its not having such a length, or so much herbage upon it in the hot season, during the summer months; that a full bite of paturage is preferable, especially for some sorts of stock, which do best where there is a good portion of keep upon the land; that allowing the land to be well covered with herbage in the spring season, it is useful in promoting its growth in the summer, and by keeping it from the effects of the heat at that dry period; that it admits of the feeding of the grasses on thin poor lands, which renders them more strong, and the land more productive of herbage; and that the animals, where there is a full bite on the land, more quickly fill themselves, chew their cud more frequently, and, of course, feed or fatten more expeditiously; others, on the contrary, equally contend, that it is well known there are two modes of stocking which starve the animals, especially some sorts, as those of sheep, which are those of flocking towards, and too lightly stocked. In close stocking or feeding, times and seasons are to be considered and fixed upon; continual hard stocking at some periods may be injurious to the increase of the herbage of the land, as well as encourage the growth of plants of the most kind, while occasionally hard or close stocking, and not stocking at all, at short intervals, will prove more beneficial; that there is not so much wafte of food in close stocking, as by understocking, and the lands are more regularly fed down; that the young sprouts or shoots of grasses are more nutrient, and more powerful in fattening stock, especially of some sorts, while short than when long; that where lands are suffered, from light stocking, to become too luxuriant in their herbage in the spring season, feed items are thrown up, to the injury and mischief of the fertility of them; but where closestocked, and feed items are prevented from rising, there will be a greater retention of vegetable matter in the soil for the production of new sprouts and shoots; and that stock, especially of some sorts, are not found to lie down and rest themselves more often in lands which have much keep, from being lightly stocked, than in those which are hard stocked, and closely fed down; while they constantly prefer those parts which are in a close state of herbage, and become fat more quickly on it than where there is a great length of coarse rank herbage. In fact, the examination of the lands of those who are the most strenuous for light stocking, does
not prove that their flock is in any way superior, or carried on better, or fattened more quickly, than those in the same vicinity, who flock closer, or in a heavier manner.

In the business of flocking lands with live-flock, it consequently seems, that their nature, quality, present rate, and different proportions of different sorts, as well as the readiness of markets, and means of procuring and providing different sorts of flock, should be well and fully considered:—also the expenses of carrying the business on, and management with respect to them in all ways, the loaves that are attending the lands, and the advantages and disadvantages of different seasons in regard to them. The plans and methods of flocking for different purposes and seasons may thus be properly determined upon and adjusted, especially where the nature of flock, and the land on which it is to be fed, are sufficiently understood.

Stocking-Up, in Rural Economy, a term signifying to grub up or eradicate anything, as trees, hedges, woods, and other such similar matters. The work is mostly performed by means of the spade and mattock in different ways, according to its nature.

Stocking Island, in Geography, one of the Bahamas, about 15 miles long and 3 broad. N. lat. 23° 30'. W. long. 76° 20'.

Stockings, the clothing of the leg and foot, which immediately cover and screen them from the rigour of the cold weather, in winter.

Anciently, the only flockings in use were made of cloth, or of milled fluffs sewed together; but since the invention of knitting and weaving flockings of silk, wool, cotton, thread, &c. the use of cloth flockings is quite discontinued.

Mazerai says that Henry II. of France was the first who wore silk flockings at his first's wedding to the duke of Savoy, in 1550.

Dr. Howell, in his History of the World (vol. ii. p. 222.) relates, that queen Elizabeth, in 1561, was presented with a pair of black knitted flockings, by her flax-woman, Mrs. Montague, and thenceforth the never wore cloth ones any more. The same author adds, that king Henry VIII. ordinarily wore cloth hose, except there came from Spain, by great chance, a pair of silk flockings. His son, king Edward VI., was presented with a pair of long Spanish silk flockings by sir Thomas Grelham, and the present was then much taken notice of. Hence it should seem, that the invention of knitted flockings originally came from Spain.

How early the invention of knitting was taken up in Spain does not appear; but though it existed there in the time of Henry VIII., who died in 1547, yet it was not practised in England till the third year of queen Elizabeth, viz. 1561.

Others relate, that one William Rider, an apprentice on London bridge, seeing at the houfe of an Italian merchant a pair of knit worsted flockings, from Mantua, took the hint, and made a pair exactly like them, which he presented to William, earl of Pembroke, and that they were the first of that kind worn in England, anno 1564. Anderson's Hist. Com. vol. i. p. 326.

The modern flockings, whether woven or knit, are a kind of plexuses formed of an infinite number of little knots, called fitches, loops, or mebes, intermingled in one another.

Stockings, Knit, are wrought with needles made of polished iron, or braised wire, which interweave the threads, and form the meshes of which the flocking consists.

This operation is called knitting, the invention of which it is difficult to fix precisely, though it has been usually attributed to the Scots, on this ground, that the first works of this kind came from Scotland. It is added, that it was on this account, that the company of flocking-knitters, established at Paris in 1527, took for their patron St. Fiaccres, who is said to have been the son of a king of Scotland; however, it is most probable that the method of knitting flockings by wires, or needles, was first brought from Spain.

Stockings, Woven, are ordinarily very fine; they are manufactured by the frame or machine, made chiefly of iron, the structure of which is exceedingly ingenious, but also exceedingly complex; so that it is very difficult to describe it well, by reason of the diversity and number of its parts; nor is it even conceived, without much difficulty, when working before the face.

The English and French have greatly contrasted the honour of the invention of the flocking-loom; but the matter of fact, says Mr. Chambers, after M. Savary, in his Dictionary of Commerce, waving all national prejudices, seems to be this, that it was a Frenchman who first invented this useful and surprising machine; and who, finding some difficulties in procuring an exclusive privilege, which he required, to settle himself at Paris, went over into England, where his machine was admired, and the workman rewarded according to his merit.

The invention thus imparted to the English, they became so jealous of it, that for a long time it was forbidden, under pain of death, to carry any of the machines out of the island, or communicate a model of them to foreigners. But as it was a Frenchman who first enriched our nation with it, so a Frenchman first carried it abroad; and, by an extraordinary effort of memory and imagination, made a loom at Paris, on the idea he had formed of it in a voyage he had made to England. This loom, first set up in the year 1656, has served for the model of all those since made in France, Holland, &c.

But this account of the original inventor of the flocking-frame seems to be erroneous, as it is now generally acknowledged, that it was invented in the reign of queen Elizabeth, in 1589, by William Lee, M. A. of St. John's college, in Cambridge, a native of Woodborough, near Nottingham.

It is said that this gentleman was expelled the university for marrying contrary to the statutes of the college. Being thus rejected, and ignorant of any other means of subsistence, he was reduced to the necessity of living upon what his wife could earn by knitting of flockings, which gave a spur to his invention; and by curiously observing the working of the needles in knitting, he formed in his mind the model of the frame which has proved of such singular advantage to that branch of our manufactures. See London Magazine, vol. iv. p. 337.

Soon after Mr. Lee had completed the frame, he applied to queen Elizabeth for protection and encouragement, but his petition was rejected. Defparing of success at home, he went to France, under a promise of being patronized and recompensed by Henry IV.: and, with nine of his servants, settled at Roan in Normandy. But by the sudden murder of the French monarch, Mr. Lee was disappointed of the reward which he had reason to expect, and died of a broken heart at Paris. After his death, seven of his workmen returned with their frames to England, and in conjunction with one Aiton, who had been apprenticed to Mr. Lee, and who had made some improvements in his master's invention, laid the foundation of this manufacture in England.

In the space of fifty years the art was so improved, and the
the number of workmen so much increased, that they petitioned the Protector to constitute them a body corporate, but their request was refused. King Charles II. in 1663, granted them a charter, extending their jurisdiction to ten miles round London. See Company.

Such is the account given of this invention by Dr. Deerling in his Hist. of Nottingham, p. 100, who has also described the stocking-frame, and exhibited several figures of this machine, and of the numerous parts of which it consists.

The frame-work, knitters being Rocking-weavers hall is situated in Red-Croft street. They were incorporated 15th Augst. 1663.

In this hall is the portrait of the author of this ingenious art, pointing to one of the iron frames, and discharging with a woman who is knitting with needles and her fingers. These words are on the picture: "In the year 1580, the ingenious William Lee, A.M. of St. John's college, Cambridge, devised this profitable art for stockings, (but being depri
ded of his frame by the Queen, but to us and to others of gold and silver, of whom much is here passed.)" Hatton's View of London, vol. ii. 607.

Yet Dr. Howell, in his History of the World (vol. ii. p. 222.), makes this invention eleven years later, viz. anno 1600; and adds, that Mr. Lee not only taught this art in England and France, but his servants did the same in Spain, Venice, and in Ireland.

Mr. Lee's invention was made about twenty-eight years after we had first learned from Spain the method of knitting stockings by wires and needles; it has proved a very considerable benefit to the stocking manufacture, by enabling England to export vast quantities of silk stockings to Italy, where, it seems, says Anderson (Hist. Com. vol. i. p. 415.) by sir Joshua Child's excellent Discourses on Trade, first published in 1676, they had not then got the use of the stocking-frame, though not much less than one hundred years after its invention.

A late writer in the Bibliotheca Topographica Britannica, No. 7, says that Mr. Lee, after some years' residence in France, received an invitation to return to England, which he accepted, and that thus the art of frame-work knitting became known in this country. Thus, be it, the invention, he adds, is most generally received, though it has also been attributed to a Mr. Robinson, curate of Thorto

ston, in Leicester. The first frame, we are told, was brought into Hinckley, in Leicester, before the year 1640, by William Iliffe; and now the manufacture of this town is so extensive, that a larger quantity of hose, of low price, in cotton, thread, and worsted, is supposed to be made there, than in any town in England. The manufacture has since employed about two thousand five hundred and eighty-five working people; the number of frames has been computed at about one thousand, and there have been also about two hundred in the neighbouring villages.

The towns of Leicester, Loughborough, Nottingham, and Derby, with the villages in their dependencies, are the principal seats of the stocking manufacture in England.

About the year 1756, Meffins. Jedidiah Strutt and William Woollatt, of Derby, invented a machine, by which, when annexed to the stocking-frame, the turned ribbed

Stocking-frame. A most ingenious machine for weaving or knitting of stockings. To comprehend the action of this machine, which is extremely complicated, it is first necessary to have a perfect idea of the nature of the fabric which is produced by it: this is totally different from cloth woven by a loom, as the slightest inspection will show; for instead of having two distinct systems of threads, like the warp and the weft, which are woven together, by crossing each other at right angles, the whole piece is composed of a single thread, untied or looped in a particular manner, which is called stocking-fitch, and sometimes chain-work.

This is best explained by the view in fig. 1. Plate Stocking-frame. A single thread is formed into a number of loops or waves, by arranging it over a number of parallel needles, as shown at R: these are retained or kept in the form of loops or waves, by being drawn or looped through similar loops or waves formed by the thread of the preceding course of the work, S. The fabric thus formed by the union of a number of loops is easily unravellable, because the inflated cap of the whole piece depends upon the ultimate fate of the first end of the thread; and if this thread is detached, the loops formed by that end will open, and release the subsequent loops one at a time, until the whole is unravellable, and drawn out into the single thread from which it was made. In the same manner, if the thread in a stocking piece fails or breaks at any part, or drops a stich, as it is called, it immediately produces a hole, and the extension of the hole can only be prevented by fastening the edge. It should be observed, that there are many different fabrics of stocking-fitch for various kinds of ornamental hosiery, and as each requires a different kind of frame or machine to produce it, we should greatly exceed our limits to enter into a detailed description of them all. That species which we have repre

sentied in fig. 1. is the common stocking-fitch used for plain hosiery, and is formed by the machine called the common stocking-frame, which is the ground-work of all the others.

Fig. 2. is a perspective view of a common stocking-frame, exhibiting as many of its parts as can be seen in a general view. The body is a wooden frame, consisting of four pillars N, and various cross-pieces, called rafters: the two uppermost, M, are placed horizontally in the frame; the other parts of the frame are situated, being fastened in a frame of wrought iron. The pieces which compose the iron frame are two folle-bars w, which are supported upon the wooden caps M, and at the ends have joints, to support the plier-bows G, G, of which they shall soon have occasion to speak. At the back are two vertical standards, V, called the back standards, which support the axis T. These standards are united by back cross-bars, which are clearly seen in the figure near V. There are likewise two front standards W, erected from the folle-bars w, w.

To give motion to this machine, the workman seats himself before it, as shown in fig. 3, and puts the different parts of the machine in motion by his hands and feet. He applies his feet upon two treadles B, B, which have cords, b, c, 2 ac, ascending from them, and passing in opposite directions round a barrel or wheel, upon the axis of which is a large wheel, D, called the flyer-wheel. By alternately pressing down one treadle, and allowing the other to rise, he can turn this wheel round in either direction at pleasure. The object of this movement will be described hereafter. There is likewise a third treadle, E, upon which the workman presses his foot, when he wishes to bring down what is called the plier-bar, marked F, the use of which will be afterwards explained. This bar is attached to two arms or levers G, which are movable round the fixed centre pins or joints j. The ends of the levers are of a curved form; hence the pieces G are called the
STOCKING-FRAME.

The preffer-bows. The connection with the tredle E is by a flagging or wire o, which ascends behind the machine, and is attached to the cross-bar H, which is extended from one of the preffer-bows to the other, and is cranked down, to avoid such parts of the machine as it would otherwise intercept in its motion. The return of the preffer and middle tredle, E, is produced by the re-action of the wooden spring 1, which is drawn into it with two sliding bars or some frames a counter-weight is used instead of the spring.

The weaver produces all the other movements by his hands for this purpose, he applies them to the ends K, K, of the hand-bar, and he can then very conveniently press his thumbs upon the thumb-plates L, L. By drawing forward or lifting up the hand-bar K, and at the same time pressing upon the thumb-plates L, or relieving them, he gives the requisite motions to what is called the frame of finkers, or simply the frame, because it contains the principal works of the machine. The thread of which the flocking is made is kept upon a bobbin M, flung upon in the front upright, N, of the frame, and the thread from this is carried upon the needles; and when it is woven into the flocking piece by the action of the needles and finkers, the piece hangs down at S, and is received upon a small roller fixed in an iron frame p, called the web, which is made sufficiently heavy to stretch the piece to a moderate tension.

As an introduction to a description of the whole machine, it will be proper to give the reader an idea of those parts which operate upon the thread, and of the motions which are given to them to produce the loops or meshes. These parts are the needles, the frame of finkers, and the preffer-bar: the needles are stationary, the rest moveable.

Fig. 1. represents what are called the needles: these are made of iron-wire, of the shape represented, and are hooked or barbed at the ends, the returned points of the hooks or barbs being made very delicate. There is a small cavity or groove punched or sunk in the item of the needle, immediately beneath the barb, of sufficient depth to receive the point, when an adequate pressure is applied upon the hook to bend the barb down. This barb then becomes closed eye, and if a thread is looped over the wire or item of the needle, and drawn forwards while the barb is thus closed, it will draw over the barb of the needle, and come off at the end of it: but if the thread is drawn forwards while the barb is open, it will be caught under the hook, and be thus detained, as shown at R. This circumstance must be particularly attended to, as the principal action of the machine depends upon it. The deflection of the barbs of the needles is produced by the edge of the preffer-bar F, which is extended horizontally over the whole length of the needles, and adjusted by preffing the foot on the middle tredle, as before explained.

Between every two adjacent needles, 1, 1, a thin plate of steel, 2, 3, is placed: these plates are called finkers; they are formed to a particular shape (as shown in fig. 4.), and are capable of being elevated or depressed, and also of being drawn backwards or forwards between the needles. These motions are given by the hands of the weaver, as the hand-bar K, which he holds, is part of the frame containing the jacks and finkers. The finker-frame consists of the hand-bar K, (figs. 2 or 4.), extending across it at the bottom; the hanging cheeks O, O, which form the upright sides of the frame; and the upper bar P, which is called the finkers-bar, because the finkers are fixed to it, being united several together in pieces of lead each an inch wide, which are cast round the ends of the finkers, and fastened by screws to the bar P.

To allow the frame of finkers to have the motions of which we have spoken, it is suspended by joints at the top of the hanging-cheeks, called the top joints: these joints are formed at the ends of the top arms, O, O, which are two horizontal levers fixed to an axis T, called the spindle-bar; the extremities of this turn on pivots, supported by the upper ends of iron uprights V, called the back standards. By the motion of the spindle-bar upon its centres, the finkers can rise and fall, and the quantity of this motion is limited by stop-screws applied to the vertical standards W. To draw the finkers forward between the needles, the finker-frame can be inclined upon the top joints of the hanging-cheeks, by drawing forwards the hand-bar K. From the middle of the spindle-bar, T, a short lever projects, which is borne upwards by a spring, Y, called the main-spring: this is supported by a piece which projects from the fixed cross-bar of the frame, and is of sufficient force to bear the frame of finkers upward, and give the top arms, O, O, a tendency to rest always against the upper stop-screws, X, of the standards W.

The hooked part or nips f (fig. 4.) of the finkers, are for the purpose of forming loops in the thread between the needles. To effect this, the nips, f, of the jacks and finkers are raised above the level of the needles, as in fig. 4., and the thread is extended across all the needles, immediately beneath the nips. If then the jacks and finkers are all pressed down between the needles, it is evident that the nips of the finkers must carry the thread down before them, and form it into loops hanging down between each needle, as shown at f. This, then, is the principal office of the finkers: but to perform the operation of flocking in the manner now described, by depressing the whole number at once, would not be practicable; because, as a greater length of thread is required when it is depressed into loops, than when it lies straight across the needles, it would require to draw the thread all at once from the bobbin M (fig. 1.), in sufficient quantity to make up the difference; to do which, the thread must slide or draw beneath the nips and the needles, which it could not do, on account of the friction.

The convenience to render this depression or looping down of the thread between the nips practicable is very ingenious. The row of finkers shown in fig. 4, is composed of two kinds, called jack-finkers and lead-finkers, which are very different in their movements, although we have hitherto spoken of them as one. The lead-finkers are all those of which we have spoken as being fastened to one bar P, called the finker-bar, which is part of the finker-frame, and which the workman moves by his hands: on this account, the lead-finkers all move together; they are one half of the whole number, and are disposed between every other needle, so that the space between each lead-finker has two needles in it. The jack-finkers are made of the same form as the lead-finkers, one being placed between each of the two needles contained between every lead-finker; therefore the lead-finkers and jack-finkers are disposed alternately to form a row, and a needle is placed in every space in the whole row. Each jack-finker is supported by a small lever, b i (fig. 3.) called a jack, freely movable on a centre-pin: the opposite end i, or tail of each jack, is preffed by a spring 1, which has a notch or indentation at a particular place; and when the jack is elevated, so that its nip, f, is above the level of the needles, i, ready to receive the thread, the end of the tail, 1, is received in the notch of the spring 1, which retains it in that position; but at the same time a flight force applied beneath the tail, 1, of the jack to lift it up will depress the nip, f, of the jack-finker, 3, between the needles. It is to be understood, that all the jacks, b i, are arranged in a row, and move upon one wire, which is a common centre of motion;
STOCKING-FRAME.

motion; but the motion is given to them one at a time, beginning at one end of the row, and proceeding one by one to the other. To effect this, a straight iron bar, or ruler, called the flur-bar, is extended beneath all the jacks, and upon this is a piece of metal, m, called the flur, travels, with rollers to reduce the friction: it is drawn by a line extended from each side, and conducted over a pulley m, at each end of the bar l, to be carried round the flur-wheel D, fig. 2. We have before explained how it is given to this wheel, by the action of the two feet upon the two treadles B, C; it is plain by this connection, that the flur, m, can be made to travel from one end of the flur-bar, l, to the other, and in so doing, that it will elevate the tails, i, of all the jacks, i, b, beneath which it passes, and produce a corresponding depression of the jack-finkers, 3, between the needles. After the flur has passed, the jacks retain the position given to them by the prelure of the springs d.

The operation of linking or forming the loops between the needles is thus conducted: the nips of all the jinkers are raised above the needles, as in fig. 4; the thread is then extended lightly across the flures of the needles, beneath the nips f. By pressing on one of the treadles, B or C, the flur-wheel D is made to turn round, and this, by the flur-line, draws the flur, m, from one end of the flur-bar, l, to the other. In its passage it encounters the tails, i, of the jack, and lifts them up one by one, which at the same time depresses the corresponding jack-finker 3; and its nip, f, links the thread between the needles, and forms a loop. As these loops are formed successively, the thread draws easily beneath the nip to produce each single loop, and the workman allows the threads to draw off from the bobbin, M, through his fingers, as fast as it is required. When all the jack-finkers are depressed, a loop of the thread will be formed between every other pair of needles. The workman then depresses the lead-finkers, 4, by pulling down the hand-bar K, and their nips carry down the thread between the remaining needles in loops, in the intermediate spaces between the forms of the loops; in doing this, he causes the jack-finkers, 4, to rise up, as much as he depresses the lead-finkers 3; because it should have been mentioned before that the first loops formed by the jack-finkers were double the depth intended, although only half the number: by this means they contained the proper quantity of thread to form the whole number of loops; viz. one between every two adjacent needles.

The jack-finkers are caused to rise up by means of the locker-bar, p, extending over all their tails i. Each end of this bar is screwed to a lever, 2, called a locker, which moves upon the fame centre as the jacks, and the front ends of these levers are made with inclined ends, so as to be laid up by wedges fixed at the back of the thumb-plates, L, which move on joints fixed to the flur-bar, and hang down in a convenient situation to be acted upon by the thumbs of each hand, when holding the ends of the hand-bar K. The weaver, therefore, pulls back the two thumb-plates L, at the fame time that he depresses the hand-bar, K, of the frame containing the lead-finkers; by which means he produces the ascent of the jack-finkers, in an equal degree to the descent of the lead-finkers, until the nips of the two arrange exactly in one line, which position is determined by proper loops attached to the flur-frame. By this means, a complete row of loops is formed, one loop between each needle.

These loops are now to be carried backwards upon the needles, into the position of S, fig. 1, so as to occupy the arch or opening, s, of the jinkers, which open part is made purposely to admit the loops last made to remain upon the flures of the needles, quite detached from the action of the flinkers, which are at liberty to form a new course of loops by the nips, f, of their points t.

If we suppose the frame has been before at work, the loops last formed, which hang upon the flures of the needles, will not be a single thread, but the loops at the upper part of the work S, fig. 1: it is only when the frame first begins to work that the loops will be a detached thread, as we have just described.

But it remains to shew how the loops are put back upon the needles: this is done by merely lifting up the hand-bar K, till the points, t, of the jinkers rise above the needles: the hand-bar is then drawn forwards a little, to advance the jinkers so much, that the points, t, which were behind the loops of thread upon the needles, will now come before them, and then the hands are depressed, to inflect the points, t, between the needles again before the threads; and by pulling back the hand-bar, the points, t, carry back the work upon the flures of the needles, so that it will be finished in the arch, b, or opening, s, of the jinkers.

When the jinkers advance or recede, they must all move together both the lead-finkers and jack-finkers, as if they were one. It is clear that there is no impediment to the moving forwards of the lead-finkers, because they are at liberty to incline or swing forwards upon the joints at the tops of the hanging-checks, O, O, which suspense the frame containing them: but for the jack-finkers to advance at the same time, it is necessary to bring forward the jacks, and their centre of motion, together with the springs and flur-bar. To admit of this motion, all those parts are framed upon a strong bar called the camel; and upon this is placed four wheels, which run upon the sole-bars, so as to become a carriage. To communicate motion to this carriage, a link is joined to a piece at each end, marked r, fig. 2 or 4, which is screwed to the flur-bar P, just within the thumb-plates L. These links are jointed at the other ends to the common centre of motion of the jacks. The joints of the pieces, r, are so adjusted, that they will exactly line with the joints which unite the jacks and jinkers together; and the links are the same length between the centres as the jacks, for which reason they are called half-centre links.

By means of this connection, the carriage, with all its appendages, viz. the jacks, with their springs and the flur-bar, are drawn forwards at the same time that the flur-frame is drawn forwards, by pulling the hand-bar K K; or, by a contrary movement, the loops of threads which were last formed upon the needles, will be carried back from the hooks or beards of the needles upon their items, as shewn at S, fig. 1, so as to be in the arch, b, of the jinkers, as before described.

The first row of loops being thus disposed of, the frame of jinkers is restored to its former position, and a second row is formed upon the items of the needles by a repetition of the same process, viz. extending the thread across the needles beneath the nips, f, of the jinkers; moving the flur by the outside treadles B C, which depresses all the jinkers, and makes a loop of double depth between every other pair of needles: this is called drawing the jacks: next preffing on the thumb-plates L, and depressing the hand-bar, K, at the same time, which elevates the jinkers, and depresses the jinkers by one movement, and produces a loop of thread between every two adjacent needles. Another complete row of loops is now formed upon the items of the needles; and this row is to be brought forwards, so as to be under the beards or hooks of the needles, in the manner shewn by R, fig. 1. This is produced by simply drawing forwards the hand-bar K.
STOCKING-FRAME.

which advances all the finkers together, and their points, 1, push forwards the thread till it comes into the beads, and these prevent it from coming off the needles.

The next operation is lifting up the hand-bar and frame of finkers as much as will raise their points, 1, quite clear up above the needles between which they were situated, and applying the foot on the upper treadle E, to bring down the finking-bar, F, upon the beads of the needles, to cloe them up, and while so closed, he holds the loops of thread at R, as if they were looped through the eyes of as many needles. The upper loops of the works which are at S, fig. 1, upon the items of the needles, in the arch, 1, of the finkers, are next brought forward upon the needles, by drawing forwards the frame of finkers; but in advancing these loops, draw over the closed beads of the needles, and consequently over the half-formed loops, which remain underneath the beads, in the position shown at R, fig. 1; or, in other words, the loops left formed, and resting under the beads at R, fig. 1, are drawn through the loops of the upper or half course of the finished work which remained upon the items of the needles, as represented at S. By this means, the loops of what was the upper or half course of the finished work, become secured from opening or unravelling, and the loops under the beads now become the last or upper course of the work, and are preferred from unravelling by the needles, one of which passes through each loop; and these loops will not be drawn off from the needles until there is another row of loops prepared, and referred under the beads of the needles, ready to be drawn through them.

When the piece of work is finished, and taken off from the frame, the last made row of loops must be secured by running a thread through them, or other means, or they would draw through the preceding loops, and release them, which in like manner would release their predecessors, and so the whole piece would unravel.

The motion of the frame of finkers, which produces the advance of the finkers towards the points of the needles, or their recessions towards the item, takes place upon the centres, called the top joints 0,0, and the wheel under the centres, as before mentioned. The quantity of motion is limited by a piece, fig. 7, called the arch, which is fixed fast against the inside of the wood-frame N, fig. 2, a part of the hanging-checks O,O, of the frame of finkers descends with a projecting part to act round this arch, which, at the same time that it limits the quantity of motion, prevents the motion being made, except in a proper succession, to produce the effects before described. Thus, when the hook is beneath the arch, the points, 1, of the finkers will be beneath the level of the needles, and then the frame of finkers cannot be raised up without first moving the lower part of the frame either forwards or backwards. In the same manner, when the hook is above the arch, the finkers cannot be depressed till they are moved. When the thread is first extended across the needles, in order to be sunk into loops, the frame is said to be over the arch, that is, the hook is at the back, or on the farther side of the arch, and by applying thereto, the finkers are guided in their sinking, that is, when they descend, they depress the thread to form the loop. When this sinking has taken place, the finker-frame will be at its lowest position, and the top arms, O, will rest upon the lower drop-crew of the standards W. When the finkers are brought forwards, to draw the loops from the items of the needles into their beads or points, the hook of the frame moves along the under side of the arch, and this prevents the points lifting up, while the lower stop prevents them from sinking down; but when the finkers are brought sufficiently forwards, the frame is lifted or thrown up by the main-spring, the hook following the curvature of the arch, until the points are completely above the needles, or the frame has reached the upper stop. The finkers are then brought forwards upon their centre of motion, while the preffer is drawn down to cloe the beads of the needles and draw the loops over them; in doing which, the hook quits the arch, and the frame moves forwards without any guide, the frame being unnecessary, because the motion of the finkers is determined by the upper stop, against which the frame rises by the action of its main-spring; and the proper degree for the advance of the finkers is determined by the drawing forwards of the frame with sufficient force to draw the loops of the work tight; this force the workman must regulate by habit, fo as make his work close.

In returning the frame of finkers, in order to put back the work upon the items of the needles, fo as to be out of the way while a new row of loops is made, the hook, 9, must be carried back beneath the arch, which will keep down the points of the finkers, fo as to prevent them from rising above the needles, as they would then quit the work they are intended to drive back upon the needles.

By the operation which we have described, one course of the work is formed; but, to render it more clear, we will continue the description, in a few words, of the working of another course. Preparatory to working it, the loops of the last course of the work, and by which the work is suspended from the needles, must be pushed back upon the items of the needles to the position S, fig. 1, fo as to come into the arched or open part, 1, fig. 4, of the finkers: this is done by depressing the finkers low enough for their point, 1, to enter between the needles, and then pushing back the hand-bar and frame of the finkers to carry back the work upon the items of the needles. This is the situation in which we suppose the frame, when the operation commences; and the frame is over the arch.

The first movement is the gathering of thread. The thread laid over is lightly extended across the needles, beneath the nips, 1, of the finkers; and by pressing the bar-treadle BC, the jack-finkers are depressed one by one, fo as to form double loops. This is called drawing the jacks.

The second movement is sinking. This is done by drawing down the hand-bar K, and bearing upon the thumb-plates, L, at the same time: the whole row of lead-finkers is thus depressed, while the jack-finkers rise, and the thread is carried down into a loop between every two needles.

The third movement is to bring the frame forwards under the arch. This is done by drawing the hand-bar forwards, and the row of loops just made is brought under the beads of the needles.

The fourth movement is to bring the work forwards from the item of the needles. To do this, the finker-frame is lifted up, by elevating the hand-bar K, so that the point, 1, of the finkers will be quite drawn out above the needles; and in this situation, the hand-bar and finker-frame being brought forwards, the breast or curved part of the arch, 1, of the finker will bring forwards the piece of work which hangs upon the items of the needles, by its loops last made.

The fifth movement is closing the work, or drawing the loops last made, through the finished loops of the work. The preffer-treadle E, being borne upon at the same moment, will bring down the preffer, and it will bear upon the beads, and cloe them, while the loops are drawn forwards; consequently the loops of the old work will be drawn over the beads, and quite off from the needles; this draws the loops thereof over the loops last made, which remain
main in the beards of the needles. To draw the work tight, the hand-bar, $X$, is drawn forwards two or three times with a slight jerk, so as to extend all the loops to their fullest quantity, and make the loops of the work unite closely.

The course is now finished; but as a preparation for making another course, the work must be carried back upon the stems of the needles into the situation of $S$, fig. 1. This is the sixth and last movement. To put back work, the frame is pulled down to bring the points of the finkers below the level of the needles; and in this position, by depressing back the hand-bar, and all the finkers together, the threads will enter between the ends of the needles, and carry back the loops of the work upon the stems of the needles, where it will remain in the arches of the finkers, so as to be detached from them, and out of the way, while a new set of loops is formed by the nips of the points of the finkers; and then the loops of the old work are to be drawn over those last made.

The movements are then repeated; 1st, gathering the thread upon the needles, and depressing it into large loops between every two needles, by the motion of the flor; 2d, finking, to make the loops between all the needles; 3d, bringing the thread under the beards of the needles; 4th, bringing the work forwards from the stems of the needles towards the beards, and changing the beards by the prelure of the plier-bar, and drawing the work over the beards; and, 6th, putting the work back on the needles, ready for working another course.

The operation of the machine proceeds in the manner described; and as each as the courses are completed, the work descends lower, and hangs down in a web from the needles. When the piece is of a considerable length, it is rolled upon a roller, in an iron frame $y$, called the web, and the weight of the frame is sufficient to keep the piece to a proper tension. The roller in the web can be turned round occasionally to wind up the piece, and is retained by a ratchet-wheel and click.

Having given an idea of the manner of the operation of this curious machine, it only remains to explain the adjustments with which it is provided, in order to make it work correctly.

The fineness of the work depends on the number of loops which the thread will make in any given length, and this will be equal to the number of needles and finkers in the same space. This number of needles in an inch is called the fineness of the frame, and changing the number of the finkers, which latter are used for the finest flockings. The gauge of a frame cannot be altered when it is once made, and the work which it will produce must always be of the same degree of fineness, although it may be made a little more dense or more open by drawing the loops very close, or by allowing a greater quantity of thread, and making the loops longer. This circumstance will evidently depend upon the depth to which the nips of the finkers descend between the needles, when they carry down the thread into loops. To regulate this depth, the needle-bar, or that piece which sustains the heads containing the row of needles, is made to rise or fall a slight quantity, by means of two long adjusting screws, the heads of which are made with notches, and springs fall into them to keep the screws from turning back; these heads are called the star, and the notches nick; one is marked $g$, in fig. 2 and 3.

The motion allowed to the frame of finkers is limited, as before-mentioned, by stops projecting from the two upright standards, $W$; and through these stops, stop-screws, $s$, are fitted, to regulate the degree of ascent and descent. The main-spring, $y$, is made of sufficient strength to lift the weight of the frame of finkers, and make them always rise up as high as the upper stop-screws will permit.

The manner of making different parts of the flocking-frame is worthy of notice. The needles are made of iron-wire, of a proper degree of fineness; it must be of good quality, so that which is liable to split or splinter, either in filing, punching, or bending, is totally unfit for the purpose. The wire is cut to lengths, and annealed or softened in a box of charcoal, in which they are heated to redness, and suffered to cool gradually; the needles are next punched with the small cavity which is necessary to receive the point of the barb: this is done by a simple screw-prefa. The point of the needle is next formed by the file and burrsifer, and the hooks are then bent to form the barb: next the needles are flattened, each with a blow of the hammer. To fasten these needles together, and fix them in the machine, they are placed parallel to each other in a mould or frame, and tin or pewter poured into the mould, round the flattened ends of the stems. The piece of lead or pewter is just an inch in width, and the number of needles which it will contain, gives the denomination to the gauge of the frame. These leads of needles are fastened to the needle-bar by a screw through each. The lead-finkers are made of steel-plates, which are put together by casting lead round them at the upper end of the frame. The rack, or piece, which contains the centre of the jack, is called the comb, because it is composed of a number of small plates, fixed into a bar by casting them with lead or tin.

The flocking-frame has undergone very few alterations since its first invention, a circumstance highly creditable to the genius of the inventor. A flocking-frame for weaving the tartan plaid hole which is worn in Scotland, is described in the Society of Arts Transactions, vol. xxix. p. 84: it contains some additions invented by Mr. John Robertson, at Stockport, in Cheshire, a town of Saxon, in the county of Chester; 3 miles S. E. of Chester, or south-east of the city of Chester, and 3 miles N. E. of Macclesfield, the county town of the county of Chester, and 3 miles W. of Macclesfield, the county town of the county of Chester, and 5 miles S. of Chester, the county town of the county of Chester.

STOCKPORT, formerly written Stokport and Stock-

PORT, a town in the hundred and deanery of Macclesfield, is situated 175 miles from London, on the banks of the river Mersey, partly in Cheshire and partly in Lancashire. The part of the town in the latter county is called Heaton-Norris, and is united to the Cheshire part by a bridge. In 1811 it comprised 819 houses, and 7522 inhabitants; whilst the remaining portion of Stockport contained 3326 houses, and 17,545 inhabitants. The population of the town and its neighbourhood is chiefly employed in various branches of the cotton manufacture. According to Melsa, Lysons's statement in 1810, there were then 25 factories for cotton goods, one silk-mill, and several establishments for the making of mullins. The parishes of Stockport contain fourteen townships, viz. Stockport, Bramhall, Bredbury, Brinnington, Dukely, Duncheonfield, Etchell's and Stockport-Eastfield, Hyde, Marple, Norbury, Offerton, Romiley, Turton, and Weaste. These are all populous, and appear chiefly to have been parts of baronies and manors; and there yet remains in some of them, armorial or architectural relics of their antiquity.

In the time of Edward I. Robert de Stockport, earl of Chester, made Stockport a free borough. In 1260 he also obtained a grant of a market, and an annual fair: at present there are four of the latter, and the former continues Friday and Saturday. Although there be no charter extant, yet a mayor is annually elected, or rather nominated, at the Lord of the manor's court. So soon as the Norman conqueror, the mayor of Stockport belonged to the De La Spenes;
it is now the property of Lord Viseount Bulkeley, in right of his lady. In the year 1773, the castle of this place was held by Geoffrey de Cottamene against King Henry II. It afterwards belonged to the Stockports, and subsequently to the earls of Warren; but the whole has been long since demolished. During the civil wars in Charles I.'s reign, Stockport was garrisoned by the parliament's army, and was considered an important post. In May, 1644, Prince Rupert appeared before it with his army; the garrison, to the number of 3,000, drew out to oppose him, but were repulsed, and the town taken. In 1745, Stockport bridge was blown up, to prevent the retreat of the rebels after their advance to Derby.

The places of religious worship at Stockport are, the parish-church of St. Mary, which, from the style of its architecture, appears to have been erected about the 14th century; the chapel of St. Peter, built and endowed, in 1768, by William Wright, esq.; a meeting-house for Presbyterians; another for Quakers; and several for Methodists. Near the town is a chapel for Roman Catholics, many persons of that persuasion, emigrated from Ireland, being resident here. The chief public institutions are, a free-school, founded, in 1497, by Sir Edmund Shaw; an almshouse, founded, in 1595, by Edward Wright; &c.; a dispensary, on a very enlarged plan, established in 1714; and several Sunday schools, instituted in 1714; one of which, conducted chiefly by the Methodists, is supported on such an extensive scale, that three thousand children are now educated in it wholly by gratuitous teachers; a large school-house erected by subscription in 1805.—Lyons's Magna Britannia, Cheshire, 4to. 1810. Beauties of England and Wales, vol. ii. p. 160. By J. Britton and E. W. Brayley.

Stockport, a town, or rather village, of America, in the state of Pennsylvania, and county of Northampton, on the W. side of the Popawtunk branch of Delaware river; from which is a portage of about 18 miles to Harmony, on the E. branch of the Susquehannah river.

Stocks, in Gardening, such young trees as are raised from seed, suckers, layers, or cuttings, and designed for the reception of grafts and buds of other trees, to continue them the fame and become trees in every respect like the parent trees from which they were taken. Stocks for general use are proper when from the size of a good large gooseberry, and the nature of the wild stock where the graft, &c. is to be planted, but they are sometimes used when two or three inches in diameter: these are made of use in most kinds of fruit-trees, and occasionally for some varieties of forest and ornamental trees, and many of the shrub kind: they should in general be species or varieties of the same genus as the trees with which they are to be grafted.

They are usually divided into three kinds; as crab stocks, free stocks, and dwarf stocks, each comprehending various sorts, both of the same and different genera, species, and varieties.

Crab Stocks.—These are all such as are raised from seeds, &c. of any natural or ungrafted trees, particularly of the fruit-tree kind; such as the crab-apple of the woods and hedges, any kind of wild thorny uncultivated pears, plums, wild black and red cherry, &c.; and also of such trees as have been grafted or budded: some sorts, being strong shoots and hardy, are preferred, on which to graft particular species, to improve the size and duration of the tree; for example, apples are very commonly worked upon the common wild crab stock, and cherries on the great wild black and red cherry stock, as tending to promote a large, hardy, and durable growth, proper for common standards and the larger kinds of dwarf trees. In using crab stocks to graft any sorts of fruit-trees, it is proper to reject such of them as assume a very wild crab-like growth, or of a flinty, thorny nature, preferring those that are the freest clean growers: sometimes, however, the appellation of crab stocks is given to all stocks indiscriminately, before being grafted, whether raised from the seed, &c. of wild or cultivated trees, until worked with grafts or buds, but with the dillinctions of wild crabs and free crabs.

Free Stocks.—This is a term commonly applied to such sorts as are raised from the kernels of the fruit, layers, &c. of any of the cultivated garden and orchard fruit-trees, and others, which often in general culture are commoner than the wild crabs, and are more proper than they for grafting choice apples, pears, peaches, nectarines, apricots, and plums upon, to improve the growth of the trees and quality of the fruit.

Dwarf Stocks.—These are such sorts as are raised from low growing trees, of a shrub-like nature, or but very moderate tree-growth, being used for the lower and middling sorts of standards and to form dwarfs, either for walls or espaliers, or as dwarf standards in small gardens, and others, which often in general culture are commoner than the wild crabs, as they never attain a large growth, sufficient to produce any considerable quantity of fruit: the codslin dwarf stocks, quince stock, morello stock, and small May cherry stock, for cherries; the bullace and mullel stock for dwarfing apricots, peaches, and nectarines, and sometimes dwarf-almond stocks for the latter, when designed to have the trees of a very dwarfish growth, either to pot for curiosity, or for forcing in small forcing-frames.

But the most dwarfish kinds are: the paradise stock, bird-cherry, black bullace, and dwarf-almond; but they are not so proper in general culture as common dwarf trees, as they never attain a large growth, sufficient to produce any considerable quantity of fruit: the codslin dwarf stocks, quince stock, morello cherry, and mullel stock, are proper for the middling or larger kinds of dwarf trees, either for walls or espaliers, or dwarf and half standards: they are all raised from suckers, layers, or cuttings.

Sorts of Stocks adapted to each Kind.—For apples, in all the sorts of dwarfs, they are tho' of their own sort, raised from the kernels of any of the cultivated apples or crab for common standards, and the latter freely by suckers, layers, and cuttings: the early sorts being preferred for the general supply of lower trees, for all common standards, and the larger dwarf pear-trees for extensive walls and espaliers: the quince stock is estimable principally for its dwarfing property, or in being productive of moderate fruiting trees for walls, espaliers, or middling standards, sooner arriving to bearing growth. In order to form dwarf pears, white thorn stocks, raised from seed, were formerly sometimes in repute, but they are very improper, as the trees rarely proper.
STOCKS.

prosper well; as the goodness of the pear is often improved or diminished by the nature of the stock on which it is grafted, it is of importance to use free stocks, raised from the kernels of the best summer and autumn pears, as much as possible; and the prime pears should be worked always on the finest tree-shoots of the most cultivated-like growth; sometimes, to improve the quality of particular choice kinds of pears, it is the practice to double-work them, which is to graft the best roots into free stocks in the spring, which shoot the same year; then about midsummer, or soon after, to bud the young shoots of the graft with buds of the prime roots of pears, suffering only the shoots from the second budding to run up to form the tree: the breaking kind of pears are often rendered less hard and flomy in this way, and the melting property of others is considerably improved. See Pyrus Communis.

And for quinces, two sorts of stocks are occasionally used, as that of its own kind, and the pear stock; the quince stock is raised from seed, suckers, cuttings, &c., and the pear kinds from the kernels of any sort of pears; but as all the varieties of quinces are so expeditiously raised with certainty the same by layers and cuttings, it renders the raising of stocks for grafting or budding them on almost unnecessary. See Pyrus Cydonia.

Also for plums, the operation is performed only upon stocks of the largest dwarf sorts, raised from the stones of any sort of cultivated plum, or by suckers and layers, as the most certain methods to obtain any particular variety of free plum stock, as the muscle-plum stock, which many prefer as the best root of all on which to work the finer kinds of plums, as generally producing very thriving moderate growing fruitful trees; raising it, not from seed, which would very exceedingly, but by suckers from the root of real muscle-plum trees, or of those upon the true muscle stock, or from layer stocks of the muscle-plum tree: the plum will also grow upon the apricot and cherry stocks, but not in a thriving state for any length of time. See Prunus Domestica.

For cherries, the proper stocks are those of the cherry kind only; as the great wild cherry stock for large trees, the cultivated garden cherries for the more moderate growths, and the bird-cherry stock for small dwarfs: the two former are raised from the stones of the fruit, and the latter also by seed, or by layers and cuttings: for general use, the wild black and red cherry stocks, being strong free growers, are preferable for all common large standard cherries, also the larger dwarf trees for extensive walls and espaliers; as these stocks, being of strong hardy growth, generally produce larger, more hardy and durable trees than the cultivated cherry stocks; sometimes stocks of the moretol and May cherry, as being moderate growers, are used to raise the smaller cherry-trees upon, either in dwarfs for low walls and espaliers, or for small moderate standards; but the former, when raised from layers, is more certain of producing the real root in its naturally moderate growth: the common bird-cherry, as being a very moderate grower, is used for standard cherry-trees on, either to plant in borders, pots, forcing-frames, or for pot for forcing, &c.: they are raised plentifully from seed, cuttings, and layers; and have the effect of dwarfing trees exceedingly, so as to bear fruit when but one or two feet high; and shooting very little to wood, generally bear abundantly for their size: and cherries will also grow upon plum, apricot, and laurel stocks, as being of the same genus. See Prunus Cerifusa.

For apricots, these prove the most durable on stocks of the plum kind, as common plum stocks of any variety for all common wall, espalier and standard trees; and the bul-

lace stock for small dwarfs; the plum stocks are raised from the stones of any kind of cultivated plum, or by suckers from the root; and the bullace from seed, suckers, and layers: though they succeed almost equally well upon stocks of any kind of plum, it is probable they may prove the most successful on the muscle-plum stock, like peaches, &c., as being of a more moderate regular growth, and more prolific nature; the bullace stock is only used occasionally to raise moderate small dwarfs for low walls, or to plant in pots, or in forcing frames for forcing: the apricot will likewise grow upon its own, and on peach and almond stocks raised from the stones, but never in so prosperous or durable a manner. See Prunus Armeniaca.

For peaches, several sorts of stocks are occasionally used; as almond, peach, nectarine, apricot, and plum stocks; they are all raised from the stones of the fruit, and the latter also by suckers and layers; but the plum stock, being the most hardy, is the most proper for general use; but the free plum stock is preferable for all the sorts of peaches and nectarines, as being productive of the most hardy, thriving, and durable trees; though it is remarkable, one sort of plum stock in particular is generally preferable on which to work peaches, which is that of the muscle-plum, as producing the most prosperous trees, and of a more moderate, regular, and fruitful growth, the fruit being of a superior quality of pith and flavor in genuine; being raised from suckers or layers of the true muscle-plum tree, or by suckers from the roots of such peach, nectarine, plum, &c., as are worked on muscle-plum stocks, which generally send up plenty from the roots annually, planting them off at one year's growth into the nursery to train them for use: double stocks, or double working, is sometimes used for the more delicate peaches, to improve their bearing, and the flavor of the fruit.

For nectarines, the same stocks as in the peach are used: as almond, peach, nectarine, apricot, and plum; all raised as for the peach-tree: the plum stock should be preferred in general as for peaches.

For almond-trees, when raised for their fruit, the approved varieties may be budded into stocks of any sort of almond, peach, nectarine, apricot, or plum, raised from the stones, and the latter also from suckers, &c.; but the trees are generally the most hardy and durable on plum stocks. See Amygdalus.

For medlars, three or four different stocks are occasionally used, to raise the approved varieties: as the medlar, white-thorn, pear, and quince stocks; the three former raised from seed, and the latter from suckers, layers, and cuttings: the medlar feeding-raised stocks are very proper to graft the approved varieties; and the white-thorn and quince stocks are only used occasionally: but free stocks, raised from the kernels, of medlars, or summer or autumn pears, are preferable to the two last for all the varieties of the common medlar, which, either on their own or pear stocks, generally assume a more free growth, and produce the fruit in greater perfection and abundance. See Mespilus.

For sweet service-trees, we either, or on the fruit-trees, the approved varieties should be grafted or budded upon proper stocks; either principally their own raised from the seed, or occasionally on pear or quince stocks, raised as for the medlar and other trees; though any of the forbus, or the pear kind of stocks, are preferable to the quince to work this tree on to have it large and durable; but quince stocks may be used to have tree's smaller growth, for low standards, espaliers, &c.

For the wild maple-leaved service berry-trees, the proper stocks are either their own kind, or those of the hawthorn,
STOCKS.

thorns, raised from the seed; they also take upon pear
stocks, &c.

For hazel-nuts, the fiber, &c. the stocks of the com-
mmon nut-tree, raised either from the nuts, or by suckers
from the root, may be used; but this method is seldom
employed. See Corylus Avellana.

For orange-trees, these are worked upon stocks of their
own kind only, as any kind of orange, lemon, or citron
stocks, raised from the kernels of the fruit; though the
Seville orange, as being a very free strong shooter, is gen-
erally preferred for orange stocks; but the lemon and citron,
being also free growers, form very proper stocks to raise any
variety of oranges on. See Citrus Aurantium.

For lemon and citron trees, these varieties are also budded
or inarched upon lemon, citron, or orange stocks, raised
from the kernels of the fruit, as for oranges. It is evident,
that in this method, for curiosity, the same stock may be
made to support two, three, or more different varieties of
fruit, grafted or budded, either all into the stock, being
previously trained with branches, forking off for the pur-
pouse one for each graft, or by cleft or crown grafting
single large stocks, with two or more different buds by in-
culation; likewise the stock being singly grafted or budded,
different sorts may be inserted into the shoots arising from
the graft or buds; and thus two, three, or more sorts of
apples may be had on the same root; and by the same me-
thod, two or more sorts of fruits may be had upon the same
stock, as plums, cherries, and apricots all on a plum stock;
or peaches, nectarines, and apricots on the same, or on
stocks of their own kind; and pears, medlars, and quinces
upon the pear stock; also red and white currants, or cur-
rants and gooseberries, on a currant or gooseberry stock;
or white and red grapes on a vine stock; likewise red and
white roses, or other different sorts, upon a common rose
stock; as well as upon numerous other trees and shrubs, which
are species or varieties of the same genus. See Citrus
Medica.

Method of Raising the Stocks.—All the different sorts may
be raised by seeds, suckers, layers, and cuttings. In the first
or seed mode, various sorts of stocks may be raised from the
flowers of different sorts of trees; as the kernels
of all the apple kinds, pears and quinces; and the
flowers of plums, cherries, apricots, peaches, and nectarines;
the seeds or flowers of medlars, services, &c.; also nuts,
when designed for stocks; all of which should be obtained
in autumn from their respective fruits when fully ripened;
and when well cleared from the pulpy substance, each sort
may be sown separately, in beds of common light earth in
the nursery, either directly, or after being preserved in sand
until February, but the early autumn is the best season; and
if the winter should prove severe, the beds of the more tender
kinds, as almonds, peaches, &c. may be covered with dry
litter to defend the seed from the frost. See Nursery.

But before the appearance of the plants above ground,
where the surface of the bed is hard-bounded or caked, it is
often beneficial to flir the surface lightly with a small iron
rake; also, if very dry weather prevails, to give frequent
small waterings, both before and after the plums are up,
repeating the waterings occasionally in dry weather all the
spring and early part of summer, to encourage a free strong
growth; being likewise careful to keep the beds very clean
from weeds, by diligent hand-weeddings; and by thus giving
every encouragement, the feeding stocks will grow so
freely during the summer, as, by the autumn or the spring
following, to be mostly of a proper size to plant out into
nursery-lines in open quarters, in rows two feet asunder,
for remain for grafting and budding upon; though, if they
have made but middling progress the first summer in the
feed-bed, and are rather small and weakly, the strongest
only should be planted out, leaving the rest growing until
the next autumn, when they will be all of full size for plant-
ing out wholly into the open prepared nursery quarters,
and the feeding plants up out of the beds, shortening any
perpendicular tap-root and long stragglers, but leaving all
their tops entire, and then planting them in lines, either
by trench-planting, slit-planting, or dibble-planting, as the
sizes of the plants admit, in rows two feet or two feet and a
half asunder, setting the plants one foot or fifteen inches
apart in each row, in an upright position; and after having
planted one row, treading the earth gently all along close
to the roots of the plants, to fix them firmly in the earth
all evenly in a straight range; proceeding in the same manner,
row and row, till the whole is planted, levelling the surface
of the ground between all the rows with the spade or rake.
Their future culture, until grafted or budded, consists in
occasional waterings in the first spring, hoeing over the
ground every summer, digging between the rows annually
in the winter or spring, and training the stocks each to one
item; preferring their top always entire, but trimming off
the strong laterals below, to encourage the strength of the
main item, when they will be fit for grafting or budding
upon, in from one to two or three years. See Planting,
In Gardening.

It may be noticed, that they are proper for working
when from about the size of a large goose-quill, as already
observed, to the thickness of a man's little finger, or a little
more; but the sooner they are worked upon, after they are
of a due size, the better they succed, and the sooner they
form trees. See Grafting and Budding.

In some cases, however, where the stocks have shot freely
the first summer after planting out from the feed-bed, many
of them may probably be of a due size to graft the fol-
lowing spring and summer, at five or six inches height, to
form dwarfs for walls and espaliers, &c. or even, in some
stocks, for full or half standards, provided the first main
shoot from the graft or bud is trained up singly, two or
three years, to form the item, of from four or five to six or
seven feet stature; however, if they have grown but moder-
ately the first and second seafons, and are not generally
in a condition for the operations of grafting or budding,
it is better to let them have another year's growth.

But in the second or sucker mode, the suckers of all the
trees which afford them should be planted off at one year's
growth, in autumn, winter or spring, which is a very ex-
pedient method of raising several sorts of stocks; so that,
after being transplanted into the nursery, they often, in one
or two years' growth, afford proper stocks for the reception
of grafts and buds; and many of them are often fit for bud-
ding in the summer following, at the proper budding season,
or for grafting in the spring afterwards.

The suckers are generally fit to take up for the purpose
of stocks, when of one year's growth, and about the size of
a tobacco-pipe, or but little bigger, and should be collected
in autumn, or the early part of winter; taking them up as
well rooted as possible, and after they are taken out, the
knobbed or tuberous parts of the old roots that may adhere to
their bottom, trimming the straggling fibres, and cutting off
all side-flotes from the item; then planting them in rows two
feet asunder, and one foot distant in the lines; treading the
mould gently to their roots, and finishing the work by levell-
ing the surface between the rows. The culture afterwards,
until grafted or budded, is nearly the same as that of the
feeding stocks, keeping them clean from weeds in summer
by hoeing, and probably some of the strongest shoots may
STOCKS.

may be fit to bud in the July or August following, though the general or greatest part will require two years' growth, before they are proper for working; still continuing them all to one stem, by the time displacing strong laterals, and preferring their top or leading shoot generally entire until grafted, &c.

The third or layer method is practiced for some sorts of flocks of fruit and other trees, and when any particular variety of flock is required, such as the paradise flock for apples, mulberry for peaches, &c. that they may be obtained of the real flock with certainty; but as this method of raising flocks would be attended with great trouble for general grafting or budding, it is only practiced occasionally. In providing them in autumn or winter, some of the young shoots of such trees as have the branches naturally growing near the ground, or in which the items have been cut down low while young, to force out branches near the bottom, to furnish shoots properly situated for laying, should be filled in the common method, when they will mostly be rooted by the autumn following, and be fit to take off and plant into the nursery, being managed as directed for the laying of flocks, &c.

In the last or cutting method, cuttings of the last year's shoots should be chosen in autumn, planting them in the nursery, in a somewhat shady border, giving occasional waterings the following spring and beginning of summer, in dry weather, when they will be mostly well rooted by next autumn, and may then be planted out in nursery-rows two feet afar, managing them as the others. They should be kept with upright items, except any should assume a fluted or crooked growth; in which case, they should be pruned down to the ground in the spring, when they will put out strong from the bottom the ensuing summer, training them to one item, and with their leading top-shoot entire as above; and according as all the sorts advance in growth, they should be deflected of strong lateral flocks below, repeating it particularly in the taller standard flocks, to encourage their upright direction more expeditiously to the proper grafting and budding heights. But the proper methods of grafting and budding, for the different sorts, are shown more fully under the culture of the different kinds, as well as under the heads Budding and Grafting.

It is related to flocks in general, but little that is satisfactory has yet been done, in either determining the utility and advantages of such as are taken from different species of the same kind, or in any other way; but an ingenious inquirer on horticultural subjects, T. A. Knight, esq., has lately been engaged in some experimental trials for ascertaining the advantages or disadvantages of using flocks of different species in the culture of the peach, the nectarine, and the apricot, which may probably throw some additional light on this intricate and imperfectly elucidated practice. It has been stated by this writer, on the authority of Sir Joseph Banks, in the "Transact of the Horticultural Society of London," that in the practice of the French gardeners, they consider flocks of different species to be necessary to correct the defects of different soils and varieties of fruit; and that the peach-tree should, in some cases, be budded upon the plum-tree, in others upon the almond-tree, and in others again upon its natural flock, that of the apricot; while, on the contrary, our gardeners supplant the plum flock to be, under all circumstances, the best adapted to the peach; and still further, that Du Hamel, to whose opinion the greatest deference is constantly to be paid, pronounces the plum flock as never to be eligible, and affirms that he has seen the peach-tree thrive upon flocks of the apricot, in soils where it would not succeed either upon the almond or plum flock. It is also stated by the last writer, that it is said to be the common practice of the French gardeners, that the peach-tree, when grafted upon its natural flock, is more liable or subject to generate gum, than when it grows upon a flock of another species; and that, whenever the tree is confined to a small space, and consequently closely pruned, this opinion is believed by Mr. Knight to be, in some cases, well founded. But as he is not acquainted with any advantages that can be obtained or derived from fecling flocks of a species different from that of the bud or graft inflected, except in cases where it is advisable to render any tree more dwarfish and governable in its manner of growing, and consequently more productive, in soils and situations where rapidity and exuberance of growth and health might prove injurious: it is indeed suspected, that the peach-tree might be budded upon its own flock, in many cases, with considerable advantage. The growth of the peach-tree, it is said, is so rapid under these circumstances, that, with the aid of artificial heat, the flock which is raised from a seed in the spring may be budding and headed down for the same season, and afford a crop to bear many peaches in the succeeding year; and for forcing-houses, where exuberance of growth may be effectually checked by a succession of heavy crops of fruit, the writer says he should prefer such trees to any others. The fruit which they afford in the first season has, however, been found to be inferior in flavour to that which older or trees of longer growth produce.

The following interesting circumstance is stated by Mr. Knight, in respect to the Moor Park apricot. In his garden, this tree, in many others, he says, becomes, in a very few years, diseased and debilitated, and generally exhibits, in spaces near the head of its stock, lifeless albunums, beneath a rough and scabrous bark. About sixteen or seventeen years ago, a single plant of this variety was, it is said, obtained by grafting upon an apricot stock; and that the bark of this tree still retains a smooth and polished surface; and the whole tree presents a degree of health and vigour, so perfectly different to any other tree of the same kind in his garden, that he has found it difficult to convince gardeners, who have seen it, of its specific identity.

It is hoped that this statement may induce the possessors of public nurseries to try the effect of flocks of different species, and particularly those of the apricot; for though it may be their interest that the trees they sell should perish, as they now generally do within a very few years, it cannot be supposed that the more responsible nurserymen would be influenced by such a consideration: besides, an additional price, which will, it is said, to some extent be necessary, if such a method should be had recourse to, will afford a fair compensation, should the number of trees on sale be in any way diminished.

Such a mode of raising and providing fruit-trees of several different kinds is certainly well worth being put to the trial, as it is of great consequence, in many cases, to have more lathing trees of such sorts than those which are at present employed in the ordinary practices of the garden.

STOCKS. Apple and Pear, for Field Fruit-groonds, in Rural Economy, the stocks which are made use of in raising and providing them with trees of these sorts, in different districts. Several kinds of stocks are employed in this instance, sometimes by way of having the branches or parts of suitable and proper trees of these kinds inflected into them, and at others as seedling-trees, without that being done, though the first mode is the most ready, and for the most
STOCKS.

most part had recourse to, especially in some districts. The pear is, however, the most advantageously raised on flocks of its own species, and lasts longer than the apple-tree.

Raising the Stocks.—In performing this, the fresh pulp of the apples affords a sufficiency of pips or kernels for the supply of the feed-bed; which, after it has been well prepared by digging and other means, has them somewhat thickly sown, or the pulp spread evenly upon it, either in the autumnal or spring leaon, and carefully raked or lightly harrowed in, so as to be well covered with the surface-mould: the latter of these season is, however, supposed to be the best and most fortunate, as there is the least danger of their being destroyed by mice and other vermin, which often greedily prey upon them during the winter months. All weeds are carefully prevented from rising during the ensuing summer-seaon; and in the second or third autumn, the young flocks are mostly ready to be put out into the nursery-ground. This is to be dug with the same care as the feed-bed; and at the time of the removal of the flocks or plants, the roots of them are to be pruned and refrained, by taking off the tap or down-dripping one, and shortening the others. They are then to be planted out in rows at three feet distance, and about eighteen inches from each other. In this method of planting them in the nursery-ground, 9522 flocks may be planted on the acre, or thereabouts. They remain in these grounds from eight to ten years, when they will mostly have attained sizes proper for being finally put out into the field fruit-gounds. While in the nursery-ground, they are kept regularly pruned and trained: the side-roots are cut off, and one neat upright stem preferred, with six or seven shoots regularly branching out each way at the head. In this state, the price for them was, some time ago, for the apple-flock 11 6d., and for those of the pear 21 6d.: consequently the profit of an acre of ground thus employed is very considerable: 9522 flocks, disposed of at the above prices, amount, it is laid, in the first cafe, to 714l.; in the latter, to 1190l. 5s.: and that after the third year, the profit may be reckoned on as near, since the occasional crops, raised in the void spaces and parts between the flocks, will pay the expenses of labour and rent.

In some districts, when the young flock plants are come up to the size of the proper flocks growing, they are planted in, the proper flocks of their ensuing growth, care is taken to select all such as produce the largest and most luxuriant leaves, as is from that character that the best expectations are formed for procuring the most profitable fruit in this view. The rejected plants or flocks are drawn out from time to time, and the preferred ones left, for the purpose of discovering their specific qualities. These, when approved of, which point is most commonly ascertained by the end of the fifth year from the time of sowing the pips, their heads being previously formed upon stumps of about five feet high, are removed to any eastern aspect, except that of the north-east; and on to the sloping sides of hills, where there is no stagnant moisture of any kind in the under soil, and are there, for the most part, planted finally out at the distances of from 25 to 30 feet apart, according to circumstances, as will be seen below.

In some districts, the flocks of these sorts of tree-plants are planted out finally sooner, or after they have had less growth, than in others; but they should never be put out in this way, until they are of sufficient strength and growth, as has been directed above.

Planting the Flocks out in the Fruit-Grounds.—As soon as the flocks have arrived at or attained the height and growth of six or seven feet, and are come about five inches in circumference, they are in a proper state for being planted out in these grounds. Where the land is in the state of grass, they are generally planted at the distance of from 8 or to 10 to 12 or 15 yards from each other, suitable openings being prepared for them in a proper manner. In Devonshire, where smaller distances are allowed, holes are previously made, in which are deposited road-scrapings or way-foils in the proportion of about two seams or horse-loads to each. Where the grounds are under the plough, the distances of planting are from 16 to 18 or more yards, with an interval of 20 and upwards, and opposite to each other in some places; in particular, the distance of the rows, however, depends greatly on the width of the ridges, as they are planted on the tops of these in most cases: if the ridges be small, every other one is omitted, in some places; and where the contrary is the case, as where they are wide, always managing so as that the last distance may be nearly preferred. In ardow land, the quincunx of planting the flocks is sometimes practised, in order that space may be gained for the spreading of the heads of the trees, as the distance allowed in such cases is less.

In the planting of the flocks in the village lands, advantage is supposed to arise not only from the manuring and keeping the mould loose over the roots of the flock plants, but from there being a considerable saving of expense in the articles of fencing and defending the plants. The young flocks or trees are to be protected and defended from external injuries of all kinds, until they have gained a considerable state of growth, and are become firm in the roots, and perfectly hard in the bark. There are different methods of effecting this, which will be noticed below.

Good flocks of these kinds are sometimes met with in the hedge-rows of fruit districts, and might, perhaps, be occasionally planted there with great utility and advantage.

In respect to the most proper time for planting out the flocks, though something may most probably depend upon the feaston and the nature of the soil, February is the most usual and probably the best, as a long series of drought is inimical to late planting, while severe frosts are not leas to that of the autumnal feaston. It is, however, much easier to protect the roots of the flocks during the winter, than to be continually watering them during the summer-seaon.

There is much less care also required in planting them out on light and loose soils, than on such as are of a heavy or of a clayey nature. In the former, it is sufficient to just dig out the holes deep enough to cover the roots perfectly, and to return the mould as it came out of them; but in the latter, the digging of holes is complete ruin to the flock plants, as the whole depth underneath the cultivated soil is so retentive as to form a sort of pool of flagrant water or moisture, and where they are even filled with good mould, it is impossible for the roots to extend themselves into the surrounding clay or clayey matter. The best practice is, therefore, probably, to take off the surface-turf to some depth in a circle of about four feet diameter, and to fill the under soil in a light manner; on this to place some good earth, and then to plant the flock, with another layer of good earth, covering the whole over with the sod or turf, generally laid upside down. The tap-roots of the flocks are to be previously cut off or shortened, and the fibres also to be pruned at the ends, when they are to be placed out in regular order, having some new earth blended and shook down among them. But before the planting, the flocks are to be headed down; or at least the branches are to be shortened to six or eight inches, to guard
STOCKS.

guard against the power of the wind, and throw the juices more into the Rems, by which the vigour of the stocks is increased. The newly planted stocks are then to be well guarded from being in any way injured by live-flock, or in any other manner, in some of the modes which are directed below.

In the filling up old fruit-grounds, or the replanting new ones on the same ground, it is considered a bad practice, in some districts, to plant the flock on the exact spot where the old tree stood; but it is otherwise, if a pear be planted where an apple grew before, especially in cafes where the surface and under soil has been well prepared by digging and properly manuring the ground.

Grafting the Stocks.—When the stocks have been three or four years planted out in the fruit-grounds, they are in a state ready for grafting, where that method is had recourse to in completing the trees. But though this mode, as being most expeditious, may have been the most frequently had recourse to, it has been supposed by some, that no method of performing the operation has yet been attempted, has been found fully adequate to the purpose. For the stocks that are inferted, in consequence of being taken from old trees, though they grow vigorously for a few years, on account of the strong growth of the stocks, they then often decay, decline, and degenerate, or run into all the infirmities of their parent trees. Of course, on this principle, the refoiring or renovation of the old fruits of these kinds would seem to be impracticable; as by the general laws of nature, each of the different beings ended with life, lives to propagate its kind, and after a time resigns its place to a successor. It has been observed, that the branch from which a twig is taken for this purpose, evidently partakes of the life of the tree to which it belongs; and that it is not less evident, that when part of a tree is detached, no new life is afforded to it, whether it be employed in this way, or placed in the ground to emit roots as a cutting; in this manner, a tree reared from a cutting, soon produces fruit in every respect similar to that of the tree from which it was taken. Also, that the habits of seedling trees are very essentially different, that their leaves are small and thin, and that the general habit changes gradually, assuming in an annual manner a more cultivated character; that if a stock for grafting with, be taken from a seedling tree of one or two years' growth, it will retain the character, and undergo the same annual change, as the seedling plant or tree from which it was procured, whatever may be the age of the stock into which it is inferted; and that it will remain unproductive of fruit or blossoms, until the seedling tree has acquired its proper age and maturity or state of production.

In support of these conclusions it has been stated, that a seedling walnut, grafted with part of the bearing branch of an old tree, produced blossoms at three years' growth; that the Spanish chestnut, under a similar process, blossomed in the year after it was grafted; and that the annual fecon or twig of a mulberry-tree thus grafted, yielded a plentiful crop of fruit, in proportion to its size, in the third year after the operation, and has continued to bear every year since. The grafts in these cafes must, it is thought, have carried the mature habits of the parent trees with them; and that, if they retain these habits, it may fairly be inferred, that they also retain the same progressive tendency to decay, diæsa, and destruction. The seeds of the fruit of the old trees should, therefore, probably be foun, and the strongest and most healthy plants selected and let aside for the purpose of cultivation, and this supply of grafts which are necessary.

In the work of grafting, the heads of the stocks are first taken off by means of a proper saw, and then rendered quite smooth by the use of a very sharp strong knife; the height of doing which depends much upon the fancy of the planter, but is mostly performed at about seven feet high. The rest of the operation is done in the usual manner, according to some of the modes commonly practiced in this fort of work, as either by the simple common method, that of the grown method, or the root and whip method. A new plan of the root kind has, in some districts, been lately had recourse to. In this, when the stocks have reached a proper age or state of growth for planting out, the ground is opened about them, and they are separated from the largest roots; of which, such are chosen as are of a sufficient size for clef-grafting, which method is to be preferred; and if the roots be inclining, they are raised to a perpendicular, without disturbing their extremities which are in the ground; the shoot, or scion is then inferted in the usual way, and rendered perfectly secure. The earth is then returned to them all round, and one bud, or at most, two, are left above the ground in order to guard against failure, which are mostly found to strike with extraordinary vigour. Where both succeed, the leaf promising is removed. The buds, which are covered with earth, show out into roots, so that when the trees are to be removed to their defined situations, they may be entirely separated from the original root on which they were grafted. Sufficient roots remain to the parent flock for the future support of it, and it may be planted elsewhere, for the purpose of either producing a fresh supply of roots for the same process, or for grafting in the fruit-grounds. It is flattened, that some trees, raised by grafts in this way, have become handsome ones eight feet high, and had fine fruit on them in the course of four years. That fix of the stocks, which had been separated from the roots, and deemed useless, on being replanted, had kernel-fruit upon them in the same length of time. This method is said to be the discovery of Dr. Cheffon of Gloucester.

In some places it is the practice, in performing this fort of work, to infert two shoots or scions, one in or on each side the head of the flock; but one is mostly sufficient to form a head large enough. With some, where two are inferted, it is the custom, however, to remove that which is the least promising, where both strike, in the ensuing spring, and with a sharp knife or chisel, to pare off the top of the flock in a sloping manner to the remaining graft, which prevents water from lodging, and the sap then becomes directed to and concentrated in a smaller compass. After this, the wounded part should be well guarded and protected, in order to promote the more speedy healing of it, and the whole graft be firmly and properly secured.

Where both the grafts are suffered to grow, the head of the tree, from becoming double, is not unfrequently separated, and the trunk rendered by strong blowing winds, or even by the weight of the branches alone.

In cafe the grafts do not strike or take, it is considered dangerous, if not fatal to the flock, to infert new scions or shoots until the third or fourth year. Where they do strike, it is but seldom that any further care is taken of them, until the trees begin to be productive of fruit. This fort of negligence is, however, highly improper and disadvantageous, as they ought to be carefully watched in regard to the progress of the shoots, and the removing and cutting off the fragging, irregular, and useless branches, as by these and other means, the interior of the trees may be prevented from becoming loaded and incrusted with a redundancy of wood. See Grafting.

Defending the Stocks.—These are to be well guarded, pro-

Vol. XXXIV.
ected, and defended, when newly planted, as well as in their growth afterwards; as they are very liable and much exposed to be rubbed, barked, and otherwise injured, in many cafes, by different flocks of live-flock, and in other ways. There are many different modes of accomplishing this; as by frames of wood differently formed and set up, by poles differently placed, and slips of strong board properly nailed upon them; by poles and rails differently contrived, and by various prickly and thorny substantions and plants twisted and tied round the flocks in different ways. But the best method is probably that of having three poles put in a fort of triangular manner about the tree or flock, so as to come within a small distance of each other at the bottom or root part, and to diverge considerably in their upward direction, and formed into a fort of frame by proper short crofs pieces being nailed against them at suitable distances apart. Though this requires more wood than some other modes, the coarser farts may answer the purpose very effectually. There are objections to many of these methods from the flocks and trees, when they begin to shoot freely, having their lateral branches rubbed greatly by them, and from the poles forming holes in the ground, by being agitated by the winds, into which the moisture is drawn from the roots of the focks or trees, as well as from other circumstances. The thorny matters are cheap methods, but they are readily removed by live-flock, by which means the bottom parts of the focks are liable to become naked and be rubbed by the sheep, which is very hurtful to them.

The trees raised and formed from focks in this way mostly come into bearing in from six to seven years after the grafting has been performed, but the quantity of fruit is seldom large for some length of time afterwards, then, however, it becomes considerable for a great number of years. See Apple Tree.

Stocks, Cippus, a wooden machine to put the legs of offenders in, for the securing of disorderly persons, and by the way of punishment in divers cafes ordained by statute, &c. And it is said that every vill within the precinct of a city is punishable for not having a pair of focks, and shall forfeit 5l.

Stocks, in Ship Carpentry, a frame erecled on the flore of a river or harbour, on which to build shipping. It generally consists of a number of wooden blocks, ranged parallel to each other, at convenient distances, and with a gradual declivity towards the water. See Launch.

Hence, we say, a flap is on the focks, when she is building. STOCKSE, in Geography, a town of the duchy of Holstein; 8 miles N. of Segeborg.

STOCKSTADT, a town of Germany, on the Main; 3 miles W. of Aachenburg.

STOCKSUND, a town of Norway, in the province of Drontheim; 60 miles N. of Drontheim.

STOCKTON-UPON-TEES, is a borough by prenotification in the south-west division of Stockton ward, and parifh of Stockton, in the county-palatine of Durham, England. The antiquity of this place may be readily inferred from giving its name to one of the county wards; but its origin is not ascertained. Stockton castle, on the north side of the town, was at one period inhabited by the bishops of Durham, who were appointed to govern the whole province committed to their care. This fertoft was on the northern bank of the river Tees, and commanded an extensive prospect over the valley and country. In the time of Charles I. it was garrisoned in behalf of the king; but afterwards fell into the power of the parliamentarians, who ordered it to be destroyed; which was so completely executed, that not a flone of the former edifice remains. The only vestiges are the moat, which defended the castle on three sides; and a barn, which appears to have flood within the area of the works. In the year 1252, Stockton was nearly destroyed by the Scots; but at the close of the civil wars it recovered its importance. The population, in 1725, amounted to 430 families; but in the reports of 1811, the inhabitants had increased to 4429, and the houses to 872.

Stockton consists of two parts; one, called the Borough, where all the land is freehold; and the other, denominated the Town, where it is copy or leasehold; the latter held under the vicar and vestrymen, and is not within the borough jurisdiction: for this reason there are two constables, with peculiar officers, though both form one parish. The civil government is vested in a mayor, alderman, and recorder, (who is alwayseward of the bishop's court-leet and baron,) besides inferior officers. The mayor is elected by a majority of the burgesses, yet it is not required that he should first have been an alderman. The situation of this town, on the northern banks of the Tees, at a convenient distance from the sea, renders it very favourable for commercial purposes: its maritime trade began to revive soon after the restoration, and the officers of the customs removed hither from Hartlepool in 1680, and lawful quays were erected in 1683. Below Stockton, the river flows in a very circuitous course; and as it approaches the German ocean, expands into a large bay, upwards of three miles in width. Stockton is probably the most handsome town in the north of England, as well for the breadth of its principal street, as the general neatness of its buildings. This street is about half a mile in length, and upwards of sixty yards broad at the market-place, which is in the centre; and this renders the entrance to the town, either from north or south, particularly impressive. Several smaller streets branch off in different directions; and at the north-east side is a spacious square, which contains some good buildings. The town hall, near the middle of the principal street, is a large square building, partly occupied as a tavern, and containing various elegant apartments, devoted to civil and other public purposes. At a short distance is a handsome old church, thirty-three feet high, of the Doric order, where the market is held; the site of which was formerly occupied by an open crofs.

Stockton was originally a chapelry to Norton, a peanfent village about two miles to the north, but was constituted a distinct parifh in the year 1711. During the episcopacy of bishop Poore, who died in 1234, a chapel of ease was erected here, which, upon becoming both ruinous and too small, was taken down, and a new church opened in August 1712. The church is a handsome brick building, with the doors and windows cafed with flone: its length, including the tower and chancel, is 150 feet; this tower is at the west end, and is 80 feet high. The vestry contains a collection of divinity, which is still increasing from donations and subscriptions. The various denominations of Presbyterians, Quakers, Methodists, and Roman Catholics, have each a meeting-house in this town; which also contains the public institutions of a grammar-school, charity-school, funday-school, and an alms-house, or hospital.

The manufactures of Stockton are fail-cloths and cordage, both of which are carried on to a great extent. The making of damalks, diapers, huckabacks, towelling, and checked linens, has likewise lately been executed in considerable perfection. Two docks for building ships are also situated on the banks of the Tees. An elegant bridge, with five arches, was erected over this river, towards the close of last century, at the expense of 8000l. The tolls on this bridge
bridge gradually augmenting, now let for 800L annually, which is appropriated to discharge the principal and interest already incurred; and when these are liquidated, the bridge will be free, and the future incidental charges be defrayed by the county of Durham, and the North Riding of Yorkshire, jointly. The shock of an earthquake was felt at Stockton in December 1780: and in August 1783, a violent fire, thunder and lightning took place, with a shower of irregular pieces of ice, some of which measured from three to five inches in circumference.

Stockton is the birth-place of Joseph Reed, a dramatic author, who was born in 1722: of Braf Crosby, esq. born in 1726, who rode from a very humble station in life to be lord mayor of London: Joseph Ritson, an eminent literary critic, was also a native of Stockton. See Ritson.

Near this town, on the river Tees, is a considerable salmon fishery; and at the mouth of the river is a fishery for cockles. About four miles north of Stockton is Winyard, the seat of sir Harry Vane Tempest, bart. The house, a hand-house, modern edifice, occupies the site of an old building, in a park which presents some interesting scenery.—Hilgery, &c. of Stockton-upon-Tees, by the Rev. J. Brewster, 4to. vol. v. Beauties of England, &c. Durham, by J. Britton and E. W. Braly.

STOCKUM, a town of Wiltphalia, in the bishopric of Olmbruck; 5 miles E.S.E. of Olmbruck. STODDARD, a township of America, in the state of New Hampshire, and county of Cheshire; about 15 or 18 miles E. of Walpole, on Connecticut river, containing 1132 inhabitants.

STODE, a town of Sweden, in Medelpadia; 18 miles W. of Sundvall.

STODGED, in Rural Economy, a term provincially signifying filed to the flitch, as the udder of a cow by milk.

STODHART BAY, in Geography, a bay on the N.W. coast of Jamaica.

STOEBE, in Botany, a name received by Pliny from the Greeks, which he says is synonymous with Pheum. If the latter be, as many have believed, our Typha, the use made of its downy feves, for stuffing cushions or beds, may account for the origin, or rather the application, of the name; roots in its primary sense appearing to have designated a plant used for burning, or for making what was, doublets, the most ancient and simple form of beds. The roots of Dioscorides however, merely mentioned by him as a well-known plant, useful for the alluring properties of its roots and leaves, is believed to be Parietaria spinosa, whose qualities answer to this description, and which is called in modern Greek ariph. How Linnaeus came to select the name of Stoebe for the genus before us, in his Hortus Cliffortianus, where, without any explanation, it is the first time appears in its works, we are at a loss to explain. The hard rigid African shrubs which compose it are, like the above Parietaria, of all things most unfit to make a bed, except for a rhenoceros or hippopotamus. He seems to have taken upon this name, for a new syndetogenic genus, because it had been variously applied by old botanists to certain compound flowers, and was then vacant, nor did he advert, in any manner, to its feve or etymology.—Linn. Hort. Cliff. 300.

Gen. Ch. Common Calyx roundish, imbricated; its scales awl-shaped, permanent, inveterating the common receptacle on all sides. Partial Perianth solitary within each scale of the common calyx, single-flowered, of five linear, acute, equal, erect leaves. Proper Cor. of one petal, funnel-shaped; its limb in five spreading segments. Stam. Filaments five, short, capillary; anthers united into a five-toothed cylinder. Fil. Germin oblong; style thread-shaped, the length of the flaments; stigma acute, divided. Peric. none, except the unchanged calyx. Seeds solitary, oblong. Down feathery, long. Proper Recept. naked.

Obst. Gaertner considers the common calyx as nothing else than, either the upper leaves of the plant, or the outer scales of the receptacle, while the partial calyx consists of the inner scales of the receptacle. According to this view of the subject, Stocke should be removed to the third, or discifol, fection of the order Polygama equalis, and we are much disposed to concur in that opinion.

The discoveries of Thunberg have greatly enriched this, as well as other Cape genera, so that Willdenow reckons up twenty species, about half of which are known to Linnaeus. But two or three of these really belong to Stoebe; Abutilon, abollished by Willdenow; see that article. About a dozen are natives of the south of Africa; one of the isles of Mauritius and Bourbon. Schizanthus, which has also a feathery seed-down, differs from Stocke in having only one flower in each outer calyx.

1. S. incana. Hoary Stoebe. Thunb. Prodr. 169. Willd. n. 1.—"Leaves sharp-pointed, thread-shaped, woolly."—Gathered by Thunberg at the Cape of Good Hope. We have seen no specimen.

2. S. aethiopica. Juniper-leaved Stoebe. Linn. Sp. Pl. 1315. Willd. n. 2. Ait. n. 1. Lamarck Illust. t. 722. f. 2.—Leaves awl-shaped, pointed, reflexed, keeled; polipithed on the under side. Stem erect.—Specimens of this plant were brought very early from the Cape; and Linnaeus foaming it in Clifford's herbarium, though not alive in his garden, founded hereinafter the genus of Stocke. Miller cultivated it in 1759, but no figure, except Lamarck's and Gaertner's, has ever appeared, Petiver's tab. 8. f. 1. being a different plant, as we shall mention hereafter. The stem is shrubby, of humble growth, with round leafy branches. Leaves crowded, almost imbricated, scarcely half an inch long, twilled, recurved, entire, concave, with a spinous point; fringed with long soft hairs towards the base. Flowers terminal, sessile, hemispherical, three-quarters of an inch in diameter. It is from this, the original species of the Hortus Cliffortianus, that the character and idea of the genus are taken.

3. S. ericoides. Heath-like Stoebe. Linn. Mant. 574. excluding the reference to Breynius and Morison. Willd. n. 3. Thunb. Prodr. 169. Berg. Cap. 339. (Eupateroideae capensis capitatus; Petiv. Gazoph. t. 8. f. 1.)—Leaves minutely pointed, linear, revolute, oblique, reflexed. Stem erect. Some ligulate florets. Native of the Cape. The stem is a spars high, determinately and repeatedly branched, twilled and leafy. Leaves about two lines long, spreading every way, oblong, with a minute point, roughish, with a few little differenced tubercles: hoary when young. Flowers round, sessile, terminal, pale red or flesh-coloured. Each partial calyx usually contains, along with its proper tubular perfect flower, another short ligulate neuter one. The seed-down is loosely feathery. Petiver's figure undoubtedly represents this plant very characteristically. That of Breynius,
STOEBE.

nus, erroneously quoted t. 9, instead of 69, by Linnaeus, is S. fufa, the leaves of which are less spreading.

4. S. prostrata. Prostrate Stoebe. Linn. Mant. 291. Wild. n. 4. Thunb. Prodr. 169.—Leaves pointed, lanceolate, oblique; woolly beneath. Stem decumbent.—Found at the Cape by Thunberg.—The stem is much branched, clothed with spreading, ovate-lanceolate, thyme-like leaves; green and smooth above; very white, with a concealed rib beneath. Flowers the size of a large pea, tawny or reddish, with very white anthers. Scales of the common calyx exactly like the leaves, in this as well as other species.

5. S. physicoides. Physic-leaved Stoebe. Thunb. Prodr. 169. Wild. n. 5.—"Leaves pointed, lanceolate, erect. Stem erect."—From the same country. Thunb. This definition is insufficient to give any distinct idea of the plant. We have seen no specimen.

6. S. gomphrenaoides. Amarantle Stoebe. Linn. Suppl. 391. Wild. n. 6. Berg. Cap. 336. Thunb. Prodr. 169. —"Houttuyn Linn. Pl. Synt. v. 4. 435. t. 34. f. 1."—Leaves elliptic-oblong, concave, fringed; woolly on the upper side; the lower ones minutely pointed.—Gathered by Thunberg at the Cape. The stems are numerous, erect, leafy, a foot high, much branched at the bottom. Leaves half an inch or more in length, imbricated; convex, green and somewhat silky, at the back, with a flabby marginal fringe. They are mostly obtuse, without any minute spiny point, except on the lower ones. Flowers round, white, rather polished, resembling the heads of a Gomphrena. Each flower appears to have a double calyx; the outer one short, coloured, and somewhat woolly; so that this species should seem rather to belong to Seriphium, as Linnaeus has marked it in his copy of Bergius.

7. S. gomphalooides. Cudweed Stoebe. Linn. Synt. Veg. ed. 13. 554. Wild. n. 7. Thunb. Prodr. 169. (Seriphium corymbiferum; Linn. Mant. 119. Gomphalium niveum; Linn. Sp. Pl. 1192. G. incanum, folio lineari cauli acuminato; Burn. Afric. 215. t. 77. f. 1, bad and incorrect.)—Leaves flat-pointed, ovato-lanceolate, concave; woolly on the upper side; polished at the back. Panicles cyme.—Gathered at the Cape by some of its earliest botanical visitors. The stem is shrubby, rigid; its upper branches leafy, woolly. Leaves erect, crowded, somewhat imbricated, half an inch long, pungent; smooth at the back and margin, curiously dotted, or reticulated. Flowers numerous, yellow, in dense, terminal, corymbose tufts; each flower cylindrical, with a tamarro, imbricated, tight, partly woolly, common calyx. Flowers two or three. Seed-down club-shaped, very shortly feathered. We cannot but conceive the genus of this plant to be very doubtful, the inner calyx being so finely distinguishable.

8. S. fucab. Rough-leaved Stoebe. Linn. Suppl. 391. Wild. n. 8. Thunb. Prodr. 170.—Leaves erect, linear; woolly above; imbricated at the back. Flowers racemose.—Found at the Cape by Thunberg. The minute carinated leaves, and outer calyx, are rough with glandular prickles. Flowers four or five. Their proper calyx is smooth, twice as long as the outer. Sometimes, but not always, the rough scales of the outer calyx surround and separate each particular flower, making the plant a true Seriphium; so nearly are these two genera related!

9. S. cinerea. Grey Heath-leaved Stoebe. Wild. n. 9. Thunb. Prodr. 169. Ait. n. 2. (Seriphium cinereum; Linn. Sp. Pl. 1316. Bryonia cineroides capensia; Petiv. Gazoph. t. 3. f. 9.)—Leaves spreading, linear; woolly above; smooth at the back. Flowers in dense whorled spikes. (See Seriphium, n. 1.) This appears however to be a true Stoebe. The common calyx has woolly obsolete scales, and contains many florets, whose partial calyx is smooth, with long bristly points, seeming to surround each floret distinctly.

10. S. fubulata. Aawl-leaved Stoebe. (Seriphium gna-phalodes; Linn. MSS.)—Leaves somewhat spreading, in-volute, pointed, aawl-shaped; woolly above; slightly mufi-cated at the back. Flowers spike. Outer calyx woolly;—Native of the Cape of Good Hope.—The stem is erect, woolly, branched, leafy, round, slightly woolly. Leaves at first erect, then spreading or recurved, hardly an inch long at most, very slender, and apparently thread-shaped, but they are concave and woolly above; the under side is clothed in a decidious filmy web, and armed here and there with prominent prickles. Spike terminal, short, ovate or oblong, rather compound, somewhat leafy. Common calyx very distinguishable from the leaves, with short, obtuse, partially woolly scales, containing two or three, rarely four, florets, whose partial calyx is long, pointed, and membranous, Seed-down loosely feathered. We cannot find that this plant has ever been published before.

14. S. plumata. Feathery Stoebe. Wild. n. 13. Thunb. Prodr. 169. (Breyenia capensis, capitulus albis plumatis; Petiv. Gazoph. t. 5. f. 4.)—See Seriphium, n. 2, where this species is properly placed, having but a solitary flower, whose long, smooth, prominent, partial calyx, projecting out of the woolly stern external calyx, is very remarkable. We cannot understand the observation in Linn. Mant. 481, "fiores 5, seve 6, flores," unless each scale of the inner calyx was taken for a floret.

15. S. fucata. Brown Stoebe. Wild. n. 14. Thunb. Prodr. 170. (Eupatorium ericoides, capitibus green; Breyen. Cent. t. 69. Abrotanoides capensis, erice folio; Petiv. Gazoph. t. 5. f. 2.)—See Seriphium, n. 3, to which genus this species undoubtedly belongs, each flower having a distinct outer, as well as inner, calyx, notwithstanding its great resemblance to Stoebe ericoides, n. 3.

17. S. aphyra. Harsh Stoebe. Thunb. ibid. Wild. n. 16.—"Leaves linear, pointless, smooth, reflexed. Flowers lateral."—This and the last were found by Thunberg at the Cape, and do not appear to be known by any other author.

Gathered by Commeron in the Isle of Bourbon. This is certainly a *Sphacelium*, not a *Stoea*. The stem is six or eight feet high, with innumerable branches, resembling a *Tamarix* in habit. *Leaves* minute, imbricated; smooth at the back. *Infra calyx* long and smooth, at length spreading widely. The outer is cylindrical, of many rounded imbricated scales, woolly within, and contains a single *flower* only. This should follow *Sphacelium fuscum* in its proper place. 4

19. *Rhincorucoris*. Rhinoceros Stoebe. Linn. Suppl. 591. Wild. n. 13. Thunb. Prodr. 170.-Leaves triangular-obovate, close-petioled. Branches downy, drooping. Clusters prolific.-Native of the Cape, and said to be the chief food of the rhinoceros. We have seen no specimen, but it is very possible, as Lamark supposes, that this may not be different from the last species.

21. *S. caerulea*. Snow-white Stoebe. Thunb. ibid. Wildl. n. 30.-Leaves triangular, obtuse, close-petioled. Flowers terminal.—In this view of the genus *Stoea*, as it stands in Wildenow, we have been chiefly solicitous to ascertain species and their synonyms. The intelligent reader may arrange some of them under this genus, others under *Sphacelium*; but the greater part must remain in uncertainty, either from the obscurity of Nature herself, in this very ambiguous cafe, or because we have not sufficient information from Thunberg, who alone has seen some of the species. The genera appear to us too distinct to be resolved into one. They require to be carefully studied by an adept, who ought to be possessed of all the known species of both, and to examine the structure of all their flowers, before he attempts to draw any conclusion respecting their generic distinctions, or even their precise place in the Linnean system.

STOECHADES, in Ancient Geography, islands of the Mediterranean sea, upon the coast of Oalia Narbonensis. These islands are the same with the islands of Hiera. Strabo mentions five of them; and three of these defer to be recorded, viz. Prote, Meta, and Iops. *Stoechades*, or the Leftier *Stoechades*, were two small islands of the five above-mentioned, situated opposite to Marseilleilles, called Ratoneu and Poméque.

STOECHAS, in Botany, *Sycos* of Dioscorides, appears very clearly, from his description, to be the *Lavandula Stoechas* of Linnaeus. (See *Lavandula*, n. 2.) The above ancient writer says it owes its name to the islands called *Stoechades*, on the coast of France, now called *Iles d'Hypere*, where it was known to grow.

STOECHAS is also the specific name of a *Gnaophiollum*, Linn. Sp. Pl. 1195. The *Sicilia* of old writers.

STOEFLER, JOHN, in Biography, a German mathematician, was born at Juttlingen, in Swabia, in 1452, and was raised from humble life into a reputable situation by his attainments. About the year 1483 he became professor of mathematics at Tubingen; and Philip Melanchthon and Sebastian Munster were his scholars. He improved geography, to which he was much attached, and constructed various maps; all which, with many MSS., were consumed by a fire which broke out in 1534. Being an industrious calculator, he computed ephemerides for many years; which were first published at Ulm in 1499, when they begin, and extend to 1531. At the latter year they commenced at Tubingen, and continued for twenty years, to 1552. He also constructed very neat mathematical instruments and globes. He composed likewise several useful works. Confiding in the reverence of judicial astrology, he is said to have predicted a general flood; which threw Europe into great alarm, so that universal terror prevailed. But when the year arrived, no inundation took place. Stoepler died at Baubraun in 1531. He was author of several astronomical works, besides the ephemerides; and he left in MS. a commentary on Ptolemy's Geography, preserved in the library of Ulm. Gen. Biog.

STOEK, in Geography, a river of Holstein, which runs into Elbe, 2 miles N.W. of Glückstadt.

STOECKELIA, in Botany, is one of those two famous genera, which Crantz, a severe critic of superior writers, made out of one single species, *Dracena Draco* of Linnaeus. For this he is held up to admiration in the *Synt. Veg.* under *Dracena*; the only vengeance which Linnaeus took, for his many petulant and unjust attacks; but it is conclusive.

STOF, in Commerce, a liquid measure at Dantzig, Riga, &c. See Tab. XXXII. under MEASURES.

STOGUMBER, or Storke-Gomer, in Geography, a market-town in the hundred of Williton and Freemansmore, and county of Somerset, England, is seated in a valley to the south-west of the Quantock hills, near the northern side of the county, and consists chiefly of two streets. A large church, dedicated to St. Mary, contains a nave, chancel, two aisles, and as many chapels; the south aisle is surrounded by an embattled tower, seventy-two feet in height. On the south side of the chancel is a tomb, with the effigy of Sir George Sydenham, and in the church-yard is an ancient stone cross. This town is endowed with one annual fair, and a weekly market on Saturday; its population in 1811, was 1214 inhabitants, who occupied 224 houses. About two miles from the church of Stogumber, are the remains of Combe Sydenham, the ancient mansion of the family of that name. Some of the old staircases are yet tolerably entire, as well as the kitchen, which appears to have been very large; and near the centre of the building is a tower. The parish of Stogumber contains an almshouse, founded by one of the Sydenham family, with a provision for it from their estate. There is also a charity of thirteen pounds per annum to the poor for ever. In this town and its vicinity, many Roman coins have been found, together with other antiquities of the same people. The adjoining parish of Bicknoller is supposed to have derived its name from two British words, signifying a small treasury, in allusion to the quantity of specie there discovered. On an eminence near the church, in the same parish, are the remains of an ancient fortification, called Tredle castle, the fosse and entrance of which still remain. We find from this, on the summit of the same hill, is another, of much smaller dimensions, called Turk's cattle; and near this spot is a beacon, which has an extensive and commanding view of the whole country. The parish of Strington, on the opposite side of the Quantock hills, contains a large intrenchment, called Doucourage castle, of a regular form, consisting of a double rampart, with a very wide and deep fosse. The church of this parish is a small building, having a nave, chancel, and an aisle or chapel: the church-yard contains an ancient stone cross. History, &c. of Somersetshire, by the REV. J. Collinson, 4to. 1791, vol. III.

STOJANOW, a town of Poland, in Volhynia; 44 miles S.W. of Lucco.

STOCAL FATE. See FATE.

STOICISM, the doctrines and opinions of Zeno's followers, called Stoics.

STOICS, a sect of ancient philosophers, the followers of
of Zeno; thus called from the Greek ὁ πόρτιος, or the porch; because the place which Zeno chose for his school was the "Porch," or painted porch, a public portico so denominated from the pictures of Polygnotus and other eminent painters, with which it was adorned. This portico, which was the most famous in Athens, was called τοῦ πορτίου, the porch.

The porchar of this sect, Zeno, was a native of Cittium, a maritime town in Cyprus, originally peopled by a colony of Phenicians, whence he is sometimes called a Phenician, and is supposed to have borrowed many of his dogmata from Phenician philosophy, which many learned men maintain was, itself, borrowed from the Jews; though it must be allowed, there appear as many things in the Stoic philosophy, borrowed from Plato's and Socrates's school, as from that of Moises. The profession of his father was that of a merchant; but his son, manifesting an early propensity towards literature, he early devoted him to philosophy. The father, having frequent occasions, in his mercantile capacity, to visit Athens, purchased for his son several of the works of the most eminent Stoic philosophers. These he read with great avidity; and when he was about thirty years of age, he determined to take a voyage to a city, which was so celebrated as a mart both of trade and of science. What were his views in this voyage, whether mercantile or scientific, is not certain. Some writers report, that he made a trading voyage from Cittium to Athens, richly freighted with Tyrian purple, and was shipwrecked not far from port; upon which he was told, consulting the oracle how he should spend the rest of his life, he was answered, ποιείν δεξία των νεκρών, by becoming of the same colour with the dead; upon which he applied himself to the study of the ancient philosophers, and became a hearer of Crates, the Cynic.

Others relate, that upon his first arrival in Athens, he went accidentally into the shop of a bookseller, and taking up a volume of the Commentaries of Xenophon, read a few passages, and that, being highly gratified by the perusal, and forming every favourable opinion of the author, he asked the bookseller where he might meet with such men. Crates, the Cynic philosopher, passed by the shop at this moment, and the bookseller pointing to him, said to Zeno, "follow that man." Availing himself of an early opportunity of attending upon the instructions of Crates, he enlivened himself in the number of his disciples. But highly as he admired the general principles and spirit of the Cynic school, he could not reconcile himself to their peculiar manners; and, besides, his inquisitive disposition would not allow him to imbibe that indifference to every scientific enquiry which formed one of the distinguishing characteristics of that sect. Abandoning Crates, he repaired to the school of Stilpo; and when his former master attempted to drag him away from it by force, he said to him, "you may seize my body, but Stilpo has hold of my mind." Having for several years attended upon the lectures of Stilpo, he had recourse to other schools, particularly those of Xenocrates, Diocorus Cronus, by whom he was instructed in dialectics, and on whom he conferred a large pecuniary gratuity for the discovery of some of his ingenious subtleties, and various other matters; and at length he offered himself as a disciple of Polemo. Polemo, however, apprized that Zeno, by removing from one school to another, was merely collecting materials to form a new system of his own, when he came to his school, said to him, "I am no stranger, Zeno, to your Phenician arts; I perceive that it is your design to creep sily into my garden, and to steal away my fruit." Polemo was not mistaken in his conjecture; for Zeno, after having made himself thoroughly acquainted with the tenets of others, determined to become the founder of a new sect, and established a school at Athens. Zeno was distinguished by that kind of subtle reasoning, which was at the period in which he flourished popular. He likewise exemplified the system of moral doctrine which he taught in his own life. We need not wonder, then, that he should attract a number of followers, and also enjoy the favour of the great. His lectures were attended by Antigonus Gonatas, king of Macedon, whilst he resided at Athens; and upon his return, Zeno was invited to his court. So highly was he esteemed among the Athenians, on account of his approved integrity, that they deposited the keys of their citadel in his hands. They also honoured him with a golden crown, and a statua of brasil. Among his countrymen, the inhabitants of Cyprus, and among the Sidonians, from whom his family was derived, he was likewise highly esteemed.

In his person, Zeno was tall and flender; his aspect was severe, and his brow contracted. His constitution was feeble; but he preferred his health by great abstemiousness. The supplies of his table consisted of figs, bread, and honey; notwithstanding which, he was frequently honoured with the company of great men. It was a singular proof of his moderation, mixed, indeed, with that high spirit of independence which afterwards distinguished his sect, that when Demochares, son of Laches, offered to procure him some gratuity from Antigonus, he was so offended, that from that time he declined all intercourse with him. In public company, to avoid every appearance of an assuming temper, he commonly took the lowest place. Indeed, so great was his modesty, that he seldom chose to mingle with a crowd, or with the company of more than two or three friends at once. He paid more attention to neatness and decorum in external appearance, than the Cynic philosophers. In his dress indeed he was plain, and in all his expenses frugal; but this is not to be imputed to avarice, but to a contempt of external magnificence. He shewed as much respect to the poor as to the rich; and conversed freely with perfons of the meanest occupation. He had only one servant, or, according to Seneca, none.

Honoured and esteemed as Zeno was by a great number of perfons, and unassuming and irreproachable as were his manners, he had his enemies. Philosophers of distinguished ability and eloquence employed their talents against him. Amongst these we may reckon Arcellaus and Carneades, the founders of the Middle and New Academy. Towards the close of his life, Epicurus, whose temper and doctrines were alike inimical to the severe gravity and philosophical pride of the Stoical sect, was his powerful adversary. Zeno is said to have lived to the extreme age of 98 years, and at last, in consequence of an accident, voluntarily put an end to his life. In walking out of his school, he fell, and broke one of his fingers; upon which, he was so affected with a consciousness of infirmity, that, striking the earth, he said, "Why am I thus importuned? I obey thy summons!" and immediately going home, he strangled himself. He died in the first year of the 135th Olympiad, B. C. 264. The Athenians, at the request of Antigonus, erected a monument to his memory in the Ceramicum.

If we compare the doctrines of Zeno with the history of his life, his heterogeneous system will appear to have been compiled out of the various tenets of the schools which he frequented; and on the credit of these he assumed to himself the title of the founder of a new sect, which spread widely, and subfitted for many ages. Of Zeno, Cicero says, that he had little reason for deferring his matters, especially those of the Platonic school, and that he was not so much
much an inventor of new opinions as of new terms. A comic poet, quoted by Athenaeus, thus ridicules the logomachies of Zeno and his followers:

\[\text{Ἀκούει ὁ Στοικὸς ὑπὸνομός κλήμ \n\text{Δόξας ἐνυπεραίως.}}\]

"Ye fages of the Porch, loquacious tribe, Traders in trites, arbiters of words, And censure! hear!"²

Zeno transferred the dialectics of Diodorus Cronus, and the moral doctrine of the Cynic sect, into his own system; the principal difference between the Cynics and Stoics consisting in this particular, that the former did maintain the cultivation of nature, and the latter affected to rise above it.

On the subject of physics, Zeno received his doctrine from Pythagoras and Heraclitus, through the channel of the Platonic school. Cicero censures the Stoics for encouraging in their schools a barren kind of disputations, and employing themselves in determining trifling questions, in which the disputants can have no interest, and which, at the close, leave them neither wiser nor better. And that this censure is not, as some modern advocates for Stoicism have maintained, a mere calumny, but grounded upon fact, sufficiently appears from what is laid by the ancients, particularly by Sextus Empiricus, concerning the logic of the Stoics. Seneca, who was himself a Stoic, candidly acknowledges this.

The Stoics, whose ruling passion was vanity, were ambitious of that kind of reputation which was derived from skill in the arts of reasoning and sophistry. The moral part of their philosophy partook also of the defects of its origin. It may be as justly objected against the Stoics as the Cynics, that they assumed a artificial severity of manners, and a tone of virtue above the condition of man. Their doctrine of moral wisdom was an oftentimes display of words, in which little regard was paid to nature and reason. It professed to raise human nature to a degree of perfection before unknown; but its real effect was merely to amuse the ear, and captivate the fancy, with fictions which can never be realized. Lastly, the physical and theoretical system of the Stoics, like those from which it had been borrowed, had, in its principles, a strong bias towards enthusiasm.

The extravagancies and absurdities of the Stoical philosophy may in some measure be ascribed to the vehement contentions which subsisted between Zeno and the Academic schools on the one hand, and between him and Epicurus on the other. Whilst Epicurus taught his followers to seek happiness in tranquillity, or a freedom from labour and pain, Zeno imagined his wise man not only free from all fons of pleasure, but void of all passions and emotions, and capable of being happy in the midst of torture. That he might avoid the torpid indolence of the Epicureans, he had recourse to a moral institution, which bore indeed the lofty front of wisdom, but which was elevated far above the condition and powers of human nature.

The natural disposition of Zeno, and his manner of life, had no inconceivable influence in fixing the peculiar character of his philosophy. By nature severe and morose, and constitutionally inclined to reserve and melancholy, he cherished this habit at an early period, by submitting to the austere and rigid discipline of the Cynics. Qualities which he conceived to contribute to his own personal merit, he transferred to his imaginary character of a wise or perfect man. His followers, therefore, affected an appearance of gravity and dignity, which they supported more by external show than by the real practice of sublime or useful virtues. Hence many of them were philosophers in words, rather than in their actions; and thus it was that their adversaries found so much scope for satirical ridicule and invective against Stoical pride and hypocrisy. Indeed, a system of philosophy, which aims at raising men above their nature, must commonly produce, either wretched fanatics or artful hypocrites. It is no proof of the perfection which some have been willing to ascribe to the Stoic philosophy, that there were among its professors many persons highly distinguished by genuine wisdom and virtue. For their uncommon merit was rather the effect of a happy temperament, or of fortunate circumstances in concurrence with those moral principles which are common to all mankind, than to the peculiarities of the Stoical system, which, as we shall presently see, were not adapted to cherish the genuine sentiments either of virtue or piety.

In forming an accurate judgment of the Stoical philosophy, it is necessary to guard against two errors into which we have been betrayed who have appreciated it too highly. We should not form our opinion of this philosophy from words and sentiments detached from the general system, but consider them in their connection both with the premises and conclusions; nor should we confound the genuine doctrines of Zeno, and other ancient fathers of this sect, with the glosses, or improvements, of the later Stoics; who, after the introduction of the Christian doctrine, artfully accommodated their language, and even their tenets, as far as possible, to the Christian model. (See Fatsa and Brucker, in his "History of Philosophy," translated by Enfield, has given an abstract of the Stoic philosophy, deduced from the writings of Cicero, Plutarch, Laerlius, Sextus Empiricus, Simplicius, and Stobaeus, compared with those of Seneca, Antonius, and Epictetus, under the different heads of philosophy in general, logic, physics, metaphysics, and morals. Our limits will only admit a few extracts. The doctrine of the Stoics, with regard to "philosophy in general," was, that wisdom consists in the knowledge of things divine and human; that philosophy is such an exercise of the mind as produces wisdom, and that in this exercise consists the nature of virtue; and consequently, that virtue is a term of extensive meaning, comprehending the right employment of the mind in reasoning, in the study of nature, or in morals. With Socrates and the Cynics, Zeno reprented virtue as the only true wisdom; but being disposed to extend the pursuits of his wife man into the regions of speculation and science, he gave, in his usual manner, a new signification to an old term, and comprehended the exercise of the understanding in the search of truth, as well as the government of the appetites and passions, under the general term Virtue. "Logic," according to the Stoics, is either rhetorical or dialectic; the former being the art of reasoning and discourse on subjects which require diffuse declamation, and the latter being the art of close argumentation, in the form of disputations or dialogue. Rhetoric is of three kinds, deliberative, judicial, and demonstrative. The dialectic art is the instrument of knowledge, by enabling a man to distinguish truth from error, and certainty from bare probability; and it considers things as expressed by words, and words themselves. External things are perceived by a certain impression made either upon the external parts of the brain, or upon the percipient faculty, which may be called an image, ἑιμαρτικός, since it is impressed upon the mind, like the image of a seal upon wax. This image is commonly accompanied with a belief of the reality of the thing perceived; but not necessarily, since it does not accompany every image, but those only which are not attended with any evidence of deception. Where only the image is perceived by itself, the
STOICS.

thing is apprehensible; where it is acknowledged and approved as the image of some real thing, the impression is called apprehension, ἀνακατάληψις, because the object is apprehended by the mind, as a body is grasped by the hand. Such apprehension, if it will bear the examination of reason, is knowledge; if it is not examined, it is mere opinion; if it will not bear this examination, it is unsatisfactory.

The senses, corrected by reason, give a faithful report; not by affording a perfect apprehension of the entire nature of things, but by leaving no room to doubt of their reality. Nature has furnished us with these apprehensions, as the elements of knowledge, whence further conceptions are raised in the mind, and a way is opened for the investigations of reason.

Some images are sensible, or received immediately through the senses; others rational, which are perceived only in the mind. These latter are called in our, notions or ideas. Some images are probable, to which the mind affords without hesitation; others improbable, to which it does not readily assent; and others doubtful, where it is not entirely perceived, whether they are true or false. True images are those which arise from things really existing, and agree with them. False images, or phantoms, are immediately derived from no real object. Images are apprehended by immediate perception, through the senses, as when we see a man; consequentially, by likeness, as when from a portrait we apprehend the original; by composition, as when, by compounding a horse and man, we acquire the image of a Centaur; by augmentation, as in the image of a Cyclops; or by diminution, as in that of a pigmy.

Judgment is employed either in determining concerning particular things, or concerning general propositions, using in the latter case our preconceptions, or universal principles, as criteria or measures of judgment. The first impressions from the senses produce in the mind an involuntary emotion; but a wise man deliberately examines them, and suspends his assent or approbation (ἐνανθίωντος) with regard to the report of the senses, till he has investigated the nature of things, and fully estimated the weight of evidence.

The mind of man is originally like a blank leaf, but capable of receiving any impressions. These impressions, made by the senses, remain in the memory, after the objects that occasioned them are removed; a succession of these continued impressions, made by similar objects, produces experience; and hence arise permanent notions, opinions, and knowledge. Even universal principles, ἡ μὲν τῆς σοφίας, are originally formed by experience, from sensible images. All men agree in their common notions or preconceptions; disputes only arise concerning the application of these to particular cases.

These three things are mutually related; the expression, the notion or image in the mind which is expressed, and the external object. Under the head of expression, dialeitcs consider vocal sound, as expressed by letters; the several parts of speech; the etymology; analogy, or anomaly of syntax; the significations of words, and other properties of language. The notion or image expressed is the ὑμνήμα, phantazy, already explained.

Dialeitcs consider things as capable of being classed under species and genera. The most comprehensive genus is that which includes all things, both real and imaginary. Of things there are four subdivisions, viz. substance, qualities, modes, and relations. Things considered with respect to speech are said to be ἀλήθες, capable of being expressed in words. Predicates are things predicated, or declared, concerning another. Hence arise axioms, syllogism, and compound, and these admit of different characters. An argument (ἀγγείο) commonly consists of a general truth admitted (ἀφήμα); a particular cause (ὑπόθεσις); and a conclusion (ἐπισήμα). Arguments admit of different forms.

According to the Stoical doctrine concerning "nature," there existed from eternity a dark confused chaos, in which were contained the first principles of all future beings; which chaos, being at length arranged, and emerging into variable forms, became the world, as it now subsists. The universe, though one whole, contains two principles, distinct from elements; one passive, which is pure matter, without qualities, and the other active, which is reason or God. Zeno, determining to innovate upon the doctrine of the Academy, and declining to adopt the Dualistic system, which held God and matter to be two principles, eternally opposite, not only differing in their essence, but having no common principle by which they can be united, and also the emanative system (see Emanation) embraced a third hypothesis, which is distinguished by the appellation of the "Stoical system." Unwilling to admit, on the one hand, two opposite principles, both primary and independent, and both absolute and infinite; or, on the other, to suppose matter, which is in its nature diametrically opposed to that of God, the active efficient cause, to have been derived by emanation from him; yet finding himself wholly unable to derive these two principles from any common source, he concluded that the matter and the active principle were so essentially united, that their nature was one and the same.

The Stoical system teaches, that both the active and passive principles in nature are corporeal, since whatever acts or suffers must be so. The efficient cause, or God, is pure ether, or fire, inhabiting the exterior surface of the heavens, where every thing which is divine is placed. This ethereal substance, or divine fire, comprehends all the vital principles by which individual beings are necessarily produced, and contains the forms of things, which, from the highest regions of the universe, are diffused through every other part of nature.

Matter, or the passive principle, in the Stoical system, is definitive of all qualities, but ready to receive any form; inactive, and without motion, unless moved by some external cause. The contrary principle, or the ethereal operative fire, being active, and capable of producing all things from matter, with consummate skill, according to the forms which it contains, although in its nature corporeal, considered in opposition to gross and flimsy matter, or to the elements, is said to be immaterial and spiritual.

Some persons have been misled in forming their notions of the Stoical system, by the bold innovations of its advocates in the use of terms; and accordingly they have inferred from the apppellations sometimes applied by the Stoics to the Deity, that they conceived him to be strictly and properly incorporeal. Whereas the truth seems to be, that, as they sometimes spoke of the soul of man, a portion of the divinity, as an exceedingly rare and subtle body, ψυχή καρπουτίου καὶ λειτουργίας, and sometimes as a warm or fiery spirit, κόρα με καιρόμενη, so they spoke of the Deity as corporeal, considered as distinct from the incorporeal vacuum, or infinite space, but as spiritual, considered in opposition to gross and inactive matter. They taught, indeed, that God is indestructible, incorruptible, and eternal; puffed with intelligence; good and perfect; the efficient cause of all the peculiar qualities or forms of things; and the constant preferver and governor of the world; and they described the Deity under many noble images, and in the most elevated language. The hymn of Cleanthes, in particular, is justly admired for the grandeur of its sentiments, and the sublimity of its diction. But if, in reading these descriptions, we habitually associate with them modern conceptions of Deity, and neglect to rec-
unto the leading principles of the sect, we shall be led into fundamental misapprehensions of the true doctrine of Stoicism. For, according to this sect, God and matter are alike unuced and eternal, and God is the former of the universe in no other sense, than as he has been the necessary efficient cause, by which motion and form have been impressed upon matter. What unworthy notions the Stoics entertained of God, sufficiently appears from the single opinion of his finite nature, an opinion which necessarily followed, from the notion that he is only a part of a spherical, and therefore a finite universe.

With respect to the doctrine of divine Providence, it appears that, according to the Stoics, the agency of the Deity is nothing more than the active motion of a celestial ether, or fire, possefled of intelligence, which at first gave form to the shapeless mass of gross matter, and being always essentially united to the visible world, by the fame necessary agency, preserves its order and harmony. The Stoic idea of Providence is, not that of an infinitely wise and good being, wholly independent of matter, freely directing and governing all things, but that of a necessary chain of causes and effects, arising from the action of a power, which is itself a part of the machine which it regulates, and which, equally with that machine, is subject to the immutable law of necessity. Providence, in the Stoic creed, is only another name for absolute necessity, or fate, to which God and matter, or the universe, which consists of both, is immutably subject.

The rational, efficient, and active principle in nature, the Stoics called by various names; nature, fate, fortune, God. "What is nature," says Seneca, "but God; the divine reason, inherent in the whole universe, and in all its parts; or you may call him, if you please, the author of all things." And again: "Whatever appellations imply celestial power and energy, may be justly applied to God; his names may properly be as numerous as his offices." The term nature, when it is at all distinguished in the Stoic system from God, denotes, not a separate agent, but that order of things which is necessarily produced by his perpetually agency.

The universe, according to Zeno and his followers, is a vast, infinite, immortal, inviolable, and animated being." But Zeno understood this doctrine in a sense different from that in which it was conceived by many former philosophers. Zeno, adopting the ideas of Pythagoras and Heraclitus, and assuming that there is no real existence which is not corporeal, conceived nature to be one whole, consisting of a subtle ether and gross matter, the former the active, the latter the passive principle, as essentially united as the soul and body of man; and supposing God, with respect to nature, to be, not a co-existing but an informing principle. Whilst the Stoics allowed that the Deity is the efficient and intelligent cause of all the effects which are produced in the world, their notions of his nature and attributes were confused and degrading. Refusing primarily in the superior celestial region, and being thence diffused, as a subtle fire through a finite world, his universal prehension is limited, and falls far short of the attribute of immensity, as it belongs to the divine nature. United to matter by the immutable chain of necessity, he wants that freedom of action which appears to be one of the most essential characters of the Supreme Being. The original communication, and the perpetual preservation of forms and qualities, by the necessary action of a subtle fire upon matter, though this principle be supposed to be possefled of reason and intelligence as well as energy, is certainly an idea of Deity, which falls far short of that pure and sublime doctrine, which represents God as creating and governing the world by voluntary agency, and with wise design. That

the Deity is, according to the Stoic doctrine, subject to the law of necessity no less than matter and all subordinate beings, Seneca, and other writers of this sect, expressly assert. "Both gods and men are bound," says he, "by the same chain of necessity. Divine and human affairs are alike borne along in an irreifiable current; cause depends upon cause; effects arise in a long succession; nothing happens by chance; but everything comes to pass in the established order of nature."

Portions of the ethereal soul of the world being distributed throughout all the parts of the universe, and animating all bodies, hence arise, in the system of the Stoics, inferior gods or demons, with which all nature is peopled. All these divinities they considered as derived from the soul of nature, and as limited in their duration. Demons were divided by the Stoics into superior and inferior; the superior, those which inhabited the sun and stars, which they considered as gods; the inferior, animated substances; the inferior, inferior, human souls separated from the body, or heroes. "Illustrious men," says Cicero, "whole souls survive and enjoy immortality, are justly esteemed to be gods, since they are of an excellent and immortal nature." Beside this, there seems little reason to doubt, that the Stoics acknowledged the existence of other inferior divinities, portions of the soul of the world, and taught that they are endowed with human passions, and therefore are proper objects of sacrifice and worship.

As the Stoics held, that all the inferior divinities are portions separated from the soul of the world, to the conception, that a period would arrive, when they would return into the first celestial fire, and supposing that, at the same time, the whole visible world would be consumed in one general conflagration.

On the subject of the origin of evil, they had recourse to fate, and taught that evil was the necessary consequence of that eternal necessity, to which the great whole, comprehending both God and matter, is subject.

Concerning the second principle in the universe, matter, and concerning the visible world, the doctrine of the Stoics is briefly this: matter is the first essence of all things, destitute of, but capable of receiving, qualities. Considered universally, it is an eternal whole, which neither increases nor decreases. Considered with respect to its parts, it is capable of increase and diminution, of collision and separation, and is perpetually changing. Bodies are continually tending towards dissolution; matter always remains the same. Matter is not infinite but finite, being circumscribed by the limits of the world; but its parts are infinitely divisible.

The world is spherical in its form, and is surrounded by an infinite vacuum. The action of the divine nature upon matter, first produced the element of moisture, and then the other elements, fire, air, and earth, of which all bodies are composed. Air and fire have essential levity, or tend towards the exterior surface of the world; earth and water have essential gravity, or tend towards the centre. All the elements are capable of reciprocal conversion; air passing into fire or into water; earth into air and water; but there is this essential difference among the elements, that fire and air have within themselves a principle of motion, while water and earth are merely passive.

The sun is a sphere larger than the earth, consisting of fire of the purest kind: it is therefore an animated being, and the first of the derived divinities. The stars too are of the same kind, fiery bodies endowed with perception and intelligence, and therefore to be ranked among the gods. They are nourished by exhalations from the seas and rivers.
STOICS.

rivers. Because the heavenly bodies are animated, they are capable of foreseeing future events, and of declaring to mankind, by certain signs, the appointments of fate.

The celestial bodies move in their orbits, in the following order: Saturn, Jupiter, Mars, Mercury, Venus, the Sun, the Moon. The moon, which occupies the lowest part of the ethereal region, is, like the rest, a fiery luminous physion of intelligence; but the fire is mixed with air; whence the spots upon its surface. Its form is spherical, and its motion spiral, and of two kinds: the one, from east to west, with the heavens; the other from west to east, through the signs of the zodiac.

Below the sphere of the moon is the region of the air. This earth is the most dense part of the world, and is the main support of nature, like the bones of an animated body. The earth, with its waters, forms a globe, which is the centre of the world; it always remains immoveable.

The world, including the whole of nature, God, and matter, subject to eternity, and will for ever subsist; but the present regular frame of nature had a beginning, and will have an end. The parts tend towards a disgregation, but the whole remains immutably the same. The world is liable to destruction from the prevalence of moisture, or of dryness; the former producing an universal conflagration, the latter an universal conflagration. These succeed each other in nature as regularly as winter and summer. When the universal inundation takes place, the whole surface of the earth is covered with water, and all animal life is destroyed; after which, nature is renewed, and subsists as before, till the element of fire, becoming prevalent in its turn, dries up all the moisture, converts every substance into its own nature, and at last, by an universal conflagration, reduces the world to its pristine state. At this period, all material forms are lost in one chaotic mass; all animated nature is re-united to the Deity, and nature again exists in its original form, as one whole, consisting of God and matter. From this chaotic state, however, it again emerges, by the energy of the efficient principle, and gods and men, and all the forms of regulated nature, are renewed, to be dissolved and renewed in endless succession.

As a necessary consequence of the doctrine of the conflagration, and subsequent restoration of all things, the Stoics maintained, that the human race will return to life. Hence it appears in what sense we are to understand the Stoic simile of the sun, which rises again after an universal conflagration, the written with so much elegance; and what meaning we are to annex to his words, when he says, "Death, of which we are so much afraid, and which we are so fear to avoid, is only the interruption, not the destruction, of our existence; the day will come which will restore us to life." This tenet is not to be confounded with the Christian doctrine of the resurrextion of the body; for, according to the Stoics, men return to life, not by the voluntary appointment of a wise and merciful God, but by the law of fate, and are not renewed for the enjoyment of a better and happier condition; but drawn back into their former state of imperfection and misery.

Man, according to the Stoics, is an image of the world; one whole, composed of body and mind. The mind of man is a spark of that divine fire which is the soul of the world. The human soul, being a portion of the Deity, is of the same nature; a subtle fiery substance, endued with intelligence and reason; but the energy of this principle is confined and retrained, in the birth of man, by the union with groser matter.

Concerning the duration of the soul of man, the Stoics entertained very different opinions. Cleanthes thought that all souls would remain till the final conflagration. Chrysippus was of opinion, that this would only be the lot of the wise and good; and Seneca seems to have entertained the same notion. Epicurus and Antoninus affirmed, that as soon as the soul is released from the body, it returns to the soul of the world, or is lost in the universal principle of fire. Some were so absurd as to believe, that the human soul, consisting of a fiery spirit condened by its union with air, is capable of being extinguished. While others, with equal absurdity, conceived that the human soul, shut up within the gross body, could not, at death, find a free passage, but remained with the body till it was entirely deprived of life. The only idea of the preservation of the soul, which seems to have been entertained by the Stoics, was that of a renovation of being, in that fated circuit of things which we have seen to be one of their fundamental doctrines. In the universal restoration of nature, some imagined that each individual would return to its former body; while others conceived, that after a revolution of the great year, similar souls would be placed in similar bodies.

The soul, conceived by the Stoics to have been material, was represented by them as consisting of eight distinct parts, viz., the five senses, the productive faculty, the power of speech, and the ruling part, or reason. Those who held the existence of the soul after death, supposed it to be removed into the celestial regions of the gods, where it remains, till, at the general conflagration, all souls, both human and divine, shall be lost in the Deity. But many supposed, that before they were admitted among the deities, they must purge away their inherent vices and imperfections, by a temporary residence in the aerial region between the earth and the moon, or in the moon itself. With respect to depraved and ignoble souls, it was a common opinion, that after death they were degraded into the lowest state of the air, till the fiery parts were separated from the groser, and rose by their natural levity to the orbit of the moon, where they were still further purified and refined: a kind of mechanical purgatory, which very well agreed with the mechanical principles of the Stoic philosophy. These fancies are treated with ridicule by Epictetus and Seneca, who frequently speak of the happiness of good men after death in terms which might have suited a better system. Seneca, confounding Marcion under the lips of his son, says, "The happy assembly of the Stoics, which is not the Deity, but ourselves, who have themselves profaned life, and obtained freedom by death, shall welcome the youth to the region of happy souls. Your father himself (for all are there known to all) shall embrace his grandson, and shall direct his eyes, now furnished with new light, along the courses of the neighbouring stars, with delight explaining to him the mysteries of nature, not from conjecture, but from certain knowledge. Like a welcome guide in an unknown city, he will unfold to the inquiring stranger the causes of the celestial appearances."

The Stoic doctrine of "Mora" is founded on the principles of physics. Conceiving God to be the principal part of nature, by whole energy all bodies are formed, moved, and arranged, and human reason to be a portion of the divinity, it was their fundamental doctrine in ethics, that in human life one ultimate end ought for its own sake to be pursued; and that this end is, to live agreeably to nature, that is, to be conformed to the law of fate by which the world is governed, and to the reason of that divine and celestial fire which animates all things. Since man is himself a microcosm, composed, like the world, of matter and a rational principle, it becomes him to live as a part of the great
STOICS.

great whole, and to accommodate all his desires and purposes to the general arrangement of nature.

To live according to nature, as the Stoics teach, is virtue; and virtue is itself happiness; for the supreme good is, to live according to a just conception of the nature of things, shewing that which is in itself eligible, and rejecting the contrary. Every man having within himself a capacity of discerning and following the law of nature, hath his happiness in his own power, and is a divinity to himself. Horace seems to have adopted this notion, Ep. i. 18.

"For life and wealth to Jove I'll pray;
Thrice Jove can give or take away;
But for a firm and equal mind,
This blessing in myself I'll find." Francis.

Wifdom, say the Stoics, consists in distinguishing good from evil. Good is that which produces happiness, according to the nature of a rational being. As the order of the world consists in the unchangeable conformity to the law of fate, so the happiness of man is motion, that course of life which flows in an uninterrupted current, according to the law of nature. Since those things only are truly good which are becoming and virtuous, and virtue, which is feated in the mind, is alone sufficient for happiness, external things contribute nothing towards happiness, and therefore are not in themselves good. The wise man will only value riches, honour, beauty, and other external enjoyments, as means and instruments of virtue; for, in every condition, he is happy in the possession of a mind accommodated to nature. Pain, which does not belong to the mind, is no evil. The wise man will be happy in the midst of torture. All external things are indifferent, since they cannot affect the happiness of man: nevertheless, some of these are conducive, others disadvantageable, to the life which is according to nature, and as such are proper objects of preference or rejection, ἐξουσίαν ἀποτελομικεῖ. Every virtue being a conformity to nature, and every vice a deviation from it, all virtues and vices are equal. One act of beneficence, or justice, is not more truly so than another; one fraud is not more a fraud than another; therefore there is no other difference in the essential nature of moral actions, than that some are vicious, and others virtuous.

The Stoics advanced many extravagant assertions concerning their wife man. For example, that he feels neither pain nor pleasure; that he exercises no pity; that he is free from faults; that he is divine; that he can neither deceive nor be deceived; that he does all things well; that he alone is great, noble, ingenious; that he is the only friend; that he alone is free; that he is a prophet, a prince, and a king; and the like. These paradoxical vauntings are humorously ridiculed by Horace, Ser. i. 1. 530:

The Stoics, however, did not suppose that their wife man actually existed; but they formed in their imagination an image of perfection, towards which every man should continually aspire.

The first object of pursuit, according to the Stoics, is not pleasure, but conformity to nature; and every one who has a just discernment of what is good, will be principally solicitous, in all his actions and pursuits, to conform to nature. This, they teach, is the origin of moral obligation. Violent emotions and passions, arising from false conceptions of good, are contrary to right reason and nature; and these it is the office of reason to prevent or remedy. Of virtues, some are contemplative, others practical; some primary, others subordinate. The contemplative scientific virtues are those which consist in just conceptions and principles: the practical, those which concern the conduct of life. The primary virtues are, prudence, temperament, fortitude, and justice. Prudence respects the choice and pursuit of goods; temperance, the government of the appetites; fortitude, the endurance of that which is commonly esteemed evil; and justice, the offices of social life.

Duties were distributed by the Stoics into three classes, as they respect God, ourselves, and our neighbour. The duties of religion are, to think justly concerning God, and to worship him piously. He thinks justly concerning God, who believes him to be the supreme director of human affairs, and the author of all that is good and fitting in human life. He worships God piously, who reveres him above all beings; who perceives and acknowledges him in all events; who is in every thing resigned and obedient to his will; who patiently receives whatever befalls him, from a persuasion, that whatever God appoints must be right; and in fine, who cheerfully follows wherever divine Providence leads him, even though it be to suffering and death.

The sum of a man's duty with respect to himself is, to fuzz his passions of joy and sorrow, hope and fear, and even pity. He who, in this respect, perfectly masters himself, is a wise man; and in proportion as we approach towards a state of apathy, we advance towards perfection.

The duty we owe towards others, is to love all men, even our enemies. A good man will love his neighbour from his heart, will refrain from injuring, and take pleasure in protecting and serving him. He will not think himself born for himself alone, but for the common good of mankind, and will shew himself kind to all, according to his ability. He will think himself sufficient; he has no care of well doing, and will never cease to do good, although he has no witness of his good deeds, nor is ever likely to receive any applause or recompence for his beneficence. The wise man never remits the punishment due to a criminal through pity, which is a weakness not to be indulged; nevertheless, in cases where reason suggests a sufficient ground for clemency, he will not treat a delinquent with rigour. He will relieve the sick, assist the shipwrecked, afford protection to the exile, or supply the hungry with food, but he will not contend for wealth with an undisturbed mind, and cherish all frymoral and impracticable. The piety which it teaches, is nothing more than a quiet submission to irresistible fate. The self-command which it enjoins, annihilates the best affections of the human heart. The indulgence which it grants to suicide is inconsistent, not only with the genuine principles of piety, but even with that constancy which was the height of Stoiic perfection. And even its moral doctrine of benevolence is tinctured with the fanciful principle, which lay at the foundation of the whole Stoiic system, that every being is a portion of one great whole, from which it would be unnatural and impious to attempt a separation.

We must then conclude, that the ethics of Zeno and his followers,
followers, however splendid, and in many particulars well-founded, devoted, as a system, from the true principles of nature, and had a tendency to produce artificial characters, and to encourage moral affectation and hypocrisy.

Zeno, the founder of the Stoical system, had many disciples and successors; such were Peripæus, Aristo the Chian, Herillus, and Sphærus. His immediate successor in his school was Cleanthes. (See his article.) After Zeno, no philosopher more truly exhibited the character, or more illustriously displayed the doctrine, of the Stoics, than Chrysippus. (See Chrysippus.) The immediate successor of Chrysippus in the Stoic school was Zeno of Tarsus, or, as some say, of Sidon. The chair was next assumed by Diogenes of Seleucia, called also the Babylonian. (See his article.) His disciple and successor was Antipater of Tarsus. The last of that series of Stoics which belongs to the history of the Greek philosophy was Poliddonius. See Polidionius.

The Stoic school was patronized by many eminent men in the Roman republic; but the man who claims more special notice, as a Stoic in character as well as principle, was the younger Cato. See his article.

The Stoic philosophy, which under the republic found many patrons, particularly among the professors of the law, continued to flourish under the emperors till after the reigns of the Antonines. Its ethical doctrine became the permanent basis of the Roman jurisprudence; and the high tone of wisdom and virtue which it assumed, induced many persons of great distinction and eminent merit to declare themselves of the Stoic sect, or at least to prefer its moral system to that of any other school. The prevalence of Christianity contributed also, in no small degree, to the success of Stoicism. Befides, the Stoic sect acquired great credit and authority from the illustrious examples of many persons of both sexes, who, in those times of civil opposition, bravely encountered death in the cause of liberty and virtue.

Among the heroes of this age, Tacitus mentions the two Arrias, the wives of Cæcina Petus and Thraeas, and Pætis the wife of Helvidius. For these and other causes, the Stoic sect, in the time of Juvenal, prevailed almost throughout the Roman empire. (Sat. xv. v. 103.) Under Antoninus Pius, schools of Stoicism were supported at the public expense in Athens, Alexandria, and probably too at Rome; for Antoninus, after he came to the purple, visited the house of Apollonius the Stoic to study philosophy. At Tarsus in Cilicia there was also a Stoic school, which produced several celebrated philosophers. The Stoic philosophy, however, struggled with powerful opposition from several quarters; and from the period when the meteley Eclectic system was established, Stoicism began to decline; and in the age of Augustus it no longer subsisted as a distinct sect. It was only during the short space of 200 years, that the Roman school of Zeno was adorned with illustrious names which claim a place in the history of philosophy. The first Stoic who merits attention in this period is Athenodorus, of Tarsus in Cilicia (see Athenodorus); Annæus Cornutus, an African, who lived at Rome in the beginning of the reign of Nero, and excelled in criticism and poetry, though philosophy was the principal object of his study (see Cornutus); Caius Mæonianus Bus, who was banished by Nero to Gyarra, but afterwards recalled by Vespasian (see Mæonius); Cheremon, an Egyptian; Lucius Annæus Seneca (see his article); Dio, of Prusa in Bithynia, called for his eloquence Chrysophom; Euphrates of Alexandria; Epictetus (see his article); Sextus, of Cheronea in Boeotia; and, last of all those whom we shall mention, the great and good emperor, Marcus Aurelius Antoninus. (See his article.) From the time of the Antonines to that of Alexander Severus, there were public schools of the Stoics in Athens and Alexandria; but their doctrine was corrupted by the prevalence of the Eclectic philosophy. In the sixteenth century some attempts were made for reviving the Stoic philosophy by Lipsius, (see his biographical article,) Galper Scipionius, Daniel Heinlius, and Thomas Gataker. See Brucker’s Hist. of Philosophy in Einfeld, vols. i. and ii.

STOICA, in Geography, a town of Hungary; 10 miles N.W. of Calchau.

STOKAIM, a town of Prussia, in Natangen; 30 miles S.S.E. of Konigberg.

STOKE, a township of Lower Canada, on the St. Francis river, N. of Alcots.

Stoke’s Bay, a bay on the S. coast of Hampshire, between Portsmouth harbour and Southampton river, S. of Gosport.

STOKE-COURCY, a parish of large extent in the north-west corner of the hundred of Cannington, and county of Somerset, England. One extremity of this parish is a long, narrow peninsula, called Start Point; which stretches nearly four miles into the sea, and terminates at the western edge of Bridgewater bay. The river Parret empties itself into the sea at this point. The town of Stoke-Courcy consists chiefly of one long street, and is situated at the southern extremity of the parish: it is studded in ancient records, the borough and honour of Stoke-Courcy, and the above-mentioned street still retains the former of these appellatives; though we do not find that it sent members to parliament more than once in the time of Edward III. It was formerly privileged with a market; this, however, has been long since discontinued; but here are yet held two annual fairs. Near the old croses, in High-street, are two fine springs, inclosed within cisterns, which, after supplying the inhabitants with water, unite with the brook that runs near the town, and fall into the sea at Stoford. The church of Stoke-Courcy, built at several periods, is a large building, with a tower in the centre, supported by four large arches. The eastern end of this edifice is of great antiquity, and was the priory church belonging to the priory of Benedictine monks, which was formerly founded near this place. The arches which separate the body of the church from the north and south aisles are semicircular, and sprang from very rich capitals. The name of Stoke-Courcy is Saxen, the former word signifying a village, and the latter the name of its original proprietor; whose ruined mansion lies a short distance to the south of the town. This parish, inclusive of Fairfield, contained, in 1811, 1208 inhabitants, and 228 houses. — History of Somersetshire, by the Rev. John Collinson, 4to. 1791, vol. i.

STOKEN, a town of Switzerland, in the canton of Zurich; 16 miles N. of Zurich.

STOKERAU. See Stockerau.

STOKES, a county of North Carolina, in Salisbury, divided, bounded E. by Rockingham and W. by Surry, containing 11,645 inhabitants, of whom 1746 are slaves. The capital is Germantown.

STOKES, a town of North Carolina, near the Yadkin; 20 miles N.N.W. of Salisbury.

STOKESIA, in Botany, was so named by L’Heritiers, in honour of Jonathan Stokes, M.D., well known as the coadjutor of Dr. Withering, in his Botanical Arrangement of British Plants; and particularly distinguished for his critical acuteness, displayed in his references to figures throughout that work. Dr. Stokes has recently published an elaborate Materia Medica, in four octavo volumes, disposed

Gen. Ch. Common Calyx ovate, somewhat imbricated, with leafy scales. Cor. compound, radiated; florets tubular, all perfect; those of the disk numerous, regular, in five equal segments; those of the radius larger, funnel-shaped, with a dilated, five-cleft, unequal limb. Stam. Filaments five, capillary; anthers united into a cylindrical tube. Fil. Germin angular; style thread-shaped, the length of the stamens; stigmas two, divided. Pet. none, except the permanent calyx. Seed to each floret, solitary, oblong; those of the disk with four angles; those of the radius with three. Down of four erect bristles in the seeds of the disk, of three only in those of the radius. Results. naked.

Eff. Ch. Receptacle naked. Seed-down of three or four bristles. Calyx leafy, somewhat imbricated. Florets of the circumference funnel-shaped, irregular. 1. S. cyanus. Blue Stokaria. Iwldl. n. i. Ait. n. i. (Carbohydrates. — Hill. Hort. Kew. 37, n. 5.) — Native in South and Central Europe. Cultivated at Kew from about the year 1766, when Mr. Gordon is said to have introduced this elegant plant. It is perennial, flowering in August, requiring shelter in winter. The stem is erect, simple, leafy, about two feet high. Lower leaves lanceolate, clasping the stem, toothed at the base; upper sessile, heart-shaped, serrated; all smooth, bright-green. Flowers large and very handsome, of a fine blue. It is by mistake that Hill and L. Heritier are cited as having given figures of this plant.

STOKESLEY, in Geography, a town in the west division of the liberty of Langbrough, and North Riding of Yorkshire, at the distance of 342½ miles north-west from London, and 43½ from York. In 1811 it contained 388 houses, and 1435 inhabitants. The lordship of Stokesley, at an early period, was granted to the family of Balbil, and was possessed by Gay de Balbil, who came into England with king William I. The manor, after descending through the family of Forster, has since been sold to the Rev. Mr. Hillyard, the present proprietor. The town is situated on the north side of a large branch of the rivers Swainby and Brimley, chiefly by one broad street. The buildings are principally modern, with the exception of the stables and the toll-booth, which have an appearance of antiquity. Though no evidence of the original foundation of St. Peter's church in this town can now be produced, yet a church is mentioned in the Domesday survey. About 1363, a chantry was founded at the Virgin's altar, within this building, by William de Stokesley, for the repose of the souls of John de Middleton and his wife. There is a church at the eastern extremity of the town, of modern erection, but the ancient town is yet remaining. The rectory-house was rebuilt in the year 1592, and is an agreeable residence, greatly improved by the present incumbent, the dean of York. Adjoining to the church-yard, on the north, stands the manor-house, a square stone edifice, with gardens, and a rising shrubbery in front. This town is endowed with two fairs, and a weekly market, held on Saturday. The petty fellows for the western division of Langbrough are held here. The parish of Stokesley is of considerable extent, and includes an area of about seven square miles. Within its limits are contained the townships of Stokesley-Bubby and Eastby, with the hamlet of Tameton, and a part of Newby. These were manorial residences held under feudal tenures; little remains of their ancient greatness are visible. Eastby Hall, formerly a seat of the lords Eures, now falling to decay, and an ancient chapel at the south end of the village, dedicated in 1540, are the only vestiges left. The environs of Stokesley are fertile, and the lands near the town chiefly laid into pasture. — Beauties of England and Wales, vol. xxvi. Yorkshire; by J. Bigland. History of Cleveland; by the Rev. John Graves, 410. 1808.

STOKEDORFF, a town of Austria; 4 miles N.E. of Sonneberg.

STOKOLETZ, a town of Croatia; 12 miles S.W. of Petrova.

STOLATZ, a town of European Turkey, in the province of Servia, on the Morava; 30 miles N.N.W. of Nisca.

STOLBERG, a town of Saxony, in the circle of Erzgebirge; 8 miles S.W. of Chemnitz. N. lat. 50° 46′. E. long. 12° 42′. — Alto, a town of Westphalia, capital of a county to which it gives name, and residence of the counts; 40 miles N. of Erfurt. N. lat. 51° 29′. E. long. 11° 5′. — Alto, a town of France, in the department of the Loire; 3 miles S.S.W. of Eichweiler. — Alto, a county situated in Thuringia; about 20 miles long and 15 broad. It affords good pasture and arable land, with some rich mines of copper and iron, some fine woods, and plenty of game; now annexed to the kingdom of Westphalia.

STOLBOVOI, a cape on the E. coast of Kamchatka; 40 miles E. of Kamchatskoii. N. lat. 56° 25′. E. long. 161° 44′.

STOLCKERN, a town of Austria; 3 miles S.W. of Eggenburg.

STOLE, STOLA, from coen, signifying a long robe, or tippet, a sarcodotic ornament, worn by the Romish patriarchs over their furpile, as a mark of superiority in their respective churches. The robe is worn by other prelates over the alb, at celebrating of masses; in which case it goes across the flamusch; and by deacons over the left shoulder, scarfsive.

The robe is a broad swath, or strip of cloth or stuff, hanging from the neck to the feet, with three croffles upon it. The bishops anciently pretended, that the patriarch-riplets were never to appear before them but in their floses, in Flanders and Italy they always preach in floses. It is supposed to be a representation of the borders of the long robe worn by the Jewish high-priests.

The robe of the ancient Romans, &c. was very different from that now in use; the former was a kind of robe fitter for women than men, though it was held a robe of honour among all nations. Kings themselves sometimes used it, and sometimes bestowed it as a reward of virtue.

STOLE, Groom of the, the eldest lord of his majesty's bed-chamber, whose office and honour is to present and put on his majesty's first garment or shirt every morning; and to order the things in the chamber.

STOLE, Order of the, an order of knights instituted by the kings of Aragon; though, as to the particular author or time of the institution, we are in the dark. The first time we hear of it is under Alphonfus V. who mounted the throne in 1416. Juquinian takes it to have been instituted about the year 1332.

STOLE, Order of the Golden, a military order at Venice, thus called from a golden flose, which the knights wore over their left shoulder, reaching down to the knee, both before and behind, a palm and a half broad. None are raised to this order but the patricians, or noble Venetians. Juffinian observes, that the time of the institution of this order is unknown.
STOLHOVEN, in Geography, a town of Germany, in the duchy of Baden, not far from the Rhine; 16 miles N. N.E. of Strasbourg. N. lat. 48° 45', E. long. 8° 7'.

STOLLEN, a town of Prussia, in the province of Oberland; 3 miles E. of Liebhadt.

STOMERZ, a town of Austrian Poland, in Galicia; 28 miles E. of Lemberg.

STOLNOWICZ, a town of Russian Lithuania; 30 miles S. of Novogrodok.

STOLPE, a town of Prussia, in the province of Ermland; 4 miles N.E. of Allenstein. — Allo, a river which rises in Pomerania, and runs into the sea; 25 miles W. of Dantzig. — Allo, a town of Anterior Pomerania; 5 miles W. of Anolam. — Allo, a town of Farther Pomerania, on a river of the same name, which here begins to be navigable to the Baltic. It contains three churches, and a Lutheran convent for ladies. The trade is considerable; 80 miles N.E. of Stargard. N. lat. 54° 25'. E. long. 16° 43'. — Allo, a river of Farther Pomerania, which runs into the Baltic at Stolpmunde. — Allo, a lake of Brandenburg, in the Mark of Pregnitz; 2 miles E. of Kyritz. — Allo, a town of Brandenburg, in the Ucker Mark; 6 miles S.E. of New Angermünde. N. lat. 52° 58'. E. long. 14° 14'.

STOLPMUNDE, a town of Farther Pomerania, situated on the coasts of the Baltic, at the mouth of the river Stolpe. 10 miles N. of Stolpe. N. lat. 54° 32'. E. long. 16° 33'.

STOLPEN, a town of Saxony, in the margravate of Meissen, with a citadel. In 1632, this town was burned by the Croats; and in 1765, the fortifications of the citadel were destroyed by the Prussians; 33 miles W.N.W. of Zittau. N. lat. 53° 41'. E. long. 14° 5'.

STOLTENBERG, a town of Pomerania; 10 miles S.S.W. of Corin.

STOLTZENBURG, a town of Transylvania; 6 miles N. of Hermensdlaft.

STOMACHACE, in Medicine, from φτόμαι, the mouth, and καύσις, emer, an erosion of, and spontaneous hemorrhage from, the gums and internal surface of the cheeks, together with an unusual factor of the mouth, is, in fact, a symptom of scurvy, or purpura, affecting that part. The term is sometimes used as an appellation of scurvy. See SCURVY and ΗΜΟΡΡΗΓΙΑ.

STOMACH, in Anatomy and Physiology. (Funiculus. Stomachus,) the large membranous bag, constituting the amplest portion of the alimentary tube; intervening between, and communicating with, the oesophagus and duodenum; receiving from the former the food which has undergone mastication, digesting it, or converting it into an uniform pulp, and transmitting it into the latter; situated in the upper part of the abdomen. It may be regarded as the commencement of the digestive apparatus; for in it the food undergoes the first change of properties in that series of changes, which ends in its assimilation to our organs: the oesophagus, which precedes it, serves merely to convey the aliment from the mouth; and the act of mastication is a simply mechanical process, auxiliary, but not essential, to digestion.

The stomach is a conical bag, being large at one end, and gradually decreasing to the other; hence the terms, great or left, and small or right extremities (extremitas oesophagi, superior, major; cardia; and extremitas pylorica, inferior, minor; pylorus.) It has two openings: a circular one with smooth sides, and no thickened or elevated ring, which is the termination of the oesophagus, and called the superior, cardiac, or oesophageal orifice; a smaller, also circular, surrounded by a thick prominent ring, called the inferior or pyloric orifice, through which the digested aliment is transmitted into the small intestine. Any perpendicular section of the stomach is circular: the largest circle is opposite to the termination of the oesophagus; from that point the diameter gradually diminishes to the pylorus, where the stomach is not larger than the duodenum. The stomach also diminishes from the oesophagus in the opposite direction, or towards the great end, and forms a small hemispherical blind bag (fundus, facies cæcum), passing about two or three inches to the left of the oesophageal orifice. The two apertures, therefore, are differently circumvallated in their relation to the two extremities: the pylorus is actually at the right extremity, while the cardiac opening is placed two or three inches to the right of the left extremity. The conical tube of the stomach is incurvated towards its small end; two-thirds of the bag, from the great end, are straight; but the remainder is bent upwards or backwards, so that the pylorus is turned towards the cardiac orifice: hence these two openings are near together on the upper or back aspect, very far apart on the front or lower. The concave line joining the former arch or curve of the stomach to the fundal or fundal curve; the convex line, by which they are united in the latter, the great arch or curvature of the stomach. The surfaces, included between these lines, are called the superior or anterior, the inferior or posterior. For the best view of the human stomach, see plate xi. fig. 1, in the Phil. Trans. 1807, in illustration of a paper by Sir Eeverard Home.

When the stomach is full, a vertical section of it, at any part, as we have already observed, is circular; when it is empty, its sides, formed of soft membranes, fall together. The organ, in the latter state, is quite flat. The size of the organ depends on the quantity of its contents, since its sides have the power of accommodating themselves to every variation of this kind. When perfectly empty, it is hardly larger than an intestine. It is difficult to determine its capacity. Soemmering says, that in an adult of middle stature it will hold, when moderately distended, from five to eleven pints of water. In various unnatural states, we find its capacity much augmented. Very frequently we find, after death, the great end more or less distended, and the small extremity empty and contracted; often too, there is a muscular confection about the middle, dividing it imperfectly into two compartments.

The stomach is situated in the epigastric region, and chiefly in the left portion of that region; its long axis being nearly transverse, or crossing the axis of the trunk at right angles. The great extremity is placed in the left hypochondrium, with the spleen attached to it behind by means of the omentum, and the diaphragm in contact with it towards the front. It stretches across the vertebral column, and ends, by its lesser extremity, in the left hypochondrium. The small lobe of the liver covers it above, being interposed between the stomach and diaphragm, so that these are in contact for a small space only at the left: the pancreas and colon are in contact with it below. The oesophagus lies on the middle of the spine: the small curvature includes, in its curve, the lobulus Spigelii and the aorta. The eniform cartilage does not answer to the middle of the stomach, but rather to its right portion: the pylorus corresponds nearly to the fundus of the gall-bladder, or to the notch between the two lobes of the liver. The openings of the stomach are placed farther back than the stomach itself; and this is particularly the case with the oesophageal: the latter is also higher in the body, by about two inches, than the pyloric. From the small arch, which is turned towards the spine, the
STOMACH.

Small omentum departs to the liver: the convexity of the great arch approaches to the front of the abdomen, and the great omentum descends from it in its whole length.

The stomach, therefore, occupies the space included between the false ribs, extending across the open interval between those of the right and left side: it does not usually descend lower than the margin of the chest, except when very full.

The relative position of the stomach is subject to change from many causes, particularly from its various conditions of fullness and emptiness. Its position in the dead subject may be called perpendicular; the bowels sink down, rather than rise, the support of the abdominal musculature is lost, and the parts naturally belonging to the epigastric region descend into the umbilical. The cæophagus descends into the stomach, and the pylorus ascends: the great arch is turned downwards, the small upwards: the upper surface is now anterior, and in contact with the front of the abdomen; the other surface is posterior; the position of the spleen, following that of the stomach, is also perpendicular, with the two extremities turned upwards and downwards. The relations of the organs are different in the living subject; the refraction of the intervals of the two arches is that the fundus of the stomach is higher; the posterior surface is at the same time rather turned upwards, and the posterior downwards; the great arch is forwards, the small backwards; and the cæophagus entering the organ, is rather inclined forwards. When the cavity is distended, all these circumstances are more strongly marked; the anterior surface is now turned completely upwards, the posterior downwards; the great arch stands forwards against the abdominal parieties, the inferior is turned directly backwards. When the stomach is in a free position, it is by the fovea gastrica that it is fastened to the wall of the body; and to this point the stomach is connected by the term cæophagus.

The cavity is not entirely occupied by the stomach, but is surrounded by a copious cellular tissue. In this situation, the stomach is not covered by serous membrane. For some distance from the curvature, on each side, the peritoneal coat can be easily separated from its connective tissue. When the stomach is distended, it rides in these situations above the peritoneal coat, and is then applied to its surface; while, in the empty state, they are in contact with each other.

The muscular covering is the thickest portion of the organ, enabling it to execute the motions which are necessary in the performance of its functions. It consists of a thin, nearly uniform layer of fibres, spread out into one continuous sheet like a membrane; and it will, of course, appear thicker or thinner, according as the stomach is contracted or expanded. Independently of this circumstance, it is found to be composed of two layers, which are then applied on its surface; while, in the empty state, they are in contact with each other.

The stomach is divided into two portions, the cardiac and pyleic. The cardiac portion is oblong, pale, not red, like those of the voluntary muscles. Two orders of fibres are easily distinguished, longitudinal and circular. The former are exterior, and much the fewest in number: they consist of the longitudinal fibres of the stomach, expanded in a radiated form in all directions from the end of that canal over the stomach. The most considerable of them run along the small arch as far as the pylorus, and may then be traced into the duodenum. Others go towards the great cæophagus, and are scattered over the two surfaces. These longitudinal fibres decussate the circular ones obliquely at different angles, and mix with them, ending amongst them. The circular fibres are much more numerous, and form a continuous covering over the whole stomach. They are rather thin at the great cæophagus, but they increase in thickness towards the opposite end. They form numerous rings parallel to each other, connected together, and extending from one extremity to the other. The individual fibres do not surround the stomach; but one ends, and another begins, and they partly turn aside to mix with other fasciculi. These circular fibres are continuous with the sheath of the cæophagus on one side, and with those of the duodenum on the other. At the pylorus they are collected into a thick ring, which forms the constriction of the canal at that part.

The mucous membrane, forming the internal surface, is the most important part of the stomach. It does not possess the fame power of accommodation to various capacities, as we find in the serous and muscular coats: hence, although it is smooth when the stomach is distended, it is collected all over the organ into numerous prominent folds, or rugae, when the cavity is contracted. The mucous coat is connected to the muscular by a very copious and loose cellular tissue, so that it can easily accommodate itself to the contractions...
STOMACH.

tractions of the latter. These rugae, which we see even in a half-filled stomach, consist merely of the mucous membrane; the feros and muscular have nothing to do with them. When the cavity is very empty, the rugae lie so close that they touch each other laterally: if the coats of such a stomach are diffused in any way, all these prominences disappear. The principal fibres of the stomach being circular, and their contraction consequentely taking place in the transverse direction, the folds produced by them are longitudinal, or follow the long axis of the stomach; these, which are the principal, are joined by smaller lateral folds. The cellular substance on the external surface of this membrane is the nervous coat of Haller, and other anatomists. It is soft, copious, whitish in its colour, and raised by inflation into the appearance of a downy or cotony texture. The blood-veals of the organ ramify in this, before they enter the mucous surface.

Besides the great folds of the mucous membrane, we observe several less considerable ones, composing a net-work with larger or smaller intervals: these are all defined by extension. The mucous membrane then appears as a smooth surface, but soft and rather pulpy; it is the kind of surface called villous, which is the usual name given to the membrane, although it does not possess the fine pointed processes which constitute the villi of the small intestines. The mucous membrane, in its most recent state, has a tint formed by the mixture of a very light red and a straw colour. Its true character is not easily seen, as the surface is generally covered by a closely adhering tenacious mucous layer. Soon after death, the translucence of the blood through the blood-veals gives a different colour to the mucous membrane. Often, even in the healthiest subjects, there is considerable vascularity observable in the mucous surface of the stomach; and more particularly when death has been accompanied by circumstances, which might impede the return of the venous blood. This appearance (which does not indicate any disease of the organ) has often been deemed the refut of inflammation. (See a paper by Dr. Yelloly, in the fourth volume of the Medical-Chirurgical Transactions.) The capillary system exists in great abundance in the mucous membrane of the stomach; so that it becomes of a uniform red, when the blood-veals are injected with fixe and vermilion.

It has been questioned, whether the fluids secreted from this surface are exhaled from its capillaries immediately, or are secreted in a distinct apparatus of mucous glands. The latter are not easily seen, but they have been described by several anatomists. After defecating them in various animals, Haller says, "they are not equally evident in man: I have generally been able to observe pores, which are visible all over the surface, and more numerous about the pylorus; from these, mucous fluid can be expressed. Others describe excretory ducts, and orifices, and fluids expressed from them. Occasionaly, there is a film of the glands themselves, of the nature of crypts, simple, round, membranous, hollow, situated in the cellular membrane under the mucous coat, and perforating the latter by their short ducts." (Elem. Physiol. tom. vi. p. 139.) Sommerring speaks of the orifices of mucous glands as being visible about the pylorus, but not always very conspicuous. (De Corp. Hum. Fabric. tom. vi. p. 225.) Lastly, they are delineated in considerable number, along the small curvature of the stomach, in the figure already referred to, published by Sir E. Home.

The mucous membrane of the stomach is continuous with that of the oesophagus on one side, and with that of the duodenum on the other; but differs clearly in its structure from both. The lining of the oesophagus has nothing villous in its structure, which is compact, smooth, and remarkably white: it is produced into the oesophageal orifice of the stomach, round which it terminates in a feathery border. See Sir E. Home's plate.

The communication between the stomach and duodenum is formed by the pylorus (janitor, siphincter), a contracted orifice surrounded by a thick ring. The serous membrane and the mucous are the same in the pylorus as elsewhere; the ring is formed by a thick set of circular muscular fibres. Someerring speaks of the pyloric ring being composed "e peculiaris glandulofo pene subfusitus?" but this does not accord with our own observation. The folds of the mucous membrane pass through the pylorus into the duodenum; consequently the orifice is plaited internally. If the stomach and duodenum be laid open after death, without disturbing the parts, the pyloric orifice will be found about equal in diameter to a goose-quill, and its circumference plaited. The finger can, however, be easily forced through it, enlarging the opening, stretching the mucous coat, and destroying the folds. It then appears a simple circular opening, with a thick prominent edge. If the small end of the stomach and the neighbouring portion of the duodenum be inflated, the pyloric constriction is very visible externally: if such a preparation be dried, it appears as if a firing had been tied round, and on cutting the parts open, a transverse production is seen, perforated in its middle by a circular aperture. Some unimportant varieties of figure have been observed in this opening: viz. it has been seen oval, or oblong, &c. instead of circular.

The office of the pylorus, as its name implies (from von, a gate, and wacht, a keeper), is to protect the entrance of the intestine, and prevent the passage of the alimentary matter, until it shall have sufficiently undergone the action of the stomach. Its muscular structure enables it to accomplish this effectually; for it can contract so as completely to shut the opening, in which state it is sometimes found after death; at the same time it has the power of relaxing, and thus allowing the alimentary pulp to pass. This contraction and relaxation are probably regulated by the existence of some relations between dilated and undilated substanres, and the peculiar sensibility of the organ; there is no mechanical explanation of the phenomenon, which is quite a vital process. The refutation of this muscular ring is different in the case of solids and fluids; it allows the latter to enter the intestinal canal easily, as we find from the rapidity with which they gain admission into the circulating system; and also from the short time after drinking, in which they flow out from the intestine, when an unnatural external opening from its canal gives us the opportunity of observation. Although the pylorus is commonly found after death of the dimensions already specified, we cannot doubt that it is much larger during the passage of the chyme; indeed we occasionally find solid substances of considerable dimensions passing this part. This is principally the case with pieces of coin, swallowed either by accident or design. Vaillant, a celebrated French medallist, swallowed twenty valuable gold medals, when purg'd by corfours; the processes of nature refined him the treasure in a short time; and he fold one of them, by anticipation, before it had made its appearance. A boy is mentioned by Hablot, in his "Question Chirurgicale sur la Bronchotomie," who swallowed several pills, which were recovered in the same way. Half-crowns, and we believe also crown-pieces of this country, have travelled safely through the alimentary canal.

The arteries of the stomach are numerous, and form of them large: they are all branches of the celiac, or its primary ramifications: viz. coronaria ventriculi, pylorica, gastrico-
Different chemical and vegetable substances produce specific effects on the stomach, which are not in proportion to any of their sensible qualities: various substances, insipid or nearly so, disturb it most vehemently, while others of powerful taste and acid nature, as the strongest condiments, which heat the whole frame, do not affect it. The diluted water of the laurocerasus, emetic tartar, and several others, are of the former kind, although they hardly excite pain in the conjunctiva of the eye. Cinnamon, pepper, and mustard, of which the slightest contact with the eye would produce excruciating agony, are not felt in the stomach.

Great variety is observed, in different animals, in the effects of various substances, both chemical and vegetable, on the stomach. Conium maculatum, hyoscymus, euphorbium, and hellebore roots, are poisons to man; while conium affords wholesome food to the cow and hare, hyoscymus to the pig, euphorbium to the goat, and hellebore to the quail. A quantity of opium or arsenic, that would destroy a man, may be taken with impunity by a dog, which, on the contrary, is much more affected than man by a given dose of jalap or nux vomica. Bitter almond, which we eat with impunity, are poisonous to dogs and various birds: the mountain parsley is fatal to parrots.

Like other parts, the stomach becomes accustomed to stimuli, and can bear larger and larger quantities of opium, of somnific and spirituous substances.

Although, in its natural state, the stomach possesses but slight animal sensibility, it exhibits the most acute feeling under disease. Cramp of the stomach, and inflammation of the organ, are as painful as any affections of any parts of the body.

The most important circumstance in the physiology of the stomach, is the secretion performed by its mucous membrane. The nature of this, and the changes it produces in the food, are considered in the article Digestion.

It is an interesting subject of inquiry, how far the secretions of the stomach, and consequently the processes of digestion, are influenced by the brain, which is the immediate source of its nerves. It is not easy to determine the point, because the eighth pair supplies the lungs as well as the stomach; consequently the division of these nerves produces effects on the process of respiration, which are soon fatal. On the other hand, if they are divided on the oesophagus in the abdomen, the injury is too great for the animal to survive in such a way as to enable us to judge of its digestive powers. The experiments hitherto made tend to show, that the brain influences the stomach through the eighth pair. Le Gallois divided one nerve in a Guinea pig of eighteen months; the animal breathed tolerably well, and continued to eat; but the belly increased proportionally in size. It died four days and five hours after the operation; the stomach occupied nearly the whole abdomen, diffused with food very little altered from the state in which it had been swallowed. Experiences sur le Prinçipe de la Vie, p. 214.

Mr. Brodie found, that the mucous and watery secretions, which diffuse the stomach and intestines in animals poisoned by arsenic, do not too rapidly take place, if the nerves of the eighth pair be previously tied, either in the neck, or in the cardia. Phil. Trans. 1814, p. 102.

It is well known that emetic tartar, injected into the veins, produces vomiting in a certain way, when introduced into the stomach: it has the same operation when brought in contact with any mucous or fereous surface, or with a wound. Mr. Magendie found that twelve or eighteen grains injected into a vein will kill a dog in half an hour. But if the

Vol. XXXIV.
nerves of the eighth pair be immediately divided, death does not take place till three or four hours after the injection. This physiologist selected three animals of the same age and weight, and injected into the veins of each twelve grains of emetic tartar. He divided one nerve in one dog; both trunks in another; and neither in the third. The latter died first; then the first; and the animal in whom both nerves were divided, lived the longest. De l'Influence de l'Emétique sur l'Homme et les Animaux, 2vo. Paris, 1814.

The muscular fibres of the stomach contract its cavity, and thus propel its contents, when they have been sufficiently acted on by the gastric fluid. Being longitudinal and circular, they can diminish the tube both in its length and breadth. The fibres contract and relax in peristaltic situations successively, and thus produce an appearance similar to that of the contractions and relaxations of the intestines: this is called the peristaltic motion of the stomach. These motions are not only visible when the organ is irritated in a living animal, but they may be seen on opening the abdomen of the recently slaughtered. The power of contraction continues for some time after apparent death, on the application of stimulants; and it may even be excited in a portion of the stomach cut out from the rest.

This contraction is completely foreign to the will: it takes place without our consciousness; and seems to result from the presence of the digested aliment. If diseased of the pylorus, or any other cause, prevent the passage of the food into the intestines, its presence irritates the stomach, and provokes its rejection by vomiting.

While the stomach is empty, it remains at rest; when the gastric secretions have acted on the food, we have already said that the muscular contraction of the organ expels the chyme through the pylorus. What is the state of the stomach, in respect to its muscular part, while digestion is going on? Is the stomach at rest, or does it present peristaltic motions by which its contents are agitated, exposed successively to the mucous surface, and more intimately mixed with the gastric secretions? Physiologists in general seem to admit the latter opinion, but we believe without any very direct proofs; which, indeed, it is not easy to obtain, as the division of the abdominal muscles, and the exposure of the stomach, cause an universal disturbance, instead of unveiling to us the natural state and actions of the animal organs. "It must be allowed," says Haller, "that for some time the action of the stomach does not direct the food to any certain point, but that the contents are driven to and fro by a peristaltic and antiperistaltic motion, which latter has been by some writers improperly disfigured. So long as both its orifices are shut, either the stomach must rest, or the food must be driven backwards and forwards. This agitation lasts while the oesophagus is closed, and the pylorus remains contracted; it ceases, when either the former or the latter gives way to the food." Elem. Physiol. lib. xix. sect. 4. § 10.

The stomach may contract in such a manner as to give its contents a direction contrary to their natural passage downwards: this is called the antiperistaltic motion. In this way air is expelled from the stomach in eructation, and an acrid liquor rises into the throat after feeding on indigestible matters, or in the affection of heartburn. In indigestion, the breath is often tainted in this way by stomachic impurities. Vomiting was considered also a result of this antiperistaltic contraction of the fibres of the stomach. Experiments on living animals, however, made this latter point doubtful. Bayle put his finger into the stomach of a dog, after giving him an emetic, and fearfully found the organ move; he observed further, that vomiting was stopped by opening the abdomen, and renewed when the wound was sewed up. chirac found that the stomach moved very feebly, if at all, under the action of an emetic; so that the violent symptoms of vomiting could not be explained from this cause. Other experimenters met with similar results, finding that the irritation of the stomach did not produce vomiting; that very little antiperistaltic motion of the stomach took place, or came on late in the process. Such was the result of Haller's investigations. The action of the respiratory powers was pointed out by Wepfer as the explanation of the phenomena of vomiting: he observed it in different animals, and has expressly referred to the diaphragm and abdominal muscles as the cause of this action, the stomach being nearly in the same position, and the same movements of other inquirers led them to the same result. "If," says Haller, "you observe a man who is sick, you will soon see that the stomach and respiratory muscles are both concerned. The original cause is in the stomach: the nausea, anxiety, feeling of depression approaching to fainting, and taking away all power of exertion, with pale face, small and weak pulse, have their seat in the stomach, and in the nerves affected by sympathy with the stomach. The organs of respiration come into action, and a violent effort or straining in the place, marked by short regular respiration; a deep inspiration, congestion of blood in the head, and pain, redness of the face, heat of the forehead, not unfrequently actual rupture of vesicles, and copious sweat as from the greatest exertion. The effects of vomiting are too violent to be attributed to the stomach: among them we may mention rupture of the oesophagus, protrusion of the stomach through the diaphragm into the chest." (Elem. Physiol. lib. xix. sect. 4. § 14.) To the same effect, Stoemming calls vomiting "motus ventriculi peristalticus inverius, cuius vi, adjuvante eam vehementissima diaphragmatis et musculorum oesophagi, quae contra eam operantur, atque os convulsivo impetu ejiciuntur." De Corp. Hum. Fab. t. vi. p. 169.

The examination of this subject has lately been refuted in France, and an interesting series of experiments, presented to the National Institute, has been published by their author, Mr. Magendie, in order to prove that the stomach is altogether inert in the act of vomiting. When one or two fingers were introduced through an opening in the abdominal parietes, it was found that the stomach did not act in vomiting; but that the diaphragm and abdominal muscles contributed to the act. At each retching, the action of the respiratory muscles could be felt, while the stomach was emptied without any diminution of volume, atmospheric air supplying the place of its rejected contents. When the incision was enlarged, so that the stomach could be brought out through it, vomiting was at an end. The retchings and efforts at vomiting could be renewed by placing the hands so as to compress the stomach. When brought out of the abdomen, and not compressed, it remained quiet, although emetic tartar was injected into the veins. The abdominal muscles being removed, vomiting was still produced by the action of the diaphragm compriing the stomach against the linea alba. If the phrenic nerves were divided so as to render the diaphragm motionless, vomiting could no longer be excited. Lastly, having tied the arteries of the stomach, Mr. Magendie removed it, substituting in its place a pig's bladder, containing a coloured fluid, which he connected to the oesophagus by means of a cannula, then leaved the abdomen, and injected emetic tartar into the veins. In a few minutes nausea was produced, and efforts at vomiting, and the animal actually vomited the contents of the bladder. On opening the abdomen again, it was found, that, on each effort
effort to vomit, air puffed into the bladder as if it had been the stomach itself. The author concludes from these facts, that emetic tartar injected into the veins does not act on the stomach, as is generally believed; but determines a convulsive action of the diaphragm and abdominal muscles. Mémoire sur le Vomissement, 8vo. 1813; or Journal de Corvisart, tom. xxviii. p. 192.

Another inquirer has taken up the same investigation, and has arrived, by experimental inquiry, at conclusions directly contrary to the preceding. After opening the abdomen, and removing the abdominal muscles, he transected a portion of intestine, and thus produced vomiting. When he had divided the phrenic nerves, and constricted the intestine through a small opening in the abdominal parietes, vomiting still took place. It even took place whenever any thing was introduced into the stomach, after cutting the phrenic nerves, dividing the abdominal muscles, and taking away a portion of the diaphragm, as far as the tendinous centre; the intestine was transected, as in the preceding experiments. He produced vomiting by injecting tartar emetic into the veins, after the abdominal muscles and diaphragm had been removed; so that the effect could not arise from any action of the emetic on those muscles, as is asserted by Magendie. These and other experiments in the same essay restore the stomach to the full enjoyment of its former rights, from which it seemed on the eve of being degraded, and go to prove, that the diaphragm and abdominal muscles are not the seat of vomiting. Mem. sur le Vomissement, par M. Maingault. 8vo. 1813; or in Corvisart's Journal, tom. xxviii. p. 193.

As the two experimentalists, whose researches we have just detailed, do directly contradict each other, we suppose that the point cannot be settled without a fresh slaughter of dogs, and a renewal of these truly barbarous and disgusting experiments. Our own opinion inclines to the side of Mr. Magendie, from observing the phenomena of vomiting both in ourselves and others; and the muscular power of the stomach, apparently calculated for the mere purpose of expelling the food through the pylorus, seems to us quite inadequate to account for the vehement and forcible rejection of the stomachic contents in vomiting. Yet we cannot but entertain doubts about the (at first sight certainly) paradoxical statement, of vomiting being excited when the stomach had been removed.

The causes that excite vomiting are numerous and various: Overloading the organ, and particularly with unusual mixtures of food and drink; the introduction of various animal, vegetable, or mineral substances called emetics; warm water, or atmospheric air; the injection of emetics into the veins, or the application of them, at least of arsenic, to a wounded surface; the dragging of the omentum in a hernia, the irritation of a broken rib pressing on it, obstruction in the course of the alimentary canal, &c. inflammation of the stomach, or disease of the pylorus: injuries of the head; calculus passing the ureters; pregnancy; particular motions of the body, as swinging, riding backwards in a carriage, turning round; to this head we may also refer sea-sickness; certain impressions on the organs of sense, as touching or seeing a disgusting object, disagreeable smells or tastes, tickling the fauces, &c. &c.

The causes of vomiting now enumerated are so different from each other, that we cannot expect to find out any circumstance in which they will all agree. Their only common character is the circumstance of their action on this viscus: they irritate it, and vomiting seems to be the common result of such irritation. Is the vomiting produced by an impression terminating in the stomach itself; or does it take place through the medium of the nerves? There are not, we believe, sufficient facts to determine this point.

As the digested aliment supplies the blood, which affords to all parts of the frame the materials of nutrition, growth and action, the right performance of digestion is a matter of the highest importance to the whole body: hence all parts sympathize with the stomach, which, in its turn, is affected by the various states of all other organs. When it is healthy and vigorous, we have a general feeling of strength and capacity for exertion. On the contrary, every faculty of body and mind seems to languish, when the stomach fails, as in dysepsia and nausea. Acute diseases of this vital organ testify its importance by the alarming sympathetic disturbance of the whole economy. A violent blow on it is sometimes immediately fatal. As digestion is ill or well performed, we are more or less sensitive to external heat and cold, to the qualities of food and drink; the fenes are more or less acute, and the passions of the mind affect us more or less easily. The fame morbid causes produce different effects according to the condition of the digestive function: when it is unhealthily executed, wounds, even in the most distant parts of the body, are much more dangerous; and their state will be immediately changed, as soon as healthy digestion returns. The existence of impurities in the stomach, as indicated by a foul tongue, tainted breath, flatulence, &c., during any great purgations, is not frequently attended with delirium and convulsions. In a word, there is hardly a disease, which is not either produced or aggravated by disorder of the stomach, indigestion as it is called.

The fact is so obvious, even to common observation, that the general debilitation and oppression of the frame from a loaded stomach have been described by poets.

At simul aphis
Muscuaria eliza, simul conchilia turdis;
Dulcia de f ilem vertent, stomachoque tumultum
Lenta feret pitiuta. Vide, ut palidus omnis
Cena defurtat dubia? Quin corpus onulitum
Hefternis vitis, animam quoque praevrat una,
Atque a fugit humo divine particulam aure.

No part is more quickly or remarkably influenced than the stomach, in all important general affections of the frame; and the state of this organ affords an important indication in the attack, progress, and decline of the disorder. Sickfulness is an early symptom in most fevers: the appetite is entirely destroyed; its return and increase are the surest criteria of abated disease and convalescence. Hardly can any part be disordered, as the eye, nose, &c., or any internal organ, or a joint, without sympathy of the stomach.

The sympathy between the head and the stomach is seen in the effects of various poisons, which, when introduced into the latter, quickly put an end to senation and voluntary motion (see Poison); in the phenomena of fick head-ache, as it is popularly and properly called (see cephalalgia); in the ataxismus, dilated pupils, itching of the nose, head-ache, paleness, delirium, and even convulsions produced by worms in the stomach; in the palsy and apoplexy produced by a full meal; in the squamae and even sickness caused by seeing or thinking of a disgusting object, &c. &c.

Numerous phenomena evince the influence of the stomach upon the heart: vis. the hurried circulation from eating or drinking strong or warm substances; the intermittent pulse, palpitation of the heart, &c. caused in some individuals by particular articles of food. We see the heart influencing the stomach, when sickfulness attends syncope. The coughing
arising from a loaded stomach, and even called the stomach cough, or from a wound of the stomach, and the effects of emetics in dittrefs of breathing, together with analogous occurrences, exemplify the mutual influence of the stomach and lungs. In hiccough, the diaphragm is influenced by the stomach, sicknees attends inflammation of the kidney, and the passage of calculi through the ureters. How powerfully the uterus acts on the stomach, is seen in the nausea, sicknees, heartburn, and depraved appetite attending pregnancy. The state of the skin in dyspepsia and other stomachic affections, and the numerous cutaneous diseaues, either caused or aggravated by disturbed digestion, clearly shew us the great mutual influence of these parts.

Respecting the circumstances which attend the introduction of poisons into the stomach, and the manner in which they prove fatal, we refer the reader to the article Poison.

STOMACH. Diseaues of the. The principal diseases to which the stomach is liable, are, inflammation; the various modifications of dyspepsia, or indigestion; and some chronic changes of its structure, which are not readily influenced by physical remedies. The two former classes of these maladies have been treated of at considerable length under their respective heads, to which we refer the reader. The acute inflammation of the stomach is described under its nosological term Gastritis: and the varieties of Indigestion are detailed under that head; and more particular explanations of certain modifications or symptoms of it, under the heads Cardialgia, Hematemesis, Gastrodynia, Nauka, Pyrosis, &c. It remains in this place only to notice those chronic diseases of structure in the stomach, which could not be included under these heads, and which are not capable of being much relieved by art. The nature of these is chiefly ascertained by an examination of the organ after death.

Both the apertures of the stomach are liable to be contracted, or to be the seat of friction, as it is technically called, under which condition suffering is produced. A friction of the cardiac, or upper aperture of the stomach, may be distinguished, according to Dr. Pemberton, from all other diseases of that organ, or of the neighbouring parts, by the production of pain on any attempt to swallow solid food. This pain has something peculiar in its nature, and is describ'd by the patient as very different from what is generally underfo'd by the word pain. It is a fort of tender, circumfered sensation about the pit of the stomach, striking through to the back, and producing a feeling of incipient suffocation. This continues till the food is rejected, which is done by an effort very unlike vomiting. It seems to approach nearer to that effort which occurs hiccough. After this rejection of the food, the patient obtains relief. In consequence of the inability to pass a sufficient quantity of nourishment through the contracted passage into the stomach, the body becomes very much emaciated, often to such a degree, that a tumour surrounding the cardiac may be discovered by a careful investigation in the region of the stomach.

A much common situation of friction is in the lower aperture of the stomach, leading into the intestines, which is called the pylorus: this, however, fortunately, is also a rare disease. Dr. Baillie mentions one case, which fell under his observation, in which the friction was so great as hardly to admit a common goose-quill to pass from the stomach into the duodenum, and it had prevented a number of plumstones from passing, which were therefore detained in the stomach: and he supposes that the passage may in some cases be entirely shut up. This friction occurring in the pylorus may be distinguished from friction of the cardiac, by the food readily passing into the stomach without exciting pain; and when it is thrown up it is by vomiting, and not by the peculiar effort before mentioned, when speaking of friction of the cardia. After the friction of the pylorus has continued some time, the body generally becomes much emaciated, as but little nourishment can pass into the intestines to be taken up by the labets, and the tumour, as in the former case, can then be discovered by examination of the abdomen. Pemberton: on Dif. of Abdom. Viucera, chap. vii.

Ulcers of the stomach occasionally occur, and have been described by Dr. Baillie as sometimes resembling common ulcers in any other part of the body, but frequently having a peculiar appearance. Many of them are scarcely surrounded by any inflammation, nor have they irregular eroded edges, such as ulcers have generally, nor are they attended with any particular diseased alteration in the structure of the stomach surrounding them. They appear very much as if, some little time before, a part had been cut out from the stomach with a knife, and the edges had healed, so as to present an uniform smooth boundary round the excavation which had been made. These ulcers sometimes destroy only a portion of the inner coat of the stomach at some one part; but occasionally they destroy a portion of all the coats, forming a hole in the stomach. It is probable that these ulcers of the stomach are often slow in their progress. They are attended with a slowly growing, uneasily feeling in the organ, and what is swallowed is often rejected by vomiting. This state of disorder often continues for a considerable length of time, and is little relieved by medicine, which may serve as some ground of distinction between this disease and a temporary deranged action of the stomach. Baillie's Morbid Anatomy, chap. vii.

Schirrus and cancer of the stomach are not uncommon affections at an advanced period of life. They appear to be more frequent in men than in women, which Dr. Baillie supposes may arise from the greater intemperance of the one sex than of the other. He admits, however, that these diseases are not entirely produced by intemperance, but only where intemperance concurs with a strong predisposition to them. It is surprizing to find the very extensive mischief which the structure of the stomach has in some instances undergone without the constitution being sensibly affected by it, provided the mischief is so situated as not to interrupt the passage of the food. Dr. Pemberton mentions that he has seen a large schirrus in the stomach, near the pylorus, with an open cancer in one part of it, which had made its way through the stomach, and then the left lobe of the liver; and an adhesion had taken place between the sides of the abdomen and the peritoneum: so that had not the patient been carried off by a disease in the aorta, it was probable that this adhesion would have made its way out through the intestines of the abdomen. Still, however, though this must have been a disease of very long standing, the body was but little emaciated, and the patient had never thrown any one symptom, by which such a disease of the stomach could possibly have been suspected. The writer of this article witnessed the existence of a solid, extensive, cancerous condition of the interior coat of the stomach, in which many large tubercles were found in a state of ulceration, in an elderly man, who, however, was not much emaciated, and who had never exhibited any more feverish symptoms, than those of slight indigestion, and, therefore, none that could lead to a suspicion of such an extensive and formidable disease. In general, however, when the schirrus has ulcerated, and formed what is called open cancer, there is a constant pain, though varying in degree, and which is increased by taking
taking any acid or acidulance into the stomach; whereas mild fluids, such as milk, gruel, &c. occasion little or no uneasiness. What is swallowed, in many cases, is often rejected by vomiting, and there is frequently thrown up also a dark-coloured fluid, which has sometimes been compared to coffee-ground. There is often an emaciation also of very fetid air. The patient commonly becomes emaciated, and the countenance falls; and the pulse is frequent, and hectic symptoms at length ensue.

The origin of the stomach, as ascertained by dissection, after death has terminated the course of the disease, is described by Dr. Baillie. "When the whole stomach, or a portion of it, is chichorous, it is much thicker than usual, as well as much harder. When the diseased part is cut into, the original structure of the stomach is frequently marked with sufficient distinctness, but very much altered from the natural appearance. The peritoneal covering of the stomach is many times thicker than it ought to be, and has almost a gritty hardness. The muscular part is also very much thickened, and is interlaced by many pretty strong muscle-tracts. The fleshy membrane is probably nothing else than the cellular membrane intervening between the falciculi of the muscular fibres, thickened from diseaze. The inner membrane is also extremely thick and hard, and not unfrequently somewhat tuberculated towards the cavity of the stomach. It very frequently happens that this thickened mals is ulcerated upon its surface, and then a stomach is said to be cancerous." Morbid Anatomy, loc. cit.

With respect to the treatment of these structural changes, little can be said; for, in truth, it must not be concealed, that secondary relief is all that can be expected under diseazes so deplorable. No physical means that we possess can change the morbid growth into healthy structure, or induce new actions. All that can be done, is to allay the pains of the patient, by administering gentle narcotics, such as eicantia and hyoscymus, and by employing a milk diet, or other soothing liquid and liquid food.

STOMACH of Birds. See Anatomy of Birds, and Digestion.

STOMACH of Fish. See Fish.

STOMACH of Flies. In examining with care the bodies of these little animals, one may perceive, that when the passage of the aliment is got beyond the lungs, and below the place where they form a port of diaphragm, the canal that served for this passage forms a large though short body, the diameter of which exceeds three or four times that of the canel itself. This body is composed of three chief lobes, and is unquestionably the stomach of the animal. The intestine goes out of it, very nearly from the same part where the other passage is admitted into it; the intestine then directs itself toward the anus, and afterward runs upward again toward the diaphragm, or bottom of the lungs; and thence, after many convolutions, many times running backward and forward, it terminates in the anus.

In caterpillars and butterflies, the canal from the mouth to the anus is only one straight intestine; but it is much otherwise in these creatures, the intestines, both in the fly, and in the worm from which it is produced, always making a number of contortions and convolutions.

STOMACH-Bugs. See EXUVIA Pntriculari.

STOMACH-Illy, in Rural Economy, a term sometimes applied to a disease in sheep that strikes them suddenly, which is probably of the braxy kind, and in which there is much pain and inflammation about the stomach. Infant bleeding is supposed to be the chief remedy. See Striking-Illy, or Blood.

STOMACHIC, Elixir stomachic, a medicine that strengthens the stomach, and promotes the office of digestion.

Of this kind are wormwood, rhubarb, mint, mastic, aloes, pepper, cinnamon, and aromatic bitters; good wine is also a stomachic.

STOMACHIC, in Anatomy, a name sometimes given to the arteries, nerves, &c. of the stomach.

STOMACHIC Coronary. See CORONARY.

STOMACHIC Elixir. See Elixir stomachic.

STOMACHIC Pills. See PILL.

STOMACHIC Water. See WATER.

STOMACHICA Ferris, the stomachic fever, a name given by Heister, and some others, to a species of fever, called by others a mesentric fever, and by our Sydenham nova fersis, in a peculiar treatise. See FEVER.

STOMATIA, in Natural History, the name of a genus of shell-fish, frequently confounded with the ear-shell.

The shell of the stomatia is formed of one piece, has no perforations in any part of its surface, and is of a depressed flat figure; and its mouth is the most patent of all the univalve shells, the limpet only excepted. It has a short spiral turn running into the mouth at the head.

There are several species of this genus.

STOMATICA, a term used by some for all medicines used in disorders of the mouth.

STOMBLE, in Agriculture, provincially a term which signifies to trample or pounce, as a wet foil by means of cattle flock, or in the time of ploughing, &c.

STOMOXYs, in Entymology, a genus of insects of the order Diptera: the generic character is: Sucker with a single-valved sheath, enclosing bristles in their proper sheaths; two feelers which are short and fetidaceous, with five articulations; the antennæ are fetidaceous. There are sixteen species, in two divisions.

Species.

A. Sheath convolute and geniculate at the Base, with two Bristles.

Morio. Black; fore-part of the thorax hairy, ferruginous; wings black, with white spots. This is found in Brazil. A specimen of it exists in the museum of Sir J. Banks. The head is ferruginous, with black proboscis, anten na, and femmata; abdomen black, with a blue gloss; the tips of the wings are whitish.

Grisca. The antennæ of this species are feathered; hairy, grey, with fetidaceous thigs. It is found in Germany. The proboscis is black, a little fetidaceous at the base; the head is white, with a fetidaceous line on the front; the wings are whitish; the legs black, with rufous thiggs.

Sibipita. Antennæ feathered; hairy, grey; sides of the abdomen pale diaphanous. It inhabits Germany. Orbits snowy; legs black, with pale thiggs.

* Calicitrans. Antennæ slightly feathered; grey, with black legs. This very much resembles the common fly, and is the insect which buzzes about the legs of cattle, making them continually flump with the feet; and which stings our legs in autumn.

Tessellata. Hairy, cinereous; abdomen grey, teffellate with brown. It inhabits Kiel, and is larger than the Sibirita; next to be described.

* Irritans. Cinereous, slightly hairy; abdomen spotted with black. This is found in many parts of Europe, as well as in our own country, and is extremely troublesome on the backs of cattle.

Muscaria. Antennæ slightly feathered; hairy, black; abdomen paler, with deep black bands. This is found in Denmark.
Danmark. The segments of the abdomen are black at the base; the wings are white.

Fugitiva. Cineous, with black 'thighs.' It is found in diverse parts of Europe, and harasses cattle, though it is of a diminutive size. The body is slightly hairy; the wings whitish.

Asiliformis. Antennae fuscaceae; the body is dusky; wings with black marginal spots. This is found in Italy. The sucker is short and yellow; the antennae are yellow, with a long fimbria hair; the legs are yellowish, hind-thighs black.

Stylata. Cineous; abdomen rufous, with a projecting style, black at the end; wings hyaline, with fine brown bands; every other one abbreviated. This inhabits Barbary.

Dorsalis. Black; abdomen fuscous on the back, with three pair of black dots. It inhabits France, and is small.

Longoce. Orbits white; thorax grey; abdomen grey-brown; legs ferruginous, black at the ends.

B. Sheads covering the Mouth, with free Bristles.

Rostrata. Thorax with obscure lines; proboscis, abdomen, and legs, asiform. It resembles the common fly, and is very troublesome to cattle.

Musciiformis. Thorax brown, with four whitish lines; abdomen black, with three pair of white lunules. This is also found in Germany. The proboscis is yellow, the tip emarginate and black.

Musciformis. Thorax brown, with four whitish lines; abdomen black, with three pair of white lunules. This is also found in Germany. The antennae are black, with a broad compressed ferruginous club; the mouth is hairy; the head is brown; the tail is blueish; legs yellow, spotted with black.

Stondle, in Rural Economy, the provincial name of a bearing tub, or any similar sort of vessel of the same kind.

Stone, Edmund, in Biography, a native of Scotland, the place and time of his birth being unknown, and an excellent mathematician. He was the son of the duke of Argyle's gardener, and probably born in the thire of Argyle, about the beginning of the laft or end of the preceding century. He was eight years old when he began to read, but afterwards he made very rapid progress by his own almoft unrivalled efforts. Before he attained the age of eighteen years, he had acquired a knowledge of the sciences in Latin, Greek, and Hebrew, and was proficient in the study of mathematics. He was of an acute and studious turn, and his mind was particularly directed to the improvement of his understanding. He was a diligent and indefatigable student, and his application to learning was unceasing.

The principal works of Stone were the following: "A New Mathematical Dictionary," first printed in 1726, 8vo; and "A Treatise on Fluxions," 1730, 8vo; the direct method being translated from the marquis de l'Hospital's "Analyse des Infiniments Petits," and the inverese method supplied by Stone himself; "The Elements of Euclid," 1732, 2 vols. 8vo., with an account of the life and writings of Euclid; besides some smaller works. Stone was a fellow of the Royal Society; and communicated to it an account of two species of lines of the third order, not mentioned by Sir I. Newton or Mr. Stirling, which was printed in the 41st volume of the Phil. Trans. Hutton's Math. Dict.

Stone, Henry, known by the name of Old Stone, to distinguish him from his younger brother John, was the son of N. Stone, a stationer. He is principally known as the copyist of many poetical works of Vertue, and they are exceedingly close in their resemblance to the originals. He passed several years in Holland, France, and Italy; but died in London in 1653.

Stone, in Geography, a market-town in the hundred of Pirehill, and county of Stafford, England, is 141 miles N.W. of London, 7 from the county town, and 34 from Birmingham. In the year 1811, this parish contained 463 houses, and 2314 inhabitants. At a remote time, Stone was distinguished by some monastic foundations. Wulfere, king of the Mercians, after lying at Grantham, was removed by the persuasion of his queen and St. Chad, to embrace the Christian faith, and founded a monastery, in 670, at this place, in expiation of his crimes. This became a college of regular canons of the order of St. Augustine. His queen, Ermesilda, next established a nunnery here; but both these houses were injured, and the inmates dispersed, by the Danes. After the Norman conquest, the college and nunnery were replenished with monks and nuns; at least it seems evident that Enfyan, a Norman, brought canons from Kenelworth, and made the establishment at Stone a more eminently collegiate house at Kenelworth, by the archbishop of Cant Pyne, about the year 1260, rendered the former independent of the latter. Several perfections of the Stafford family were interred in the church at this place, to whom some fine and curious tombs were reared; but these were removed, at the dissolution of the priory, to the church of the Augustines at Stafford-Green. A new church has been erected on the site of the old structure.

Stone consists mostly of one long street, in which is a newly formed market-place. In the town is a free-school, and an endowed grammar-school. There are a weekly market on Tuesday, and three annual fairs. By means of the Trent and Mersey canal, which comes to this place, there is regular and cheap communication with many of the great manufacturing and commercial towns of Lancashire, Staffordshire, Warwickshire, and more distant counties.

Near Stone, lord Archibald Hamilton, in the year 1773, built an elegant house, called Sandoon-Hall. This was formerly the property of the Erdfwick family, one of whom, Sampson Erdfwick, was authorized a topographical account of this county; and lies interred in the church of Sandon. Statues of himself and his two wives constitute parts of the monument, on which is a long and curious Latin inscription. He was born in this village in the middle of the sixteenth century, and died here April 1609. See Fuller's Worthies of England. Alco Chalmers's Biographical Dictionary.

In the vicinity of Stone was Afton-Hall, an ancient and magnificent mansion, surrounded by a moat, terraces, gardens, and a park. A large manufactory was erected in the gardens at this place by Sir James Simeon, who also rebuilt the house. The property now belongs to Edward Weld, Esq. of Lulworth castle, in Dorsetshire—Beauties of England.
STONE.

&c. vol. xiii. from Shaw's History, &c. of Staffordshire; and Penant's Journey from Chester to London, 8vo. 1811.

Stone, in Natural History and the Arts, is an inerated mass of earth. The solid parts of the globe are principally composed of stones, formed of the different earths more or less combined with each other, and in different states of induration. The physical and chemical properties of stones fall properly under the investigation of geology, yet the mineralogist, too, must study the order in which they are arranged over each other in the great sandy mists that compose rocks and strata, constitutes a part of the science denominated geology.

The ingenuity and industry of modern naturalists have led them to form a variety of systems in the arrangement of fossils in general, and of stones in particular; some of the principal of these may not be improper to enumerate. Some have founded the basis of their system on the figure, colour, structure, and other external and visible characters; calling in the aid of chemistry, so far at least as the mineral acids would affum it. Others, as the prospected chemists and metallurgists, have established their arrangement chiefly on chemical principles, as more immediately leading to the origin of fossil bodies in general. And, at present, mineralogists seem more intent on this view than ever, and probably the due consideration of the volcanic system will open new sources of information in this way.

With respect to the systematic arrangement of stones, Breconius, in 1730, distinguishes them into such as are permanent in the fire, such as the lapis calcarius, amiantus, albitubs, and fuscors; calcinable, such as the calcareous, flint, marmor, gyptum,spathum, flatacites, fissional, and specilais; and those that are vitrifiable in the fire, such as the arearia, arenarium, gemma, granatus, file, quartum, crytallus, and fluor. The other fossil bodies he ranges under the several classes of earths, salts, sulphurs, figured stones, petrifactions, calculi, semi-metals, and metals.

Wallenius, in 1747, divides stones into calcareous, as the calcareus, marmor, gyptum, and spatum; the vitrecis, as effliss, cos, files, petrufiles, quartzum, and crytallus; the argillaceus, as mica, amiantus, and albitubs; and sana, or rocky stones, as the amfite, mixtas, grites, and petrosa. The other bodies pertaining to the fossil kingdom, he classes under the general heads of earths, lean, fat, mineral, and arenaeous; minerals, sulphurs, semi-metals, metals, concrete subfiances, such as the pori, petrificationed, figured stones, and calculi.

Wolterdof, in 1748, divides stones into the vitrecis, as gemma, crytallus, quartzum, arenarium, cornes, koptum vitrecs, fens, and pumex; the argillaceus, as the amfites, albitubs, alcalium, and spatum crytallum, and the albitubs, as the calcareus, marmor, spatum alcalium, tophus, flatacites, and margodes. The other fossil subfiances he divides under the titles of earths, argillaceous and alkaline; salts, acid, alkaline, and mean; bitumen, fluid and solid; semi-metals, fluid and solid; metals, noble and ignoble; and petrifactions of fanguous animals, of insects, of tectaneous animals, of vegetables, and of marine bodies.

Carthusian, in 1755, distinguishes stones into the lamellos, as spatum, mica, and talcum; lamasommum, as amiantus, albitubs, and alcalium; fuscors, as files, quartzum, calcarus, guypus, fissional, and specilais; and cemented, as arenaeous and jalis. The other fossil bodies he classes under earths convertible and insoluble; salts, alkaline, acid, mean, and flypic; inflammables, both genuine and spurious; semi-metals, not malleable, sub-malleable, and fluid; metals, flexible, hard, and fixed; and heteromorphs, including the true and spurious petrifications, and the figured subfiances.

Jofi in 1757, distinguishes terraneous bodies into the noble, as the adamas, sapphire, smaragdus, amethystus, topazius, turcois, opalus, cryolitius, and hyacinthus; the semi-noble, as crystallus, cameo, chalcedonius, cryolithus, sardionus, malachites, and lazuli; opres ignobilis, as talcum, mica, molybdens, vitrum molochium, stelaiitis, cornes, jalis, and albitubs; calcareus, as marmor, gyptum, and spatum; and vitrecis, as cos, quartzum, files, chifus, serpentinus, tripomex, granites, fissional, argillae, margus, limus, and umbra. The other fossil bodies rank under the heads of metals, noble and ignoble; semi-metals, fluid, hard, and mineralized; salts, acid, alkaline, and mean; and petrifactioned animals, plants, obscurum, and figured, and crystall.

Cronstedt, in 1758, arranges fossils under the classes of earths, calcareous, silicious, granate, argillaceous, micaeous, fluent, albitubs, zeolitic, and magnetian; salts, acid and alkaline; philogonic bodies; and metals, perfect and semi-metals.

Vogel, in 1762, distinguishes stones into the argillaceous, calcareous, margeuseous, felentic, pyromacous, fchibous, folious, plumous, saline, metallic, fusile, petrae or rocky, and new; and the other fossils under the earths, argillaceous, calcareous, silicious, margeuseous, felentic, talcous, micaeous, inflammable, saline, metallic, and mould; petrifactions of animals, plants, lithophyous, lithomomous, and pori: salts, flupetic, fusile, such as are capable of being hardened, volatile, and alkaline; combustibles, as sulphureous, bituminous, fervum, and balans; and metals, perfect and semi-metals.

Next, in his " Lithogeognosia," distinguishes stones into calcareous, gypsumous, argillaceous, and aprous.

It has been doubted by some of the most respectable mineralogists, whether we ought to defend below what are called general distinctions in the fossil kingdom, because the subjects are infinitely various, and the gradation by which they run into each other is in general imperceptible in the various combined forms in which they are found in the earth. Nevertheless, some distinctions of this kind seem to be quite necessary in systems established principally on external characters.

Linnaeus and Wallerius have been among the first who attempted the arduous task of fixing the specific characters. For this purpose, Linnaeus has formed a set of terms that express all distinctions in the figures of fossil bodies, in their crust or outward appearance, their superficials, their corresponding particles or fibres, in their texture, whether plated, figial, &c. in their hardness, or in their colour, and in the alterations they undergo by solution, both by acids and by fire.

The chemical systematics and metallurgists, in their arrangements, usually begin with the earths, concerning them as the basis of stones: Linnaeus begins with the latter, professing to take a middle way between the mere metallurgists, and those who characterize from external appearance only.

He divides the whole regnum lapidum into three classes, under the names of petra, minera, and fossilia, each being subdivided into several orders, and comprehending in the whole fifty-four genera.

To the first class belong petra, or stones, which he defines to be fossil bodies, originating from a terrestrial principle by external pressure; these are simple, as in their composition they are destitute of saline, inflammable, and metallic principles; they are fixed, not as being entirely and intimately soluble in any menstruam; similar, as they confound of homogeneous component parts. Of these there are five orders; viz.,

1. The hemce, or flaty stones, which originate from vegetable earth, are combustible, and leave goshs light ashes. Under this order there is one genus, viz., the fchifus, or fclay,
STONE.

flate, including thirteen species, among which the most distinguished are the table-flate, black flate, blue house-flate, and black crayon.

2. The calcareae, or calcareous flones, which originate from calcareous marine animal bodies, become light and porous in the fire, and fall into an impalpable powder, and effervesce, and are soluble in acids, unless they are previously saturated with an acid, as the gypsum. This order comprehends four genera, viz. marble, of which there are fifteen species, such as the black flaty marble, the Parian marble, and all its varieties; the Florentine marble, the white grain lime-flone, the faly lime-flone, &c.; gypsum, or platter-flone, of which there are three species, such as the common plaster, alabaster, &c.; flint, or fibrous alabaster, including four species, as the fibrous gypsum, or English talc, &c.; and jasper, or spar, of which there are fourteen species, some soluble in aqua fortis, as the soft spar, refracting spar, or illand crystal, subdiaphanous compacta spar of different colours, pellucid coloured spar, as foplar topaz, emerald, and faphire, &c.; and some not soluble in aqua fortis, as the fossil spar.

3. The argillaceae, or argilaceous flones, which originate from the silicified sediment of the sea, are somewhat unctuous to the touch, and hardened in the fire. To this order belong three genera, viz. talcum, or foap-earth, including twelve species, as the ruddle, fialith, or French chalk, or foap-earth, fapent-flone, and hornblende, &c.; amathus, or earth-flax, of which there are ten species, as the asbestus, plumeof asbestus, mountain cork, and aluta, or mountain leather, &c.; and mica, or talc, of which there are ten species, as Mufcoy glass, gold glimmer, and green talc, &c.

4. The arenite, or sand-flones, which originate from the precipitation of rain-water, are extremely hard, strike fire with ease, and by trituration, yield a very rough powder. This order comprehends three genera, viz. the cos, or whetstone, of which there are seven species, as the gronite, filtering-flone, mill-flone, building-flone, &c.; the quarts, including eight species, as the pellucid rock quartz, coloured rock quartz, red, blue, yellow, &c. milky quartz, granulated quartz, pebble quartz, &c.; and the fleas, or Flint, of which there are sixteen species, some being vague or loose flints, as the common flint, gun-flint, Egyptian pebble or Mocoa-flone, opal, onyx, or cameo, chalcedony, cornelian, &c.; and some being rock-flints, as the agate, petroflex or chert, jasper, &c.

5. The argilaceous rock or compound flones, which originate from a mixture of the four preceding orders variously conglutinated; the interfaces, usually filled up with quartz, spar, or glimmer. Of this order there is only one genus, viz. the saxum, or rock-flone, including thirty-nine species, as the porphyry of different colours, the trapassum, or trap-flone, the granite, the fubrum, or founder's-flone, the filicinium, or pudding-flone, &c.

The second class of fossil bodies are the minere, or minerals, which Linnaeus defines to be fossil bodies originating from a saline principle by crystallization; they are command, as consisting of a base, united with saline, inflammable, or metallic principles; and they are soluble, perfectly, in an appropriate menstruum; of these there are three orders, viz.

1. Salis, salts, or crystals, which are rapid bodies soluble in water; distinguished from each other by their different effects on the organs of taste: under this order there are six genera, viz. nitre, of which there are nine species, as the salin, or native salt-petre; the quartzofe, or mountain crystal; fluor, or coloured crystal, from the varieties of which are the true byacinth, the fale topaz, ruby, emathyb, sapphire, beryl, and emerald; and the calcareous, as the hexagonal truncated spars, the fulillum, or sparry fine-flone, &c.; natron, including fourteen species, as the salin, or native mineral alkali, sapphireum, and Epsom salt; the lapidofe, or spatofe, decadedrous natron, the gyppic, pellucid, fuliform natron, the feltenis, or rhombic natron, the byodon, or pyramidal, or dog-tooth spars, &c.; borax, of which there are six species, as the saline, or tincal, or native borax; the lapidofe, to which belongs the gemma nobilis, or lapidofe, prismatic, pellucid borax, with truncated pyramids, and as varieties of this species, the yellow or topaz, the pale green or chrysolite, the sea-green or beryl, and the deep green or emerald, the bafatines, the tournaisin, the garnet, and the margodes, or opaque, argilaceous, tessellated borax; the maris, or sea-flate, of which there are nine species, as the salin, or sea-flate, fountain, and hot-bath salt; the lapidofe, or Bononian flone, sparry fluor, or Derbyshire spar, &c.; aluïm, or alum, including fix species, as the native, or native alum, plumofe, &c.; soluble, or auum-flone, flone-alum, or calcareous alum-flone, called Roman alun; and lapidofe, to which belong the lapatofe alun, or siala amethysty, the gemma, pretiosa, or diamond, ruby, and sapphire, &c.; vitriolium, or vitriol, of which there are eight species, as the simple, or thole of iron, of copper, and of zinc; the compound, or picro-vitril, or vitriol, of which there are ten species, as the chalybeate, or iron vitriol, or vitriol, &c.; and the lapidofe or spatofe vitriol of zinc.

2. Sulphurae, or inflammable bodies, flaming and odorous when burning; soluble in oil, and distinguished from each other by their different effects on the organs of smell; of this order there are five genera, viz. ambra, or ambergris, including two species, as the grey and the brown; fucillum, or amber, of which there is one species, as the electric amber, and the varieties of diaphanous, opaque, yellow, brown, and that which includes infusions; bitumen, of which there are ten species, as the naphtha, petroleum, or rock-oil, maltha, or Jews' pitch, mumin, or feum minerals, alphaltum, or fossil pitch, ampelette, or peat, lithanthrax, or common coal, or schilfofe bitumen, gaggas, or jet, fulillum, or calcareous fetid bitumen, of which there are the varieties of compact, granulated, squamofe, and crystalline, and the hepaticum, or liver bitumen; pyrites, or sulphurs, including seven species, as native sulphur, opirniment, crystallized pyrites, or marcasite, figured pyrites, iron pyrites, copper pyrites, of which there are four species, as the dark aquline, and liver-coloured pyrites; and arsenes, comprehending eight species, as the solid tenebricus, or arsenic, the fandarcha, or red arsenic, mineralized with sulphur; the arsenical marcasite, the arsenicum albicans, or arsenic mineralized with iron, &c.

3. Metallae, or metals, which are shining heavy bodies, fubbish in the fire, and soluble in appropriated acid menstrua; distinguished from each other by inspection: of this order there are two subdivisions, into semi-metals not malleable, and metals malleable. The first subdivision includes two genera, viz. hydargyrum, or mercury, of which there are five species, as virgin, or native quicksilver, cubic crystallized quicksilver, cinabarin, with the varieties of lamellated, granulated, and crystallized, and pyrrhicol, cuprosus, stone mercury, &c.; molycidanum, or wad, or black-lead, of which there are three species, as plumago, or black-lead, or wad, or sulphur faturated with iron and tin, manganasia, or black manganese, and fopma lupi, or red manganese, or wolram; fibrum, or antimony, of which there are four species, such as native regulus of antimony, crystallized fibrum, fibrous, lapidofe, or common antimony, and red antimony; mineralized with fulillum, or arsenic; of which there are eight species, as crystallized zinc, that mineralized with sulphur.
STONE.

Sulphur and lead, or iron, that mineralized with sulphuretted iron, fibroze zinc, calcamine, or stone zinc, or zinc mixed with martial ochre, blind or mock-lead, or black jack, or semi-tuffellated black zinc, and red zinc, or micaceous liver-coloured zinc: *bijmuum*, or bismuth, of which there are four species, as native bismuth, common bismuth, mineralized with sulphur and arsenic, mural, bismuth, and bismuth mineralized with sulphur only: and *cobalt*, of which there are four species, as crystallized cobalt with sulphur, arsenic, and cobalt mineralized with arsenic and iron, pyritico cobalt and flag-cobalt.

The second subdivision comprehends malleable metals, and of these there are fix genera, *vix. flammum*, or tin, including four species, as crystallized tin or tin-grains, tin-boat, *flatace*, or tin, of which there are ten species, as native lead, cubic lead crystallized, cubic lead mineralized with sulphuretted silver, or galena, filiated lead-ore, greenish arcanical lead-ore, sparry arcanical lead-ore, &c.: *ferrum*, or iron, including twenty-seven species, as native iron, in grains, crystallized iron, such as obey the magnet, to which is added the denomination by part: another iron-ore, fine-grained iron-ore, common iron-ore, pyritico iron-ore, talcy iron-ore, calcareous iron-ore, emery, &c.: such as do not obey the magnet, of which there are red micaceous iron-ore, blood-iron, red blood-iron, spars-like iron-ore, &c. for the magnetic, or the magnet: *copper*, or copper, of which there are sixteen species, as copper precipitated upon iron, native copper, crystallized octahedral copper, pyritico yellowish-green copper-ore, pyritico purple copper-ore, soft pyritico grey copper-ore, footy, pyritico arcanical copper-ore, white arcanical, pyritico copper-ore, indurated ochreous red copper-ore, which is sometimes liver-coloured; sandy ochreous copper-boat, green and blue copper-boat, lapis lazuli, lapis armenius, or blue calcareous copper-boat, malachite, or green gyphoeus copper-boat, nickel, or copper mineralized with sulphur, arsenic, and iron, &c.: *argentum*, or silver, of which there are nine species, as native silver in various forms, horn silver-ore thinning, submalleable, and somewhat diaphanous, mineralized with sulphur and arsenic, glass silver-ore, or lead-coloured malleable silver-ore, mineralized with sulphur, red silver-ore mineralized with sulphur and arsenic, white silver-ore mineralized with arsenic, copper, and sulphur, grey silver-ore mineralized with sulphur, antimony, copper, and iron, silver-ore mineralized with arsenic and iron, silver-ore mineralized with sulphur and zinc, and footy silver-ore mineralized with arsenic and copper; and *aurum*, or gold, of which there are two species, as native gold, found in various forms, as in thin plates or leaves, solid, or in thick pieces, and a crystalline form; it is also found imbedded in quartz, talc, and sinnabar, and in rivers in loose grains and lumps, called gold-dust; and mineralized pyritic gold-ore.

The third clafs are fossils, which are bodies originating from different modifications of the subject comprehended in the preceding classes: of these there are three orders, *vix.*

1. *Petrificador*, or such fossil bodies as represent in figure certain animals or vegetables, or parts of them. The true petrifications are such as have the texture and organic parts of the bodies entirely filled up with fowy paricles, either of a calcareous or flinty, and sometimes marcellific nature: there are others in which the bodies are preferred and unaltered, as having left only the animal gluten: others, again, are only bodies incrusted with flatace, or calcareous matter: and frequently they are only impressions received in their soft state. Of this order there are eight genera, *vix. zeolitites*, or the petrifications of mammalies, including four species, as bones of men, remains of the rein-deer, foal, ivory, and turquois, or teeth jointed by copper: *orniticolites*, or petrifications of birds, in whole or in part, and of their nests, of which the first species are scarce, and are usually alacritical incrustations: *amphibolites*, or petrifications of amphibias, of which there are fix species, as of an entire tortoise, of a toad, of the skeleton of a crocodile, of an entire serpent, of various nates, as of the rana, bull-fish, &c., and glosseopes, or shark's teeth: *sibbolidites*, or petrifications of fishes, including three species, as those of entire skeletons, with the fins in state, and in marble, and the bufonites, or grinding teeth of the wolf-fish: *entomo-olites*, or petrifications of insects, including three species, as the cancri or petrified crab, lobster, &c. paradoxus, or unknown insect, petrified, and insecta inclosed in amber, which indeed are not proper petrifications: *belminolites*, or petrifications of worms, including twenty-four species, as the corn ammonis, orthcocerates, or straight nautilus; ano- nites, as the various anoma, gryphites, or crown-foam; Jew's *flatace*, supposed to be spines of echinites, madreporas of various kinds, entrochus, flata-foones, sleemantes, &c.; *physolites*, or petrifications of plants, of which there are seven species, as of the entire plant in coal-flate, of ferns in state, of roots in marble, of wood in various flates, as of lime- stone, agate, flint, sand-foone, and state; of leaves in state and marble, of flowers in state, and of fruits in coal first, commonly cones of the pise, nuts, acorns, &c.: *grapto- lites*, or foones resembling pictures, including eight species, among which are Florentine marble or flate, resembling ruins; dendrites, representing woods, landscapes, &c. arising from vitrioic solutions inflatuated between the plates of fittle foones, or in marble.

2. *Concreta*, which are flight conglutinations of different kinds of earths, whose specific differences arise principally from the nature of the component parts: of this order there are fix genera, *vix. calculi*, or animal concritions, including eight species, as the flone in the kidney, or bladder: tartar of the teeth, of the lungs; *bezoar-foone*, formed in the abomasus, or fourth stomach of ruminating animals; *tophite*, or impurities of various kinds, formed in the heart-foone, the bones, pearls, and crab's eyes: *tartari*, of vegetable concritions, of which there are two species, as yeal, and red and white tartar: *setites*, or concritions within the cavity of foones, of which there are the true, having a loose nucleus, as the geodes with an earthy nucleus, and the aquilines with a flomy nucleus; and the spurious, as the haemachates, or flinty setites, with a fixed crystalline nucleus, marble *setites*, including dog-tooth spar, and echinated setites, including fluor crystals: *pumice*, or concreitions by means of fire, including eight species, such as black flatte pumice, white pumice of iron-furnaces, red copper pumice, foot, ashes of volcanoes, Rhenish mill-foone, vitreous pumice, or black and green Iceland agate, &c.: *flataceites*, or concritions by means of air, including twelve species, as vegetable incrustations, drop-foone, solid and branched marmoreous flatace, solid flatace, red flatace, zeolite, &c.: and *topbus*, or concreitions in water, including twenty-two species, of which there are the metallic tophes, as the marly toph-foone, the tubular, merry, ochaceous topbus-foone, the sandy ochaceous fes topbus-foone, the brown iron-ore in various forms, &c.; and the simple tophes, as alum toph, concritions of tea-kettles, pea-foone of hot springs, oesocolla, or bone-binder, solid black schisto toph, &c.

3. *Terra*, or earths, which are fossile substances not conglutinated, but usually in a slightly cohering or pulverized state;
STONE.

State: of this order there are five genera, viz. ochra, or ochres, or earths of metals, of which there are fifteen species, some in the form of powder, as ochre of iron, green and blue ochres of copper, native ceras, ochre of cobalt, &c.; and others plumocele, or germinating ochres, as copper blue, or plumocele copper, flowers of antimony, plumocele bismuth, with sulphureted antimony and arsenic. &c. : areno, or sands, including fourteen species, as sea-fand, coloured sands, sand of heaths, fabulum, or common sand, micaceous, or glittering or writing sand; gold, iron, and frit sand, &c. : argilla, or clays, boles, and marles, including twenty-one species, some simple, among which are porcelain clay, tobacco-pipe clay, China porcelain earth, Lennian earth, fuller’s earth, tripoli, or rotten stone, brick-clay, potters’ clay, boles of different colour, &c. ; others mixed, as fermenting clay, marle, umbre, marle of the Nile, &c. : calx, or chalk, comprehending nine species, some soluble in acids, as creta or chalk, mineral agaric, shell-chalk, or mouldered shells, &c. ; some not soluble in acids, as true mineral agaric, gypteous gur, or lac lune; and others granulated or sandy, as alabaster, chalk, soluble arenaceous calx of the isle of Ascension, and lenticular granulated calx; and humus, or mould, of which there are fourteen species, as the impalpable vegetable mould, common black mould, depauperated mould of heaths, spongy mould of marshes, alpine earth, turf, mould of lakes, or mud mould, red mould, animal mould, &c. See Linnet Systema Naturae, tom. iii. 1770, pa. 881; and Pullesey’s General View of the Writings of Linnaeus, 1781, p. 151—166.

M. Da Costa, in his Natural History of Fossil, 1757, distinguishes stones into four general classes. The first class comprehends those stones which are found forming continued strata, coarse, hard, and rough, of a lax texture, of a visible grit or grain, resembling sand in form, usually immersed in a cementitious matter, of little brightness, and scarcely capable of any polish: of this class there are two genera, viz. stones hard and rough, composed of a visible grit, not of a laminated structure, and splitting equally in any direction, called psadoria by Hill, of which there are the alkaline sand-stones, as the Portland-stone, free-stone, &c. ; sand-stones not acting on acids, as the whetstone, altrum, mill-stone, grind-stone, &c. ; and sand-stones imperfectly described by authors; and stones harsh and rough, composed of a visible grit, of a laminated structure, and splitting only horizontally, or into plates. See Flag. See also each stone respectively.

The second class comprehends stones that are found forming continued strata, of a close, solid, smooth texture, or composed of no visible grit, and generally defective of brightness, though in some degree capable of a polish: of this class there are two genera, viz. stones of a close solid texture, of a plain uniform structure, and splitting with equal ease in any direction, distributed, according to their colours, into black, white, ash, and grey, red, brown, blue, green, and variegated, each of which is again subdivided into alkaline stones, and those which are not acted upon by acids, comprehending the Purbeck-stone, oil-stone, &c. and stones called clates.

The third class comprehends marbles and marmoroide.

The fourth class includes the marmoro-profera, the granites, and the porphyries. See Fossils.

For an account of the modern systems of geology, see Rock, Strata, and System of Geology.

In the sequel of this article, we shall consider stone as applicable to architecture and sculpture.

Stone for Architecture and Sculpture. The application of stone to the construction of houses, appears to have been almost coeval with the establishment of civilized societies. The advantages which stone possesses over wood, in hardness, strength, and its capability of refining the action of fire, would naturally direct those tribes or nations that resided in countries where stone was plentiful, to employ it in architecture. Thus we find in America, where the human race was in its rudest state, no sooner were men collected in large bodies, under the kings of Mexico and Peru, than they began to build houses of stone.

In Assyria, where one of the first great monarchies was founded, the people were deprived of the use of stone, the ground being formed to a great depth of alluvial soil brought down by the rivers Tigris and Euphrates. To overcome this difficulty, they made artificial stones, by baking square masses of clay in the sun. Bricks formed in this, or in any other manner, are properly artificial stones, and have been formerly used to supply the absence of natural stone, by the Egyptians, the Assyrians, and the Romans, as well as by the moderns.

In the choice of different stones for public or private edifices, the contiguity of certain stones, and the ease with which they could be obtained and worked, would be first attended to, particularly in the early periods of architectural science: but there cannot be a doubt that durability and beauty were soon regarded as essential qualities of buildings, and those stones which possessed these properties in a remarkable degree, were sought for with great avidity, and conveyed to distant countries at a great expense.

Such was the care of the ancients to provide durable materials for their public edifices, that, had it not been for the defolating hands of modern barbarians, and the inevitable destruction attendant on warfare, many of the temples and other public works of the Greeks and Romans would have remained perfect to the present day, uninjured by the action of the elements during a period of more than 3000 years.

On the contrary, in modern Europe, and particularly in Great Britain, there is scarcely a public building of recent date which will be in existence a thousand years, hence. Many of the most splendid works of modern architecture are hastening to decay, in what may be justly called the very infancy of their existence, if compared with the date of public buildings that remain in Italy, in Greece, in Egypt, and the East. This is remarkably the case with the three bridges of London, Westminster, and Blackfriars, the foundation of which began speedily and visibly to perish in the very lifetime of their founders. The same observation is applicable to Somerset-house, and many other public buildings in London; the fine chiselling of the alto relievo figures having already disappeared by the action of the elements mouldering away the stone. The most careless observer may notice, that this effect is more rapidly taking place in some stones than in others in each of these buildings, though they are all of Portland stone, a calcareous stone, called roe-stone by mineralogists, and obtained from the Isle of Portland.

We have reason to know, that very little attention was paid to the selection of the stones during the building of Somerset-house; and the damaged ones, or those which contained hollows lined with clay, were not rejected, but the hollows were filled up with mortar. No soft calcareous stone, such as Portland stone, can be very durable in a climate like that of England, where it must be exposed to the action of frequent rain; and for the foundation of bridges, scarcely any stone could be more unfit.

The qualities requisite for building-stone in bridges or water-works, are hardness, tensility, and compactness, with the
the property of refilling the decomposing effects of water
and the atmosphere. Beside the strength necessary to sup-
port their own weight in such buildings, they may also
have to refit the impetus of floating bodies, and particularly
of large masses of ice. Tho' flowers which are the hardest,
are not precisely those which have the most tenacity or
toughness, of which we have a familiar illustration in com-
mon lime-stone and glass; the latter, though much harder,
is far more easily flintable than the former.

In public national buildings, intended to preserve the
memory of the ages in which they were constructed, and to
perpetuate the state of the arts at the period of their erec-
tion, beside the properties which ensure durability, we
require a certain degree of beauty in the stone itself.

The causes that accelerate the decay and destruction of
stone in buildings, are nearly the same with those which oc-
casion the destruction or wear of rocks on the surface of the
globe: they may be class'd into two kinds, those of de-
composition, and those of disintegration. By the former,
a chemical change is effected in the stone itself; by the
latter, a mechanical division and separation of its parts.

The decomposition takes place, when the stone contains
parts that are more or less soluble in water, or which enter
into combination with oxygen or acids. To have a distinct
idea of the decomposition of stones, we must first consider
the elementary parts of which they are composed: these
are either siliceous, aluminate, or limey. (See Silice, Alum-
inate, and Lime.) to which we may add magnesian, which, though
of more rare occurrence, enters largely into the composition
of serpentine and some lime-stones. Iron, in different states
of oxidation, and in different proportions, enters also into
the composition of almost all stones, and is frequently an
important agent in their decomposition. The different
kinds of building-stones may, therefore, be class'd as si-
laceous, argillaceous, calcareous, and magnesian.

Of these, the siliceous are the least liable to decomposi-
tion; silice being insoluble in water, or any of the acids, except
the fluorine, which is never found in a large portion of stone,
and composed almost entirely of silice, if compact, may be con-
sidered as the most durable; but they are frequently brittle,
and extremely difficult to work. When the stone is com-
bined with a certain portion of alumine, as in some horn-
stone and jasper, it constitutes a stone which may be re-
garded as imperishable, when compared with the duration of
stones and empires. Such stones frequently contain im-
bedded crystals of quartz and felspar, and are then deno-
minated porphyries. Porphyry, with a compact siliceous
base of hornstone or jasper, is far more durable than granite,
and is peculiarly appropriate for columns or obelisks, de-
tined to transmit the events of former times to distant ages
of the world. Some porphyries are also very beautiful, and
take a high polish.

Granite (see Granite) is a compound siliceous rock,
which varies much in the proportion of its constituent parts;
and its degrees of induration. Compared with many rocks,
granite may be considered as forming a durable building-
stone; but those granites that contain much white felspar,
and only a small proportion of quartz, like the greater part of
the granites of Cornwall and Devonshire, are liable to de-
composition and disintegration much sooner than many of
the Scotch granites, in which the quartz is more abundantly
and equally disseminated. In the selection of granite in
Cornwall and Devonshire, the preference is given to that
which can be raised in the largest blocks, and worked with
the greatest ease; and for common purposes, or for paving
stones, it may answer very well; but for the foundations
and piers of bridges, the harder granite will be found much
more durable. The present state of Cornwall proves the
rapid disintegration and decay of its granite rocks. The
felspar in that granite contains a large portion of potash, and
to this its more rapid decomposition may be principally
ascribed. The naval hospital of Plymouth (an establish-
ment which does honour to the country) is built of Cornish
or Devonshire granite, which appears to have been well
selected. It has been erected about 70 years, and exhibits
no symptoms of decay, except in the columns forming the
colonnade in front of each building; here, on their expo-
red sides, we have observed the felspar to be disinte-
grating, and lichens have already attached their roots to
some parts of the surface.

With granite may be class'd all granitic rocks containing
a large portion of siliceous earth, particularly sienite. (See Sienite.) This rock was extensively quarried by the
Egyptians at Sienna, in Upper Egypt, and afterwards by the
Romans; and many works constructed of this stone, pre-
serve the marks of the chisel fresh to the present day.

Of the rocks here enumerated, we have abundance in various
parts of the British empire; and in the construction of na-
tional works, the selection of the stone should not be left to
the discretion of architects, few of whom have made mine-
ralogy any part of their studies. Many of the sand-stones,
in what are called the secondary strata, are composed of
grains of silex; and where these are united by a siliceous
cement, they are almost as durable as granite. In siliceous
sand-stones, the coarnees or angles of the grains is of far
less importance than the substance by which they are united.
Those which are united by ferruginous clay, are very liable
to perish by exposure to the atmosphere. Some siliceous
sand-stones appear to be of alluvial formation, and have
their parts so loosely cemented, that they are quite unfit for
architecture: such is the sand-stone rock on which the town
and castle of Nottingham are built.

In the series of strata which alternate with coal, there are considerable beds of silici-
aceous sand-stone, which vary much in their quality; some being
almost pure, others being almost purely siliceous. Of the latter kind are some of the
lowest beds in Yorkshire and Derbyshire, which have been
denominated mill-stone grit, being formerly used for coarse
mill-stones. Kirkstall abbey, near Leeds, is built of this
stone: it is now a ruin, but the stones which remain are
perfect, and preserve their angular sharpness as fresh
as if they had been recently worked, though six hun-
dred years have elapsed since the erection of this building.

There is a quarry of similar stone in the neighbourhood
of Wakefield, extensively worked at present. It may be proper to ob-
serve, that in all quarries of sand-stone, the first stone vary con-
siderably in their power of resisting the effects of the
atmosphere. Some strata are marked with frits and veins,
and these are frequently found to be more perishable than
the general mass of the stone. We have known such stones
preferred for the fronts of buildings, on account of their
fupposed beauty; but, in the course of a very few years,
the coloured parts began rapidly to decay, by the action
of water on the iron, which these parts contain more abun-
dantly than the rest of the stone. From what has been
stated, it may be seen that stones, which are purely siliceous,
are of all others the least liable to decomposition; but where
there is an admixture of silex with different substances, great
skill is required in their selection for durable architecture.
Some directions for the choice of such stones will be subse-
quently given.

Argillaceous stones, or those which contain in their com-
position a considerable portion of clay, are generally found
to contain also a large portion of iron. This metal appears
to have a greater affinity for argil or clay than for any other earth, and is frequently combined with argillaceous flints in the proportion of one-fourth of the whole mass. The iron is frequently in the state of black oxyd, and in this state rapidly combines with a larger portion of oxygen, when exposed to the atmosphere, and thus occasiona the surface of the stone to swell and shiver away. We have seen flint of this kind in their native beds, some hundred feet under the surface, so extremely hard that they refilied the point of a pick, and could only be removed by blastig; yet when the same flint was exposed for some months to the air, it became soft, and shivered into small pieces.

It rarely happens that builders or engineers have sufficient mineralogical science, to enable them to anticipate the changes which will be effected by air and moisture on the materials they felect. The lofs which this ignorance has occasioned in the construction of many public works is well known. A remarkable instance of this kind took place a few years since in Paris. A gentleman was walking with an eminent mineralogist in one of the newly erected public edifices. They were particularly struck with the appearance of the walls, some large columns that supported the roof. On a closer inspection, the mineralogist predicted that they would perish in less than three years. About ten months afterwards, the gentleman had occasion to pass through the same building, and observed workmen were then removing the columns, and replacing them with a different flint; the decay having been so rapid, as to render their removal necessary.

In forming the tunnel of the Huddersfield canal, in Yorkshire, through Pule Mofis, a lofty mountain three miles in breadth, the workmen, in one part, had to cut through a dark argillaceous flint, so extremely hard, that they were obliged to remove it by blasting. On account of its hardness and compactness, it was deemed unnecessary to wall the passage in the part which was cut through this bed; but in a few months after the access of air, it shivered and fell in, and the removal and repair occasioned much delay and expense. Many bafaltic rocks, which are almost as hard as flint in their native beds, on exposure to air or moisture, are soon covered with a brown incrustation, which penetrates deeper and deeper into the flint till the whole is reduced to a soft pulvulent mass: this is occasioned by the rapid absorption of oxygen, the iron in the bafalt being in a low state of oxygenation.

On this account, bafaltic flint are ill suited for durable architecture, though there are some flint of these clays which appear more perfectly vitrified, and reflect the action of the atmosphere for ages. This is also the case with lavoas which are nearly allied to bafalt: some lavoas rapidly decompose and form a fertile soil, others remain unchanged for centuries. In all flint called argillaceous, the quantity of alumine, or pure clay, is, in fact, generally less than that of the other earths. Alumine or clay, when pure, is soft and unctuous, and absorbs more than 2:4 times its own weight of water. It communicates, in a greater or less degree, its own properties to flint, where it is combined in the proportion of from 30 to 30 per cent. The properties of clay are lost by vitrification, or by exposure to a strong heat, as we may observe in the process of brick-making. In the West Riding of Yorkshire, it is frequently the practice to mend the roads with argillaceous flint, but it is soon reduced to mud, to prevent which, it is piled in heaps, with alternate layers of coal, and burned before it is laid upon the roads: this makes it more durable, but the heat is seldom sufficiently powerful to vitrify the flint, and the roads frequently want repair. The remains of vitrified forts in some parts of Scotland, prove that the North Britons were acquainted with the durability imparted to argillaceous flint by exposure to great heat. In situations at a great distance from the durable building-flint, it would be advantageous to have the bricks employed in the construction of bridges exposed to a greater degree of heat, and vitrified on the surface. This may be more easily effected by a mixture of calcareous earth with the clay.

Calcareous flint includes all the different kinds of lime-flint, from the most crystalline marble, to chalk and calcareous sand-flint. Of marbles, there is an almost infinite variety; indeed every variety of lime-flint that admits of a good polish is denominated marble. (See Marble.) The lime-flint or marbles that occur in primitive mountains, among blocks of granite, gneiss, and mica-flate, are generally the most durable, as they are highly crystalline; and many of them contain a considerable portion of siliceous earth, which communicates a greater degree of hardness to such marble. Though calcareous earth is in a certain degree soluble in water and carbonic acid, yet in its most indurated state, as in primitive marbles, the action of the atmosphere produces no change in the course of centuries; but when exposed to the constant action of water, the decomposition is more rapid. Those marbles which are the most uniform in their texture, which possess the greatest degree of specific gravity and hardness, and which will receive the highest polish, are those which will prove the most durable. There is another test applicable to marbles, and all flint purely calcareous, which affords no bad proof of their durability.

Let all weight of different marbles be cut into cubes, or any other regular figures, and immerse in dilute muriatic acid of the same degree of strength as marble which dissolves most slowly, will be the least liable to decay.

Some lime-flints confit of calcareous earth, combined with a considerable portion of magnesia: the primitive lime-flints which contain this earth have a milky whiteneis. All lime-flints of this kind dissolve very slowly in acids; and such of them as polishe the other properties of hardneis, and an uniform texture, may be considered as the most durable of all marbles. The importance of an uniform texture is evidenced in the different durability of the Parian and the Penticelic marbles. They were both extensively employed by the sculptors and architects of ancient Greece. In the age of Pericles, the preference was given to the latter. The Parthenon was built entirely of marble from mount Pentelicus (Penticelic marble), near Athens. Many of the Athenian statues, and the temples of Ceres or Eleusis, were of this marble. The preference arose from its superior whiteneis, and probably from its vicinity to Athens. It is remarked by Dr. Clarke (Travels, vol. iii.), that while the works executed in Parian marble remain perfect, those of Pentelic marble have been decomposed, and sometimes exhibit a surface as earthy and rude as common lime-flint. This is principally owing to veins of extraneous substanies which intersect the Penticelic quarries, and which appear more or less in all the works executed in this kind of flint. The Parian marble has some of what appears to be a waxy appearance when polished; it hardens by exposure to the air; it receives with accuracy the most delicate touches of the chisel, which it retains for ages, with the mild lustre of the original polish. The Medicean Venus, the Diana Venatrix, the colossal Minerva (called Palladi of Veletas), and the statues of the Capitolins, are of Parian marble. The Parian tables at Oxford are also of this flint. The marbles of South Britain, those of Devonshire are by far the most beautiful; for the Anglesea marble, as it is called, is principally pure serpentine (see Serpentine); though it is called by professor Jameson,
STONE.

In the late edition of his Mineralogy, with granular lime-tone. The Devonshire marbles have scarcely been noticed by mineralogists, but many of them possess a degree of beauty scarcely inferior to any of the foreign marbles, particularly those of Babicomb. They are veined and spotted with a variety of colours, from a bright red to a beautiful dove-colour, and are susceptible of a very high polish. The altar, and the interior of Lord Clifford’s elegant chapel at Ugbrooke, near Chudleigh, are executed in this marble, which may vie with the most costly marbles of Greece or Italy. The great national work called the Break-Water, at Plymouth, is formed of blocks of Devonshire marble: it is an artificial mole of vast extent, intended to form a bay, where our largest fleets may ride in safety. The marble is procured at Cat Down quarries, close to the water’s edge, from whence it is conveyed in boats about two miles, and thrown into the sea. The blocks are raised of vast dimensions by blasting, and from their hardness and size may exhibit the decomposing effects of sea-water for ages, particularly if the western side should get a covering of sand. The continuity of the flone necessarily determined the choice where some million tons were wanting to complete the work, but there cannot be a doubt that the granite of Cornwall would have made a more durable barrier.

Among the secondary lime-flones, there are some which contain a considerable quantity of magnesia, particularly in the counties of Nottingham, York, and Durham. These lime-flones have generally a yellowish colour: they diffuse slowly in acids, and form a very durable flone for architecture. York Minster is said to be built of this flone.

The roc-flone, particularly that of Portland and Bath, is very extensively employed in architecture: it can be worked with great ease, and has a light and beautiful appearance; but it is porous, and poissies no great durability, and should not be employed where there is much carved or ornamental work, for the fine chiselling is soon effaced by the action of the atmosphere. On account of the ease and cheapness with which it can be carved, it is much used by our English architects, who appear to have little regard for futurity.

The chapel of Henry VII. affords a lamentable proof of the want of the architect to the choice of the flone. All the beautiful ornamental work of the exterior had mouldered away in the short comparative period of three hundred years: it has recently been caved with a new front of Bath flone, in which the carving has been correctly copied; but from the nature of the flone, we may predict that its duration will not be longer than that of the original. Probably the architect was limited by contract, which precluded the use of a more durable, but more costly flone. Portland, as well as Bath flone, varies much in its quality, and we think greater attention was paid to its to the chiselling in the construction of St. Paul’s church, than in many of the modern edifices built of this flone. Though we have observed many flones in the upper part of the building mouldering away, yet, on the whole, it is less injured by the weather than Somerset-house. In buildings constructed of this flone, we may frequently observe some of the flones nearly black, and others presenting a white clean surface. The black flones are those which are more compact and durable, and prefer their coating of smoke: the white flones are decomposing, and presenting a fresh surface, as if they had been recently scraped. This effect is strikingly exhibited in the columns of Somerset-house, in which black and white flones may be seen alternating in the same column.

Some of the lower beds of chalk are occasionally used for building-flone, though, from its loose texture, it cannot possess great durability. We have seen the cloisters of Wellminster Abbey repaired with a flone of this kind, so soft as to yield to the nail; and on inquiring of the workmen why they made use of such a material? the reply was, “the cheapness of the cutting.”

Alabaster or gypsum is sometimes employed for ornamental architecture. The name alabaster is also given to stalactitical lime-flone. (See Stalacite.) This variety of lime-flone poissies nearly all the properties of granular lime-flone. The gypsum alabaster is a sulphate of lime, and possesses a considerable degree of solubility in water. Dr. Watfson, in his Chemical Essays, states, that he suspended two ounces of this flone in a pail of water forty-eight hours, changing the water several times, and found at the end of that time it had lost one-thirtieth part of its weight. From the solubility of gypsum, it is obviously improper for any purpose where it is to be exposed to the action of rain or water.

Of the magnesian flones, there is only one applicable to purposes of architecture; this is serpentine, which has been fully described under that article.

The disintegrating causes to which building-flones are exposed are moisture, variation of temperature, and vegetation: the action of these is distinct from that of decomposition. The earths which are not soluble in water are capable of being mechanically suspended in it, when minutely divided. A drop of water, constantly running along the hardest flone, marks its path by cutting a furrow in the surface, according to the well-known adage:

“Gutta caveat lapidem non vi sed saepe cadendo.”

This cause is, however, flow, compared with others which are constantly operating. Water inulmates itself into the minute pores and crevices of flones, and being expanded by variation of temperature, and particularly by froth, breaks, and, under the hardest flone, or shivers off a portion of the surface. Those flones which have a laminated structure are more liable to be injured by the effects of froth, from the facility with which water inulmates itself between the laminae.

Lichens and mosses fix their roots on the surface of flones, particularly on those argilaceous flones which yield an earthy smell, when breathed upon. By inulminating their roots, they accelerate the decay of such flones, and prepare a vegetable mould for plants of a larger growth.

In calcareous and other sand-flones, where the cementing material is of a soft kind, it is washed out by rain, and the flone falls in pieces, or moulders away. In general, those flones which are the most hard, compact, and uniform, in their texture, and which can be brought to the smoothest surface, are those least liable to disintegration. In order to form a judgment of the durability of any building-flone, which has not had the test of experience, it is desirable to examine it in its native bed, particularly those parts of the bed which have been long exposed to the air. This may not unfrequently be done in some part of the country where the flone is quarried; for as each stratum rises in a certain direction, it will come to the surface somewhere, if not covered by foil. The flone, in such situations, offers certain indications of the effect which atmospheric agency produces upon it. Where this examination cannot be made, all flones that are not calcareous may be in some degree proved, by observing what effect is produced by immersing them in water for a given time, by exposing them to a red heat, and to froth, or by covering them with dilute nitric acid for several days. Those flones which absorb the smallest quantity of water, and which are least changed by the
the action of heat, frost, or acids, may be fairly considered as most capable of refilling the decomposing or dilute-grating effects of moisture and change of temperature. We have before suggested a test in the choice of calcareous stones. It has recently been the practice to rub the calcareous sand-stones with oil; and this must to a certain degree refit the absorption of water, and contribute to the durability of the stone.

Foreigners generally class building-stones into two kinds, hard and soft. In the latter they comprise all stones that can be cut with the faw in any direction, and with some degree of ease: the hard stones are all those which cannot be worked by the same process. In England, the name free-stone is given to all the softer stones, which can be cut easily with the faw into large blocks suited for building-stone: it includes a variety of sand-stones very different in their nature.

Experience has taught our architects, that all stratified stones lay much longer, when laid in the same direction which they had in their native quarries; a circumstance which ought always to be attended to by the master. As stratified stones generally split with the greatest ease in the direction parallel with the surface of the strata, it is obvious that they will bear less pressure in this direction than in a line perpendicular to their natural position.

The following table shows the value at Rome of marbles, alabaster, and hard stones, regulated by the cubic Roman palm, which is about nine inches in each dimension. The fciudo, which contains one hundred bajacchi, is about 4. 6d. English.

The prices of the above stones are enhanced not only by their size, but by any extraordinary beauty of colour which each specimen may possess.

STONE, in Agriculture. It is a point not yet determined, whether stones are hurtful or beneficial to arable lands. Examples are not wanting on both sides of the question, though, in general, it seems rather to be carried for them. However, nothing can excuse leaving a stone in any ground so large as to interrupt the plough. If they are very large, they should be blown to pieces with gunpowder, and then be carried off. Some spots, very fertile in several kinds of grain, seem to consist of nothing but stones; and instances are given of fields being rendered barren, by taking away the stones which covered them. Theophrastus accounted for this in a hot country, where it happened to the Corinthians, by saying that the stones sheltered the earth from the scorching heat of the sun, and thereby preserved its moisture. The same holds true even in our colder latitude, where the heat of the sun is lefs apt to hurt us. And Evelyn is clearly of opinion, that husbandmen rather impoverish than improve those grounds which are almost covered with stones, especially where corn is sown, if they pick them off too minutely: because they thereby expose the land too much to the effects of heat and cold. Certain it is, that a moderate mixture of small gravel prefers the earth both warm and loofe, and prevents too sudden exhilarations. But it seems highly probable that there must be some farther reason, beyond what has been yet asigned, for the benefit arising from the stones.

However, the concealed stones should be always removed from lands that are to be kept in a state of tillage, otherwise many accidents must happen in ploughing, by the straining and breaking of the ploughs, and the destruction of other implements. And where the lands require underdraining, it may often be proper and beneficial, as well as a cheap method, to have the stones made use of, and gathered from the ground; and by such means, two objects may be accomplished at once. See Clearing of Land, and Draining of Land. See also SPRING and SURFACE Draining.
STONE.

In some places it is met with a few inches under the surface, like a clove pavement. In whatever position or size these stones inlet the land, it is there the prevailing opinion, that until it shall have been in some measure cleared, by digging, or ploughing and picking, little hopes of succcess can be entertained, even from the best modes of cultivation; although instances of the contrary may sometimes be produced. Lands have been cleared of this stone, by screening the whole masts of flinty matter and earth as deep as the yellow clayey under-earthen, in the same manner as masons screen the sandy materials for their mortar, with very great success and advantage, though at much expense. The refuse stones, in this or other ways, are purchased at one shilling the load from the farmers, for their use in repairing the roads. The round cobble stones, picked from the land, are much used in the south of Lancashire, and probably in some other places, for paving the roads.

Whatever may be the cause of the productivity of tillage-lands, so bet with loose round stones as scarcely to have any appearance of earthy matter or mould amongst them, the writer of this article has over and over again seen vast crops of different sorts of excellent grain produced on such land. See STONY LAWN.

STONE, as to the Origin and Formation of, M. Tournefort, on his return from the East, in the year 1702, proposed to the Royal Academy a new theory.

On a curious survey of the famous labyrinth of Crete, he observed, that several people had engraved their names in the living rock, of which its walls are formed; and what was very extraordinary, the letters whereof they confided, instead of being hollow, as they must have been at first, (being all cut with knife-points,) were prominent, and stood out from the surface of the rock, like so many baflo-reliefs.

This, he says, is a phenomenon no otherwise accountable for, than by supposing the letters of the letters filled individually with a matter issuing from out of the subsidence of the rock, and which even if used in greater abundance than was necessary for filling the cavity. Thus, the wound made by the knife healed up, much as the fracture of a broken bone is consolidated by a callus, formed of the extravasated nutritious juice, which rises above the surface of the bone: and this resemblance is the more just, as the matter of the letters was found whitish, and the rock itself greyish.

Something very like it is observed in the banks of trees, in which letters have been cut with the knife; so that the poet had reason to say, that the characters grew as the trees themselves grew: "Crepitent illae: creceptis amores." M. Tournefort supports his opinion by similar calluses apparently formed in several other stones, which had re-united after, by accident, they had been broken.

From these observations, he says, it follows, that there are stones which grow in the quarries, and of conformation that are fed; that the same juice which nourisheth them, serves to rejoin their parts when broken; just as in the bones of the animal animal. And this branch of the science, when kept up by handagers, and in a word, that they vegetate.

There is then, says he, no room to doubt but that they are organized; or that they draw their nutritious juice from the earth. This juice must be first filtered and prepared in their surface; which may be here esteemed as a kind of bark, and hence it must be conveyed to all the other parts.

It is highly probable, that the juice which filled the cavities of the letters, was brought thither from the bottom of the roots; nor is there any more difficulty in conceiving this, than in comprehending bow the sap should pass from the roots of our largest oaks to the very extremities of their highest branches.

It must be owned, that the heart of these trees is exceedingly hard; and yet those of Brazil, called iron-wood, guaiacum, and ebon, are much harder. Coral is as hard in the sea as out of it; and sea-mushrooms, which every body allows to grow, are true stones, and fo, like the common stones, are used in America to make lime.

Some stones, then, he concludes, must be allowed to vegetate and grow like plants. But this is not all: he adds, that probably they are generated in the same manner; at least, that there are abundance of stones, whose generation is inconceivable, without supposing that they come from a kind of seeds, in which the organic parts of the stones are wrapped up in little; as those of the largest plants are in their seeds.

The stones called Cornu Ammonis, Lapis Ludovici, of Verona, thofe of Bologna and Florence, the several kinds of pyrites, crystals of the rock, and an infinity of other stones, he supposes to have their several seeds: as much as mushrooms, truffles, and various kinds of mosses, whose seeds were a long time before they were discovered.

He continues, how should the cornu Ammonis, which is constantly in figure of a volute, be formed without a feed? Can it be that same figure in little? who moulded it so artfully? and where are the moulds? Far from this, these kinds of stones are found in the earth, like common flints. Nor were either their moulds, or any thing like them, ever discovered.

M. Tournefort examines the several kinds of stones above mentioned, and finds them under the same necessity of feed. Again, that immense quantity of pebbles, with which the Crou of Arles is covered, he thinks a strong argument in behalf of this theory.

The country there, for twenty miles round, is full of round rough pebbles; which are still found in equal abundance, to whatever depth you dig. M. Pierefo, who first propounded the generation of stones by means of feeds, (though he took the word feed in a very different sense from M. Tournefort,) first brought this extraordinary collection of them as a proof of it. In effect, how could so many similar pebbles be formed? There is no saying they are coeval with the world, without asserting, at the same time, that all the stones in the earth were produced at once; which were to go directly contrary to the observations above mentioned.

Among the seeds of stones, M. Tournefort observes, there are some which do not only grow soft by the juices of the earth, but even become liquid. These, then, if they penetrate the pores of certain bodies, grow hard, petritify, and assume the figure or impression of the body: thus, what we call fæuntites, concubites, myrtulites, ofractites, nautulites, echinolites, &c. are real stones, the liquid seeds of which have infinuated into the cavities of the shells called fæten, cuhbus, myrtus, ofra, nautus, and echinus. On the contrary, if these liquid seeds fall on flints, on shells, sand, &c. they enclose the several bodies, and, animating between these forms, kind of cement, which yet grows like other stones. It is highly probable, that such rocks as are only an assemblage of cemented flints, have been formed by a number of these liquid seeds; in like manner as the quaries full of shell: unless the rocks have enveloped these bodies in their growth.

He even supposes, that there are seeds of real stones enclosed in the spawn of certain shell-fish; as well as that hard solid matter defined for the forming their shells.

There is, says he, a particular kind of shell-fish, called ...
STONE.

Pholas, which are never found any where but in the cavities of flints, which are always found exactly fitted to receive them. Now, it is highly improbable the first should come and dig such a notch to spawn in: it is much more likely, that the flones they are found enclosed in were at first soft; and that the matter of which they are formed, was originally found in the spawn, in like manner as the matter which forms the egg-shell is really found in the seed thereof.

From the whole he concludes, that the seed of flones, and even of metals, is a kind of dust which probably falls from them while they are alive, i.e. while they continue to vegetate as above. This dust may be compared to the seeds of several plants, which no microscope ever yet discovered; though their existence is not at all to be doubted.

Probably, flints and pebbles are among flones; for it is a notion new: Pliny affirms us, that Theocharitus and Mithridates believed, that flones produced flones: and Gregory Nazianzen adds, that there were authors who even believed, that flones made love, &c. &c. &c. De Virg.

All this, however, is founded on the imperfect knowledge of those times.

Since M. Tournefort’s days, we have discovered other ways of formation for the lapis Judaeicus and corum Ammonis; the first being only a petrifaction of the spines of echinus marinus, and the other of a shell-fish nearly allied to the nautilus kind. See fossil, Judaeicus Lapis, and Cornu Ammonis.

M. Geoffroy accounts for the origin and formation of flones in a different manner. He lays it down as a principle, that all flones, without exception, have been fluid; or at least a soft paste, now dried and hardened; witness the flones in which are found foreign bodies; witness also figured flones, &c.

On this principle, he examines the formation of the different kinds of flones; and shews, that the earth alone suffices for the fame, independent of all flaks, sulphurs, &c. The metallic particles contained in flites give them their colour; but these are only accidents: for proof of which, he inflects the faphylites and emeralds of Axerigne, which lobe all their colour by a moderate fire consuming their metallic parts; but without any damage to their transparency; they being hereby rendered mere crysals.

To view rock-crystal, indeed, one would not take it for earth; and yet earth it must be, not water congealed, as the ancients imagined.

M. Geoffroy conceives two kinds of primitive particles in the earth. Thole of the first kind are exceedingly fine, thin lamelles, equal to each other, or nearly so. Now, when these meet together, from any cause whatever, in a sufficient quantity, the regularity and equality of their figures determine them to range themselves equally and regularly; and thus to form an homogeneous compound, which is very hard, from the immediate contact of the parts; and very transparent, by reason of their regular disposition, which leaves a free passage to the rays of light every where; and this is crysital.

The parts of the second kind have all sorts of irregular figures, and make accordingly form assemblages that are much more opaque, and less hard. Now crysital is formed wholly of parts of the first kind; and all other flones of a mixture of the two kinds of parts together: this mixture is absolutely necessary, in order to unite and bind together the parts of the second kind, and give them a hardness and consistence, without which they would only make a sand or dust. Water now appears the fittest vehicle to carry the parts of the first kind. This is seen from several petrifying springs, which incrustate the pipes through which their water is conveyed, or even solid bodies laid in them for some time. The water does not dissolve those earthy parts; it only keeps them in fusion, as it does the juices with which plants are fed.

This water, thus charged with earthy particles of the first kind, M. Geoffroy calls the fomy, or crystalline juice, of which those bodies are primarily formed. See Crystal.

Some look upon flones as unorganized vegetables, and that they grow by the accretion of flaks, which often shoot into angular and regular figures. This, it is said, appears in the formation of crysals on the Alps; and that flones are formed by the simple attraction and accretion of flaks, appears by the tar tar on the sides of a clarret-velvet, and especially by the formation of a fome in the human body. Henkel has thrown together some very ingenious thoughts on this abstruse subject, in a treatise published in the year 1734, where he builds no opinions on any other basis than that of facts, observations of nature, and experiments.

He supposes that the earth was at first every where soft on the surface, and that this soft matter by degrees hardened, and formed flones of several kinds. He seems to imagine, that the surface of the earth was a second time all reduced to this soft state by the universal deluge at the time of Noah, and that this matter afterwards hardening into flones of various kinds, included the shells of sea-fishes, and other animal remains of the produce of the seas, in flints, in lime-flone, or in whatever other substance the matter, among which they lay, chance cowden.

Thus may the sea-shells, found finely in the middle of hard flints, or lodged in vast numbers in the infra of earth, lime-flone, or marble, be accounted for.

Nor is water alone the agent that may have made these changes in the once soft parts of the earth’s surface; we can by fire reduce the poorest earths into a sort of glafs, a hard transparent body, not a little resembling the nature of flint, or the other semi-pelleucid flites. Fire is of power to do great things in the bowels of the earth, and the way to learn what changes it may there make in flones, is to try its effect upon the several different kinds of flones and earths here.

By experiments of this kind we learn, that of the several species of flones in their present state, some are reduced to a friable mass, and finally to powder, by the force of fire; others are hardened by it; others are melted, and become a kind of glafs: and by experiments on the other sullflue substances, it appears that the original matter of all flones has been earth, either of the nature of chalk, marble, or clay; and that many of them have been greatly altered by receiving metallic or other mineral matter into their earthly matter, at the time of their formation; and all seem to have owed their change into their hard state, either to fire alone, or to saline, oily, metallic, or saline sulphureous matters, either conjunctly with the force of this agent, or alone. Henkel, Lithogenes.

Thole flones which are formed in their present state, immediately out of fluids, have been produced either by congelation, a rude coalition, or crystalization; and that all the gems have been once fluid is plain, from their imperfections in certain instances, as from their containing grains of sand, or the like extraneous substancess, firmly embodied in them. If these, the hardeft of all flones, have been once fluid, there is no reason to dispute, but that all the other kinds may have been so, which are lefs hard and lefs perfect. For the formation of flones, according to modern systems of geology, see Rock, Strata, and System of Geology.

Stones, Formed, among Naturalists, mineral, or fomy matter,
STONE.

matter, cast in the cavities of certain sea-shells, or other parts of marine animals.

Of these, some are found quite naked and bare; others have the remainder of the shell about them; and among these there are also found many real shells, scarcely at all altered from their recent state, buried at great depths in the earth, far from seas, and even on the tops of mountains.

This is by most supposed an effect of the general deluge, and by many is thought a convincing proof of the truth of that history; but there have been many who have affirmed, that these bodies can convey no such proof, since, as they affirm, they are not, nor ever were, marine animals, or owed their form to such, but mere lyellus natures, shells formed in the places where they are found, having no relation to animals of any kind, but only accidentally resembling them. But the adherents of the former opinion have rather the better side of the argument.

It seems, indeed, contrary to the great wisdom of nature, which is, in all its productions, to design every thing to some determinate end, that these bodies should have been so nicely formed by a mere plastic virtue in the earth, or endured with all the characters and necessary parts of animal covering, &c. for no other end but merely to exhibit such a form, without having any relation to the uses these particulars are appropriated to in the animal. But if the origin of shells, found in the shape of shells, be doubtful, yet the real shells found in the earth cannot be supposed to have been formed there: yet these are found at so great distances from the sea, and not only in the low grounds and hillocks, but in the highest parts of the loftiest mountains, even without the least particle of fleshy matter about them; mere shells unpetrified, uncorrupted, and of the exact figure, structure, and confidence of the sea-shells, which are now habitations of living animals of the same species.

That nature should form real shells, without ever intending them for the sovereing of an animal, seems no way probable; and indeed, were it true, would give great strength to the atheist's opinion, that all things existed by mere chance, and were intended for no end or use. Nor are the shells the only influences of these fossil bodies perfectly resembling animal ones, but we find with them other parts of animals, as the teeth of fishes and land animals; which, though met with buried in earth, or on the tops of mountains, are plainly the same with the substanaces produced by the fishes, &c. Of this kind are the teeth of the several species of sharks, called quires, those of the wolf-fish, called ceblis, and the like.

The very inspection is abundantly sufficient to prove, that these were once parts of animals; but were that insufficient, they have not, even in this their fossil state, so far divested themselves of their animal nature, but that they carry proofs of it; and Columna has evidently proved their true origin from these. He observes, that all animal and vegetable substanaces, whether of a woody, bony, or fleshy nature, by burning, are changed first into a coal, before they go into a calx of ashes; whereas fleshy substances, on the contrary, do not burn into a coal, but are reduced at once into their calx or lime, or else into glafs. But these teeth, supposed by some mere productions of the earth, all burn first into a coal, while the fleshy matter adhering to them does not; whence alone it is sufficiently plain, that they and that substance are of very different kinds, and that they are truly of a bony, not a fleshy nature. It is also repugnant to that great maxim, that nature does nothing in vain, to suppose these teeth formed in the earth where they are now found, since they could there have no use as teeth, nor the vertebra, or other bones, as bones. It is very certain, that nature never made teeth without a jaw, nor shells without an animal inhabitant, nor bones without the rest of the body they belong to; these things are not made in this separate and uselesse state in the element to which they naturally belong, much les in a form in which they are not usefull, or one.

Their very substanace and place also evince plainly, that they were not formed where they are now deposited, for they are usually lodged in stones, and stones contain not the matter of which they are made: and as to their place, they might have been lodged there either when formed, which proves our assertion, or else they must have been at some time generated all of a sudden there, or have grown from a small origin, increasing by little and little, as the animal substanaces which they resemble do. Now, if the fleshy, in which they lie, was formed before them, and they were formed on a sudden in it, how came the cavity there just to correspond to their size? and if they grew by little and little, how could they form a cavity in the stone, without bursting or cracking it?

It is also no small proof of these teeth being of a marine or animal origin, that they are not regularly shaped at the bafe, but are all broken, and that in various manners, which proves very plainly, that there has been no vegetation in the case, because in all other figured fossils they are never found mutilated or imperfect. It cannot, with any shew of reason, be supposed that these teeth were thus broken within the body of the stone where they now lie, but it is plain that they were lodged in the stone at a time when it was soft, and were before that broken off from the jaw of the creature in this irregular manner.

It is likewise no weak argument, that these bodies are not formed at this time in the stone, that they are all found perfectly alike; for, if they were continually increasing in size and number, it is probable that the new formed ones would be some way different from those which were of older date. The variety of species in the glossopetrae alone may evince, that they belong to the animal to which they are attributed, since they are of very different kinds. See Glossopetrae, and Serpentes Tongues.

The perfection of the figures of these bodies is a farther proof of their origin from animals which they reprent, since in all crystallizations there are many imperfect and mutilated figures, nay more than perfect ones.

To all this it may also be added, as an unanswerable proof of the fossil shells having been marine, and having lived in the sea, that these shells are found with injuries which could have been no way else received. The perfect animal, and some other shell-fishes, have bony tongues, with which they bore regular holes through the shells of shell-fish of other kinds, in order to make their way in, and prey upon their flesh. These holes are always easily known by their regularity and shape; and shells bored through in this manner are not only frequent on our shores, but there are such also found fossil, bedded in the strata of earth or fone; and surely, if falls could be allowed to have shot into the figures of real shells, they could never be suppos'd able to shoot into the figures of such wounds, as a few of those shells have received in their recent state from other animals.

The general opinion is, that the deluge brought all these shells into the places where we see them; but this seems not easily conceived; and as there is no argument so good, but that being carried too far it will make against its purpose, fo the laying too much to the effects of the general deluge, has made many believe it has done nothing at all.

These formed stones and real shells are both found in vast strata on the tops of the highest mountains, the Alps, Apennines,
STONE.

Apennines, and others in different parts of the world. The deluge lasted only ten months, and probably the tops of mountains were not covered half that time; and these immense quantities of shells cannot be supposed either to have bred there in that time, or to have been carried so high in such prodigious numbers. It is more probable that the tops of mountains were once not high, but bottoms of the sea. The history of the marine bodies they contain is then very plain, and earthquakes may have raised them, or they may indeed not be so high above the level of the sea, as we at first sight suppose. If, indeed, we adhere to the letter of the text, in the Scripture history of the creation, we can find no account for these bodies from that time; for if the creation of fishes succeeded the separation of the land from the water in all parts of the globe, they could not be then deposited there; but it is possible, that at the creation the whole earth was not all at once uncovered, but only those parts where Adam and the animals were created, and the rest gradually afterwards, perhaps not in many years, as there seems no necessity of understanding the account of the creation to have been in fix natural days. If we may thus understand, and conjecture in this respect, it is not difficult to conceive, that during the years in which the earth remained covered with sea-water, shell-fish might breed and multiply abundantly all over its bottom; and this bottom being afterwards elevated, deflected by the sea, and made dry lands, these shells must be elevated with it, and retained in thofe flat Beds, which afterwards hardened into the various kinds of earth and stone: and something of this kind seems to have been the cause, much rather than, according to Dr. Woodward, that all stony matter should have been dissolved by the deluge, and afterwards have concreted again. Ray's Physico-theological Discourses. For other hypothesis and observations relating to this subject, see Adventitious Fossils, Marine Remains, Petrifications, Seminum, and Shells.

STONES, Solutions and Colours of. The various beauties of the form and colour of the several more precious stones, cannot have been always the admiration of the curious part of the world, and the ingenuity of the ablest chemists hath been tried, in attempting to counterfeit them; and much may be gathered even from their attempts, which have not succeeded, toward the learning of the true nature and history of these beautiful bodies.

The beautiful figures of the Florentine marble, whose veins represent trees, rivers, and ruins of buildings, are well known; as are also the delineations of trees and shrubs in those species of white agates, called Moos agates. All the stones of this kind are natural, for art has yet not been able to come up to any counterfeit of them; but it is not so in regard to those agates which represent regular figures of beasts, &c. there are all ablast by art, and that by a very simple and easy process; and M. Du Fay, in the Memoirs of the Paris Academy, has given at one view the several ways, then known, to penetrate into the substances of agate, marble, &c. and to lodge figures in them.

The stones subject to be figured, divides into two classes, the harder and the softer. Of the harder kind, are those which reftit the force of acids, even of the most powerful kind, and of this class are agates, onyxes, and all that are vulgarly comprehended under the general name of the gems, or precious stones, with crystal, porphyry, granite. These, and the like stones, are not soluble in any of the known acids, yet these fame acids, impregnated with the solutions of metals, are capable of penetrating very deeply into them, and tingling them with different colours.

The simple agates and jaspers, and other stones of the like uniform structure, are easily coloured in an uniform manner; but those which are variegated with veins are composed of several different sorts of matter, and therefore are less easily, and less evenly stained. As the tinging matter does not penetrate the several beds, or veins, in the same manner, therefore, all that can be done to these, is to add spots and veins to their natural ones, but they cannot be tinged throughout to one uniform colour, as the chalcedony or white agate may.

If a small quantity of a solution of silver in spirit of nitre be poured upon one of these agates, and the stone exposed to the sun, it will in a few hours be tinged to a reddish-brown colour; and if more of the same solution be added, and it be again exposed, the colour will become stronger, and will penetrate deeper into the body of the stone; and if the stone be not too thick (e.g. more than a fifth part of an inch), and the solution be rubbed on both sides, it will tinge it throughout. Nor is this all the effect, for it will give it several veins and lineations, which were not distinguishable in it before; the reason of which is, that in all these stones there are some parts harder than the rest, and consequentlly more difficultly coloured, and these remaining, therefore, paler than the rest of the mals, make the lines and veins in it.

If there be added to the solution of silver, used for this purpose, a fourth part of its quantity of foot, and as much of tartar, the colour becomes grey; and if, instead of this foot and tartar, the same quantity of plumebo alum be used, the stone will be tinged to a deep violet colour, tending to black. A solution of gold gives agate only a pale brown colour, and that penetrates but a little way into it; and a solution of bismuth gives a colour, which appears white when the light falls directly upon it, but brown when it is held against the fun-hine, or a candle; and all the metallic and mineral solutions, employed in the same manner, affect the stone more or less in the same manner.

The expatting of the stones to the sun is a very necessary article in the process, since without that the tinge is but very faint, and penetrates but to a very little depth. To trace in the chalcedony, or white agate, figures of any determinate kind, the usual method is this: before the stone is polished, mark out the intended figure with the point of a fine needle, and afterwards with a brush, or a pen, follow those lines with a very strong solution of silver.

One would imagine that the dendrite, or delineations of trees in Moos agates, might be imitated in this manner; but it is difficult to give the due blackness of colour, and to mark the figures with a like precision and exactness. See AGATES.

If any stone should, however, be suspected to be adulterated, or counterfeited in this manner, it is easily brought to the trial; for if it be thus made, a small heat over the fire will almost entirely divest it of its colour, and the rubbing a little spirit of nitre or aqua fortis over it will have the same effect. In both cases the stone may, however, be refretted again to its beauty: in the firft, by tingling it anew with the same liquor, and in the latter, by only exposing it for several days to the sun.

It is well known, that by means of fire alone the amethyst, the sapphire, and the other gems, may also be wholly divested of their beautiful colours. The method of doing this is, to put the gems into a crucible, surrounding them with sand, or with reel-fillings; then putting them into the fire, they lose their colour as they become hot, and are taken out wholly colourless. If the white agate be calcined in this manner alone, it becomes of a cloudy or opaque white.
STONE.

white; but if it has before been stained with the solution of silver, those spots or flaws become of a yellow colour, which aqua fortis afterwards has no power to take away. If the agate be calcined first, and afterwards rubbed over with the solution of silver, it receives some spots and lines of brown. The cornelian loses a great part of its redness by calcination, and becomes of a dusky flesh-coloured white; and the corococox fume, treated in the same manner, loses all its colour, and the delineations disappar of two or three places.

There are many stones on which the solution of silver has no effect; of this number are all the gems, rock crysral, and the like. The dendrites of Catalonia is also of this kind; and of this stone the artificers relate an odd phenomenon, which is, that if it be fawn under there is very few delineations observed in it, but if it be split by a blow, it is usually found full of them. The reason of this is only that these delineations are so many flaws and cracks, and the stone breaks easiest in these places.

The effect of the solution of silver is different, as to degree of colour, on different stones. The oriental agate receives from it a deeper and blacken tinge than the common chalcedony. Some agates, naturally distinguished by their yellow spots, receive a purple colour from it. The jade stone, used by the Turks, takes only a faint tinged of brown. The common prime emerald, or root of the emerald, becomes blacker with it. The oriental granite is tinged in many places with a violet colour by it; this is principally effected in the white parts. The solution does not act much on the black ones, only that it takes some of them away. The serpentine marble receives an olive colour from it; but it is remarkable that the amathustes, and the talcs, and other foliaceous stones, are wholly unaffected by it.

There is another method of staining some stones of a colour more truly black than that which the solution of silver communicates to most of them, and with this farther difference, that the colour being produced by fire, has not been destroyed (says Dr. Lewis) either by moderate fire or by aqua fortis. Pieces of different stones, marbles, pebbles, flint, &c. may be rubbed together with a saturated solution of copper made in aqua fortis; when dry, let them be put into a crucible, and kept for a little time in a fire just sufficient to make the vessel almoost red hot. All of them will be thus stained in the parts moistened with the solution of a black colour, durable, and very deep, though it penetrated only a very little way into the substance of the stone.

Dr. Lewis fuscets, from some experiments on the solution of silver applied to different substances, which he has mentioned (Phil. Com. of Arts, p. 350;) that this solution stains stones only in virtue of their containing a calcareous earth, or such an earth as the acids is capable of dissolving: if this be the case, there is no wonder that some of the hard stones should be stained, and some of the soft unaffected by it.

Marble being a substance much softer than agate, receives the colours with much greater ease, and the doing of this in an accurate manner has been the subject of the attempts of many eminent men.

Kircher has given some directions for the staining of marble, which have been translated word for word in the Philosophical Transactions; but they are so indeterminate and uncertain, that nothing can in reality be learned from them. See Colouring of Marble.

Many others have written also on the same subject, but M. Du Fay is the only one whose experiments are plainly and clearly laid down, and may be followed by any body.

This gentleman chose the common white marble without veins for making his experiments, for the same reason that he chose the plain agates, because in the veined ones there are several different sorts of matter, all of which are not to be penetrated with equal ease. The solution of silver penetrates into marble to the depth of an inch, or more, and gives a tinge, reddish or purple at first, and afterwards brown, from which colour it never varies afterwards. It always takes off the polishing by the marble, eating away a part of its surface. The solution of gold does not penetrate so deeply into marble as that of silver, but it gives a beautiful violet colour.

Both these operations are much afflicted by exposing the marble to the sun. The liquors usually diffuse themselves, and spread every way in the marble, so that it is not easy to make any figure with them that shall keep its outline tolerably regular. And this imperfection appears to the lefs, according as the solution is the more satured, so as to dry or crystallize the more speedily. An easy method of avoiding this inconvenience, says Dr. Lewis, is fuggated by the practice of the engraver; for the means, by which he confines the aqua fortis on his copper-plates to the minutest strokes, would doubtless answer the same intention here. The surface of the stone being coated with a proper tenacious substanse, which the acid cannot act upon, as the composition called etching-wax, which consists of refrinos fluids melted with wax, or boiled with oil to a due consistence; and the drawing being made in this ground, so that each stroke may reach down to the stone, it may be presumed that the solution of silver, afterwards applied, will go no where spread farther than the parts thus laid bare. See Colouring of Marble.

The solution of copper gives marble a beautiful green tinge, but it does not penetrate deep, and on the application of boiling water becomes black; when the surface is polished off afterwards, however, it becomes again of a beautiful green. Beside the powerful acidic menfrums, there are many other liquors which have a power of penetrating deep into marble. Of this nature are all the oily fluids; but the exprest oils have this disadvantage, that they leave a satins in the marble which will not suffer it afterwards to take a good polish.

All substances which can penetrate marble, can carry colours into it; but such are most eligible, which having lodged the colours, evaporate, and leave them there, without injuring the stone. Spirit of wine is of this number; it is excellently qualified for the extracting of beautiful tinctures, and links them very deep. Oil of turpentine also has its value, but it does not take tinges so well as the spirit. Some have recommended lixiviums of the first alkaline falls, but they very rarely produce any beautiful colour. In the using of these fluids the marble is to be gently heated, and the spirit is by that means evaporated before it is cooled, leaving its colour always behind.

White wax penetrates very deep into hot marble, and conveys colours into it in a very beautiful and determinate manner. There are, however, but few bodies, which will impart their colours to wax, and therefore this valuable means is of a very limited use.

Several of the gums alone are also able to tinge marble very strongly. Dragon's blood, and gamboge, if rubbed on hot marble, penetrate to the depth of about a twelfth of an inch; the gamboge requires the marble to be hotter than the other, and tinges it to a very beautiful yellow; the dragon's blood tinges to a red in different degrees, according to the heat of the marble.

If these gums have been used to polish marble, there is no farther caution necessary than the cleaning them off.
STONE.

from the surface with a little spirit of wine: but the way to make them sink deeper into the stone, is to take off the polish by rubbing the surface with pumice, or the like, and then the gums sink much farther, and the colours appear very beautiful when the marble is polished again.

Though these gums act alone, yet they will succeed much better if diffused in spirit of wine, and applied with a pencil; for by this means they sink deeper in, and the figures traced out will keep their determinate form and outlines, these solutions of ink, fixing immediately, without spreading any way. It is also remarkable, that the solution of dragon's blood hardens the marble, and renders it less soluble in acids than before; so that if a piece, stained in part with this solution, be afterwards rubbed over with an acid dissolvent, and its surface eaten away to some depth, the parts which are coloured will all stand out above the rest. A tinture of Brazil wood in spirit of wine tinges marble red; and if the heat given to the marble be greater, it becomes purple: but both these colours fade a little in keeping. A tinture of cochineal gives a purplish-red; and the more the oil is heated, the farther the colour penetrates, and the deeper it is.

In oil of turpentine, the colour of cochineal penetrates much deeper into the marble, but it has a brownish cast. Alkanet root, by means of spirit of wine, gives also a red colour, which, if the heat be too great, changes to brown; and this, and most other of the like matters, tinge the marble, in tinture with spirit, to a flight depth; and in oil of turpentine they sink much deeper, but then the oil leaves a greatly appearance upon the marble.

If verdigris be boiled a considerable time in white wax, it tinges marble, when rubbed hot upon it, to a beautiful green, little inferior to that of the coarser emeralds, and the colour spreads itself very equally, and penetrates to a third of an inch deep; if the marble be made too hot, the colour becomes that of the jadé-stone. Alkanet boiled in white wax gives a flesh colour, which penetrates very deep; and the roucou boiled in wax makes a permanent yellow, which also sinks very deep. The best way of heating marble for this purpose is to lay the piece, intended to be stained, upon a bed of sand, a foot of an inch deep, upon an iron plate; this is to be set over the fire, and when of a proper degree of heat, the colour is to be applied. The just degree can only be found by experience, and it varies indeed in almost every colour; but, in general, the finer colours require the marble to be of such a heat, that the hand can just bear to be laid upon it, and the others require a somewhat greater degree than this.

Black is, of all colours, the most difficult to be given in this manner to marble; and perhaps, indeed, it is impossible to impart that colour in any degree of perfection; and that for this plain reason, that all these colours only fill the interstices between the granules of the marble, those granules themselves remaining unaltered; thus, in the other colours, the whiteness of the granules is only a heightening to the tinge, making it brighter, and a little paler; but the whites can never fail to appear distinguishingly as such in black, and by that means destroy that colour.

Dr. Lewis observes, that he has stained the porous marbles, which admit water to sink into them, of a full black colour with china ink, other by applying on the warm marble an ink already made, or by the alternate application of astringent liquors and solutions of iron; but with the more compact marbles this method did not succeed, though they were heated so far as to make the liquors boil upon them; however, by a solution of copper, managed as above related, and by a solution of the metallic part of cobalt in aqua regia, employed in the same manner, the most compact pieces were stained black; though the process requires too great a heat to be practiced on marble without danger of injuring the stone. The colour which solutions of gold communicate to marble, in its deep shades, obtained by repeated applications of the solution, approaches very near to black.

Next to black, blue seems the most difficult, of all the colours, to be given to marble. M. Du Fay, however, having found, by M. Geoffroy, experiments, that oil of the thyme, by long fusing with spirit of sal ammoniac, acquired a blue colour, tried this mixture, and found it succeed very beautifully; but this is one of those colours which require the marble to have but a very small degree of heat, since a greater would evaporate them before the colour had time to penetrate.

When the oil of thyme is digested with the volatile spirit, it becomes first yellow, then red, then violet, and at last of a deep blue. In six weeks' digestion it had acquired a pale blue, and in this state gave little colour to marble: after standing for six months, it was distilled almost to a black hue, and being now applied on warm marble, gave the stain defiled. M. Du Fay also stained marble of a blue colour with tinture of archel. The tinture of it in water is applied on cold marble, and renewed as it evaporates, till the colour is sufficiently deep. He says, that he few pieces of marble thus stained, which in two years were not feebly changed.

The colours of the gums may be laid on when the marble is cold; and on heating it afterwards, they will sink into it. See Colouring of Marble.

There is another very elegant sort of workmanship to be performed on marble, that is, the tracing of figures in relief in it; and this is done much more easily than might be imagined, there being nothing more required to it, than the faving of the parts which are to be left in relief, by covering them with a varnish, and eating away the rest by means of an acid. For this purpose, let the designed figures be traced in chalk upon the marble, and cover them with a varnish, made by dissolving a piece of common red sealing-wax in spirit of wine; then pour on the marble a mixture of equal parts of spirit of salt and distilled vinegar, and this will eat down all the ground, and leave the figures standing, as if engraved with immense trouble. The adding of the colours before described, to these marbles afterwards, in a regular manner, will give them a surprising beauty. Mem. Acad. Par. 1728 and 1732. Lewis's Phil. Com. of Arts, p. 436, &c.

Mr. Müller, in graining some aurum fulminans, made by dissolving gold in aqua regia, and precipitating it with salt of tartar, together with some red glas powdered, and a little water added, found that this mixture stained the onyx, or chalcedony, of which the mortar was made. He was rubbing this mixture together to make an enamel colour, and leaving it three or four days in this little mortar, he found, that not only where it had been rubbed against the bottom of the mortar, but where it had accidentally splashed against the sides of it, and on the surface of the pellet, it had tinged them both very deeply to a fine red, leaving the intermediate parts without, or as it were, onyx, or chalcedony colour, wholly unaltered. The polish of the stone was not injured in the places where it was thus stained, nor could any art get out the colour, though it was tried with alkalis and other sharp liquors. This colour was not given to these parts of the stone of the mortar in simple blotches, but formed itself into regular lines, as we see the natural colours.
of stones do; but this not in the same degree of colour, but some of the lines were deeper, others paler.

This experiment was repeated in several other mortars of the same stone, but without success; on which the stones, of which they were composed, were examined with the help of glasses, and it was found that this mortar chanced to be made of a more flaky chalcedony than any of the others; though it appeared equally solid and beautiful to the naked eye, and bore a polish no way inferior to them. It may be worth while, on this occasion, strictly to examine stones of this chalcedony kind, and on meeting with a plate of one of them of this flaky kind, to cover it with this mixture, and by that means give it a series of lines, which must make it a very beautiful and valuable stone. The polish will not be injured by this; or, if it should, the adding of a new polish will not at all affect the colours. In the same manner the texture of stones, intended for any other experiments in staining, should be considered, and the choosing of proper ones may make this process succeed on them. Phil. Trans. No 1799.

STONE, Medical, a term used by some to express those particular stones, which for their real or imaginary virtues have, at one time or other, been made ingredients in medicinal preparations.

The opinions of the ancients, in regard to the virtues of gems and precious stones, were very whimsical. They supposed that they had certain sympathetic properties, and that the wearing of them on the finger, or carrying of them in the pocket, would cure diseases, render the gods propitious to their prayers, or save them from thunders. These have been deferentially laughed out of the world in our more enlightened times; but it has remained a question, and does so even to this time, whether or not some of the gems have not real medical virtues, naturally resulting from their parts, and constitutive matter. See Gem.

STONE, Meteoric, in Meteorology. Meteoric stones, or aerolites, are those stones which have been observed to fall from the atmosphere. (See Falling Stones.) In addition to the description of these stones, and the particular phenomena attending their fall, under that article, we shall state that numerous facts of a similar kind have since been noticed in various parts of the world; and the evidence of their actual descent from the atmosphere is full and satisfactory, though the mode of their formation still remains involved in much obscurity. The opinion that these stones are of atmospheric origin, and that the elements of which they are composed have been either held in solution in the air, or were formed there by the union of gaseous fluids, appears to us to agree better with the phenomena than any other which has yet been advanced. Though it may be difficult to explain the sudden formation of a solid mass of stone in the air, yet we have instances of a formation somewhat analogous occurring very frequently; thus, during violent thunder-storms, mazes of ice fall down in the hottest months of summer, sometimes weighing several ounces, and even pounds; and were the temperature of the earth constantly below 32° of Fahrenheit, they would remain as solid stones on the surface of the earth. The matter of which these masses of ice are formed, existed previously in a state of elastic aqueous vapour in the atmosphere; but by what process it was suddenly consolidated, during thunder-storms, is at present almost as inexplicable as the formation of meteoric stones. The nature of our atmosphere is but imperfectly known; for though we are acquainted with the proportions of oxygen and azote which it contains, we are not certain whether they are chemically combined, or only mechanically mixed; and with respect to the aqueous vapour, and other substains which are diffused through the different regions of the air, our knowledge is still more imperfect. Thus, though we know that, in the hottest months of summer, an immense quantity of water is rained into the atmosphere from the surface of the earth and seas, yet when this evaporation has continued for several weeks without rain, and consequently the atmosphere is charged with water, yet if it be examined by the hygrometer, it is not found as a liquid state. The importance of electricity, in all atmospheric phenomena, is universally admitted; but the mode of its operation is very little known. When these subjects are better understood, we have no doubt that the formation of meteoric stones will receive much elucidation. From the examination of rain-water, collected at a distance from towns, it is proved that lime and other substances exist in the atmosphere; and it is not improbable that the elements, of which meteoric stones are formed, may be sublimed from volcanoes, and diffused through the higher regions of the air, intermixed with hydrogen, or other inflammable gases (of greater levity) at present unknown. When these explode suddenly, large concretions may be formed; or, by slow combustion, they may form flowers of sulphur, or other substances, in a diffused or less compact state. In the Annales de Chimie, tom. ixxxv. p. 262, many curious instances of this kind are related, from which we select the following, as intimately connected with the descent of meteoric stones.

We ought probably to rank with meteoric stones the ignited bodies, or fire-balls, which are only distinguished from them by their substance not being metallic. Like meteoric stones, they generally fall in the warmest months, and in calm weather; they burn in the same manner, and traverse their path with the same velocity; their explosions are nearly similar, and that of 1772 had a rotation round its centre. These ignited globes have a roundish form and gelatinous consistence. A globe of fire which fell in the East Indies, in 1218, left, after a dreadful explosion, a round large heap of gelatine, of tolerable consistence. A similar mass, but grey and frouzy, was found at Coblenz, after the explosion of a ball of fire. Journal de Physique de Gilbert, tom. vi.

Silberschlag relates having seen the residue of an ignited globe, which presented a gelatious appearance, of a whitish colour.

The meteors called falling stars, do not appear to differ from globes of fire; they leave behind them gelatious mazes,
STONE.

maisses, falsely attributed to birds of prey, since they contain nothing which announces an animal origin. If igneous globes do not always leave similar residues, it is owing to their being composed of entirely combustible elements, and to their being consequentially dissipated before they reach the ground. We may refer to this kind of phenomenon, the globe of fire which, according to Geoffroy, burnt in the Palace du Quelen threat on the 4th of January, 1771, that which was observed in Anaphantine in 1803, and in Suffolk in 1802. With these globes of fire may be classed the flowers of fire, which can only be distinguished from them by their greater diffusion. In the fire-balls, the flame diffused substance is concentrated in one mass. A shower of fire made great ravages in Germany in the year 834, and burnt up whole villages. Another shower of the same kind fell, in 1571, in the grand duchy of Hesse: after a dreadful explosion it flowed through the streets, but without causing the destruction of the houses. A third shower of fire took place, in 1678, at Sachsen-Haufen, and the inflamed matter burnt half an hour in the streets before it was extinguished. Finally, that which fell over the city of Brunswick in 1721, was so violent, that they attempted in vain to extinguish it by means of water. The difference remarked between showers of fire, and those of an oily substance, which have frequently occurred, appears to consist in this—the substance of the former is in a state of phosphorescence, which is not the case with the latter. We may place after these singular flowers, those of a mucilaginous nature. As chemistry shows that mucilage approaches to the nature of honey and sugar, we might refer the honey-dews, as they are called, to the fame phenomena, for it is difficult to consider them as excretions of plants, as some have asserted. One of these flowers of dew took place at Ulm so recently as 1802, and in such abundance, that every thing exposed to it, as well as the surface of stagnant waters, was covered with it. It may, perhaps, be presumed, that the matter of which meteoric fônes and fire-balls are formed, is sometimes precipitated, in a very minute state of division, in flowers of sulphur or sand, and what have been falsely called flowers of blood.

The shower of brimstone which fell at Copenhagen in 1646, was accompanied with heavy rain, and the air was infected with the smell of sulphur. A shower of the same kind also took place at Copenhagen in 1665, after a very violent storm: the substance precipitated, emitted a strong smell of sulphur when thrown into the fire, and with spirit of turpentine it formed a kind of balsam of sulphur. In 1801, the rain which fell at Raftstadt was so sulphurous, that it was used to prepare matches. A red mineral shower fell in Westphalia in 1543, at Lowen in 1760, and at Embden in 1571: the latter was so extensive, that over the circumference of 10 or 12 leagues, all bodies exposed to it were dyed red. Similar showers fell in Ruffia, Swabia, near the lake of Constance, and at Lucarno, in Upper Italy; in the latter end of 1775. At Lucarno the atmosphere became quite red previously to the shower. The rain was almost as thick and heavy as snow, and the residue left by it was reddish, with an earthy appearance. In January 1810, a similar shower fell in the mountains of Placentia; its first appearance was white, but after some elapses of thunder it became red, and finally white again. In certain places it was of a flesh colour, but in others it was of a very deep red, and it always preferred its colour after having been melted. There are too many testimonies in favour of showers of sand having fallen, to allow us to deny the fact. One was observed at Bagdad in 930. (Quatre-mere Memoires fur P'Egypt.) Long before it fell, the sky was darkened by a red cloud, from which an immense quantity of reddish sand was precipitated, entirely different from the sands which exist in that country. A shower of ferruginous rain was observed in the Atlantic, lat. 45° and long. 53°, at a distance of five or six leagues from the main land: this shower was preceded by a strong light; it lasted upwards of nine hours, the air being calm during the time.

Showers of sulphur appear to admit of a more easy explanation than many of the above phenomena. Sulphuretted hydrogen gas is constantly emitted into the atmosphere from volcanoes and other sources; were this collected and exploded, or slowly burnt, a quantity of liquid sulphur would be precipitated.

The writer in the Annales de Chimie, before referred to, has attempted to generalize the circumstances attending meteoric fônes, but he appears to want sufficient data to establish some of his conclusions.

“First: The fall of these fônes,” he observes, “is most frequent in the months of June, July, and August. Of 65 or 70 of these recorded showers of fône, nearly two-thirds have occurred in the above months; and the influences of their occurrence in the winter months are very rare indeed.

“Secondly: From a catalogue drawn up with great care it appears, that only seven instances occur of fônes falling between midnight and noon. On one occasion only, this phenomenon was observed between 11 o'clock in the evening and 6 o'clock in the morning, whilst we have evidence of thirty-six having taken place between noon and midnight, and the greater part of these fell between 5 o'clock in the afternoon and sunset.” We may observe, that the defect of these fônes could not be so frequently noticed in the night as during the day, and therefore we do not think the author's conclusions on this head entitled to much notice.

“Thirdly: The number of these showers of fône decreases with the distance from the equator. These phenomena are more frequent in Italy, France, and Germany, than in the northern countries of Europe.

“Fourthly: We know,” says the author above referred to, “that no falls of sulphur having taken place in cloudy weather, or during a high wind, or a heavy continued rain or snow.”

The weather has been noticed during forty-three falls of fônes; twenty-nine fell in warm and serene weather, and two when the sky presented some scattered and inflatated clouds; the remaining twelve were accompanied by violent storms of rain and hail. Out of twenty-nine falls of fônes which took place in serene weather, twenty seemed to issue from a very extensive but round cloud, black or variable in colour, according to the colour of the fônes themselves. Thus, the cloud was white in the fall which took place at Burgos, and the fônes were also white. At all times the cloud seems essential to these meteors, for from it proceeds the noise which accompanies or precedes the fall of the fônes, as also the fônes themselves.

It may not be improper to remark, that the great fône which fell on the wold of Yorkshire, was unaccompanied with any meteor or light, and the sky was hazy. The progres of the great meteor in 1783, was unattended by any cloud; and though it exploded in various parts of its course, no desert of fônes was noticed. The cloud, which, from various authentic accounts, appears to be generally attendant on the fall of meteoric fônes, is supposed by some philosophers to contain these elements in a vaporous state. This cloud has sometimes been observed to have a rapid motion round its centre. During a very considerable fall of fônes in the department of the Lot and Garonne,
STONE.

Garonne, in France, Sept. 5th, 1814, a small white round cloud, but greyish in the centre, appeared to move with great rapidity over the district, where the flones fell: explosives, accompanied by lightning, immediately succeeded: the sky in other parts was serene; at the same instant, the cloud appeared to divide into three or four parts, and fall to the ground, leaving behind a train of rainbow-coloured light, with a red point at the top. The flones in their fall appeared to diverge, striking the ground obliquely in various directions. They do not differ in their composition from other meteoric flones. We have thus endeavoured to select some of the most interesting facts that have been recently noticed in this department of meteorology; and in the present state of information on the subject, it is of far greater importance to science to collect facts, than to advance the most elaborate speculations on the mode by which these singular bodies are formed.

It has been stated by Mr. Bakewell, in his Introduction to Geology, that what we already know with respect to the formation of flones in the atmosphere, may elucidate, in his opinion, the appearance of new flones, which have thone for a few years and then disappeared. The simplest form of matter with which we are acquainted, is that of gas or vapor.

"Let us for a moment consider the elements of which all terrestrial substances are composed as existing in this simple state, when the fiat of Almighty Power impressed upon the whole the various affinities by which they coalesced, and formed a fluid or solid mass. During their union, intense light and heat would probably be evolved, presenting to the distant inhabitants of the universe the appearance of a star of great brilliancy, but of short duration. The sudden concretion of flones makes in the atmosphere, with the intense light attendant their formation, may be analogous to the gaseous state of a planet." As we consider, however, that the phenomena of the appearance and disappearance of flones are satisfactorily explained upon other principles, we shall content ourselves with referring to the publication above cited, and to the article Star.

STONE, Rocking or Logan, in Antiquity, a name given to a majestic mass, the weight of which, from moving on a small point, or pivot, was susceptible of being moved, or rocked to and fro, with very little force. These flones appear to have been objects of curiosity, wonder, and superstition, in remote ages, and in different countries. Many of them are still remaining in the mountainous parts of England, Wales, and Scotland, as well as on the European continent. Some of the ancient writers have noticed these flongan objects; and certain modern antiquaries have studied themselves, and tried with their readers, in alluing to them different supernatural properties. Pliny says, that at Harpasa, a town of the Lofa, there was a rock of such a wonderful nature, that if touched with the finger it would shake, but that it could not be removed from its place with the whole force of the body. Ptolemy Hephthion mentions a Gygonian flone near the ocean, which might be agitated by the talk of an alphabet, but could not be removed by the greatest human force. Dr. Stukeley considers the word Gygionus to be purely Celtic; and says, that Gwngog signifies Mottains, the rocking-flone. Although it is very evident that most of these rocking-flones are strictly natural in form and situation, yet it is generally supposed that others are artificial, or placed in their respective positions by human art. In the parish of St. Lewis, Cornwall, on the coast, on a promontory called Castle-Terry, are three groups of rocks, on the top of one of which was formerly a very large flone, so evenly poised, that by a very slight pressure it might be moved from one side to another. It was popularly called the Logan-flone, and has generally been visited as an object of curiosity; but it is now immovable. There are other rocking-flones, which are so peculiarly shaped and situated, that Dr. Borlase, and some other antiquaries, consider they were erected by human strength. Of this kind the doctor thinks the great Quoit, or Carnkew, in the parish of Tywideneck, Cornwall, to be. It is thirty-nine feet in circumference, and four feet thick at a tangent, and stands on a firm substratum. There is a remarkable flone of the same kind on the island of St. Agnes, in Scilly. The under rock is ten feet six inches high, forty-seven feet round the middle, and touches the ground with no more than half its base. The upper rock rests on one point only, and is so nicely balanced, that two or three men with a pole can move it. It is eight feet six inches high, and forty-seven feet in circumference. On the top there is a batin hollowed out, three feet eleven inches in diameter at a medium, but wider at the brim, and three feet deep. From the globular shape of one flone, the doctor thinks it highly probable that it was rounded by human art, and perhaps even placed on its pedestal by the strength of man. In Sithney parish, near Helston, in Cornwall, stood the famous Logan or rocking-flone, commonly called Mén-Amber, g. d. Men-an-Bar, or the top-flone. It was eleven feet in length, six feet wide, and four feet deep, and so nicely poised on another flone, that a little child (as Mr. Scawen in his MS. says) could instantly move it, and all travellers that came this way defied to behold it; but in the time of Cromwell, when all monumental rocks were desecrated, one Superflous. Then gre is a nor a Pendennis, by much ado, caufed it to be undermined, and thrown down, to the great grief of the country." Borlase says that it has marks of the tool on it. There is a rocking-flone in Perthsire, near Balvaird Castle, in the Ochil hills, Scotland, on the estate of Mr. Murray of Conland.

That these rocking-flones were employed by the Druids, to surplice and deceive the credulous, is very probable; but tradition has not informed us for what express purpose they were intended. Toland thinks the Druids made the people believe that they only could move them, and that by a miracle; by which pretended miracle they condemned or acquitted the accused, and often brought criminals to confess what could in no other way be extorted from them." Carew, in his "Survey of Cornwall," 4to, thus apostrophizes the Logan-flone:

"Be thou thy mother Nature's work,
Or proof of giant's might,
Worthless and rugged though thou flow,
Yet art thou worth the fight.
This hugey rock one finger's force
Apparently will move;
But to remove it, many strength
Shall all like feeble prove.

Borlase, in his "Antiquities, &c. of Cornwall," folio, 1769, has devoted a chapter to this subject, and gives also views of different rocking-flones.

STONE of Scandal. See SCANDAL.
STONEs, in Mythology, were objects of religious worship among the ancients, before the true church was invented. They were unburnt shapeless masses, called by the ancients ELEUSIS. (See BERTYLES.) Pausanias speaks of the statues of Hercules and the Cupid, which were merely such masses of stone. He adds, that there were seen, even in one place, 30 square stones, which had the names of 30 many divinities.

STONEs for Mills. Preparation of. The means of forming them for the purpose of grinding. In small corn-mills, where only one pair of stones is in use, they are, it is said, roughed on the surface, to enable them to tear, bruise, and reduce the grain, by the use of a small hand-pick. Stones thus prepared and refined were used for making corn-meal, which is best and most refined when rough, and large in the grain; but they are not capable of grinding barley or peas to that fineness of flour which is necessary for some uses. It is requisite to have a separate pair of stones for this purpose, which are dressed on the surface, with a small chisel, in grooves running in from the circumference to the centre, so as to form a wheel, in stone wool.

STONE-Dike, in Agriculture, that fort of dike or mound which is formed with stone and earth. Those dikes should, it is said, consist of a double face to two-thirds of their height, and the other third be of single stones, built up in an open form and manner, so as to hang firmly on each other. They are made in the Highland sheep districts, where this manner of forming them is much had recourse to, five or five and a half high from the surface of the ground. A dike thus built, when well executed, and filled with thorough-bred, thick, and defensible, it is said, to be a kind of animals, none of which are fond of venturing over it; whereas a green sod on the top of a double-faced wall invites the sheep to attempt clearing it, which they not unfrequently do with facility. These dikes are equally durable and cheap; even more so than the turf or sod covered or coped stone-walls, while they are greatly more effectual. They are the most proper for confining of sheep; and on farms purely of this kind, are perhaps the best fort of convenience for restraining them of any yet known. They have different names in different sheep districts.

The term is sometimes written stone-dyke.
STONE-Drain. See SPRING-Drain and SURFACE-Drain.
STONE-Picker. See PICKER.
STONE-Pickers, the name of such persons as are employed in picking stones from off the ground. In order to prevent the loss of time in filling and emptying the barrows, and that of having recourse to the team, the use of one horse and a light cart is advised, which attending seven or eight men, boys, and girls, may run over forty acres in about four days. It is advised by Mr. A. Young, that by farthing in a dry season, an opportunity should be taken to stone-pick the grass and clover fields intended for mowing. In this work, no stones are, he says, however, to be taken, but such as would impede the scythe. It is often the case, he adds, that the pickers, who generally like the work, will over-pick if they are not attended to, and propose to pick fields which are not to be mown; but this is on no account to be permitted, if the stones be not much wanted. It has been often remarked, and is a known fact, that too much stone-picking has done a very sensible mischief, in many cases where picked by authority of parliament for turnpike roads. And Mr. Macrae, of Suffolk, affirms it experimentally.

Observations have been made in other places, which clearly shew that the stones should not be wholly picked off many farms of land.
STONE-Roller. See ROLLER.
STONE Arabia, in Geography, a settlement in Montgomery county, New York, on the N. side of the river Mohawk, four miles from it, begun by some Germans; situated on an eminence about 54 miles W. of Albany. The soil is excellent, and the people industrious. It has two churches, a Calvinistic and a Dutch Reformed. Stone Arabia is a part of the polit-township called Palatine, (which see,) 51 miles from Albany, erected from the W. part in 1808. This polit-township is well watered and has many fine mill- sects, the land of which is under high cultivation. It was first settled by some German families in 1724. Palatine village has about 35 dwellings, some stone, &c. and a stone church; 55 miles from Albany. In 1810 the population of Palatine was 2111.
STONE Creek, a river of West Florida, which runs into the Mississippi, N. lat. 32° 8'. W. long. 91° 13'.
STONE Indians, Indians of North America, situated on the Aminiboine River. See ASHIBOINE.
STONE Island, a small island near the E. coast of Newfoundland, near Cape Breton, and one of the three islands which lie off Cape Breton.
STONE Mountain, a mountain that lies between the states of Tennessee and Virginia. N. lat. 36° 40'. E. long. 81° 40'.
STONE's River, a river of Tennessee, which runs into the Cumberland, fix miles N.E. of Nashville. N. lat. 36° 5'. W. long. 87° 49'.
STONE's Fort Gut, a creek on the S.W. side of the island of St. Christopher's, E. of Old Road bay, and between that and Sandy Point, with a fort on a point of land, on the W. side.
STONE Reef, a small island and rocks of Denmark, in the Little Belt, near the N. coast of the island of Allen.
STONE River, a river of North America, which runs into Lake Athapescow.
STONE, in Commerce, denotes a certain quantity or weight of some commodities.
A stone of beef, at London, is the quantity of eight pounds; in Herefordshire, twelve pounds; in the North, sixteen pounds.
A stone of glass is five pounds; of wax, eight pounds.
A stone of wool (according to the statute of 11 Hen. VII.) is to weigh fourteen pounds; yet in some places it is more, in others less; as in Gloucestershire, fifteen pounds; in Herefordshire, twelve pounds.
Among horse-couriers, a stone is the weight of fourteen pounds.
The stone troy, in Scotland, contains sixteen pounds, the pound being two marks, or sixteen ounces.
The stone, called flax in Germany, varies very much in different parts of the continent; at Amsterdam, a flem or stone is eight pounds; at Berlin, the centner or quintal weighs
STO

weights five drams or stones, each of twenty-two pounds: at
Hamburg and Prague, a stone of flux is twenty pounds, and
a stone of wool or feathers is ten pounds. See

WEIGHT.

STONE-Sucker, in Ichthyology. See PETROMYZON.

STONE-Ware. See POTTERY.

STONE Blue, a preparation used in washing of linen. See

BLUE, INDIGO, and SMALT.

STONE-Braalh, in Agriculture, a term sometimes applied
to a looie flivory fort of soil or land. It has a surface of
greater or less depth, mollify of a looie, dry, friable fort of
fandy, lime-flowy, chalky, or loamy materials, which seem to
be formed from abraded matters of these flowy kinds, and
abounding with many fragments of them. In many dif-
tricks and places, these lands of this fort are chiefly of the lime-
floes and chalk kinds. It is a fort of land that prevails
much in some counties, as in Oxfordshire, Somerfethshire,
Bedfordsire, and probably in some others. It is sometimes
of a springy, spewy nature, refting upon deep beds of a blue
clayey, marly quality, under which is a vein of white marle,
extremely rich in calcareous matter, and below that rock of
the rough white lime-flowy kind. The blue and white
matters have occasionell been spread out over the surfaces
of these lands, and found very beneficial. These lands, in
some cafes, form excellent soills for the turnip husbandry, and
are very productive in wheat, especially where they are of the
more calcareous kinds.

They ansuer well for inclosing too in some inftances, in-
stead of being cultivated on the common field plan, as is still
too much the cafe in many places, notwithstanding the im-
provements which husbandry has lately undergone.

A variety of different covenants are suppofed necessary
for tenants in cultivating stone-braalh farms, as may be feen
in the Corrected Report of the Agriculture of the County of
Oxford. See SOIL.

STONE-Breach, the name of a perennial plant of the
weed-kind, common in pasture grounds. The root has a
sharpth and aromatic taste. The stalks are round, fkreaked,
and reddish towards the bottom. The leaves are smooth, of
a dark green, and divided twice, into long, narrow, sharpl
segments. The footstalks are membranous at the bafe. The
flowers grow in loose umbels, and are of a pale yellow
colour. The seeds are oval, skreaked and red at the top. It is
a plant of the faxifrage kind, which has been suppoled ben-
eficial in meadow lands, as improving the qualities of the
cheese and butter, which are made from the milk of the cows
which are pastured upon them.

STONE-Brether, in Ornithology, the name of a small
bird of the canathen, or fallow-finch kind, the motacilla rubi-
cola of Linnaus, called by some authors rubetra and muf-
sicapa, and in some cafes the fome-smich and the moor-sitting.
See Motacilla.

The head, neck, and throat are black, but on both sides
of the latter there is a white bar; the feathers on the back
are edged with towny; the lower part of the back, jiff

VOL. XXXIV.

above the rump, is white; the end and exterior side of the
two outermost feathers of the tail are of a pale rufus-colour,
the reins are black; the breast is of a deep reddish-yellow;
the belly of a lighter hue; the quill-feathers dusky, edged
with dull red; those next the body marked with a white
spot near their bottoms; and the coverts of the wings are
adorned with another. The head of the female is ferrug
ous, spotted with black, and the colours in general less
vivid: in both sexes the legs are black.

These birds are common, during summer, on heaths and
gorly grounds, but in winter disappear into marshes, &c. with-
out quittit the island: they make a very loud and often
repeated note. Pennant.

STONE-Crop, in Botany. See SEDUM.

STONE-Crop Tree. See Crenopodium.

STONE-Curlew, in Ornithology, the English name for the
cuculenuus, a bird of the colour of the curlew. See Stone-
Curlew.

STONE-Smich, a common English name for that spe-
cie of canathene, which we more frequently call the fome-
chatter.

STONEHAM, in Geography, a township of Middlesex
county, Massachufetts, incorporated in 1725, and containing
407 inhabitants; 10 miles N. of Bolton.

STONEHAVEN, a sea-port town in the parish of
Dunottar, and county of Kincardine, Scotland, is 107 miles
by sea from Edinburgh. It consists of two large streets of
houses, built on fens granted by the earls maritichal,
within whose estate, before their forfeiture, it was situated.
There is a fine harbour formed by a natural basin, defended
by a high rock upon the S.E., which extends into the sea,
and upon the N.E. by a quay, very convenient for the un-
lading of goods.

A manufacture for house-linen has been established here,
and the town has been improving for some years past.
The sheriff’s court for the county was removed from Kincardine
to Stonehaven in 1650, and in consequence of the gaol for
the county, and county courts held here, the town is much
benefited. The public revenue of Stonehaven consists
chiefly of shore dues, which amount to about 45L. annu-
ally. A great deal of lime is brought to this part; and
from four annual fairs, the revenues of the town are aug-
mented.

Stonehaven is a borough of barony, of which the jurisdic-
tion is by the charter vested in magistrates choften by the
superior and feuers. In 1793 the town contained 1072 in-
habitants, independent of the additional suburb. —Beauties
of Scotland, vol. iv. Carlile’s Topographical Dictionary
of Scotland, 2 vols. 40. 1813.

STONEHENGE, in Antiquity, an assemblage of up-
right and proffate stones on Salisbury plain, England, sup-
posed to be the remains of an ancient Druidical temple, which
claims particular notice in this work, as being often referred
to in foreign and English books, and from having been very
inaccurately described in most of those publications. Next
to the vast and far-famed pyramids of Egypt, Stonehenge,
and other remains of the same class, rank among the most
curious and most remote monuments of antiquity. These
are all anterior to written evidence, and are consequently
involved in the most abstrufe mystery. Hence they have
also occasioned much speculation; and many volumes and
essays have been written by English and continental anti-
quaries, with a view of explaining the origin and uses of
such structures. On the present occasion, it is intended to
describe clearly and explicitly what Stonehenge is, and
what it has been; to detail the opinions of different writers
on the subject, and thence endeavour to deduce a probable

Man and
and rational inference refleeting this and other similar monuments.

Stonehenge, situated about two miles directly west of Avebury, and seven north of Salisbury, in Wiltshire, is an ancient and certainly very extraordinary monument of a remote age. From its singularity, and the mystery attending its origin and appropriation, it has excited more surprize and curiosity than any other relic of antiquity in Great Britain. When viewed at a distance it appears but a small and trifling object, its bulk and character are lost in the extensive space which surrounds it; and even on a near examination, it generally fails to satisfy or gratify the expectations of the stranger, who usually visits it with exaggerated prophecions. To behold this "wonder of the world," as it has been termed, with interest and satisfaction, it should be viewed with an ardent eye, and contemplated with a mindstoried with antiquarian and historical knowledge.

In various parts of the united kingdom, and also in foreign states, several circular erections of upright stones are to be found, some of which consist of a single, and others of complex circles; but Stonehenge is of a different and different character and clafs, and is, we believe, wholly unlike any other monument now remaining in Europe. Many of the stones in this temple have been squared or hewn by art; and on the top of the outer circle has been raised a continued series of squared stones, attached to the uprights by mortises and tenons, i.e. regular cavities in the horizontal stones, and projecting points on the perpendicular ones; whereas nearly all other examples, of what is generally called Druidical circles, are composed of rough, unhewn stones, and are without impostes.

By the plans, view, elevations, &c. in Plate Stonehenge, it is presumed the reader will be enabled to comprehend clearly and readily the original and present form, arrangement, and proportions of Stonehenge. A is the ground plan of the stones, as remaining in 1816: the darker parts shew those that are standing, and the light tints the fallen stones, or fragments; whilst the dotted lines indicate the impostes, or stones refting on the uprights. B is a view of the structure from the south-west, shewing part of the ditch and vallum; also two stones attached to the vallum, and remote from the body of the temple. C is a geometrical elevation on the north-west side, to shew the difference between the temple and the vallum c, the stone d within the ditch, and the stone a, still farther from the temple. Two stones, one now standing, a, and the other fallen, d, is presumed, formed part of a long avenue, similar to others at Avebury (see Avebury); b, a barrow; c, the vallum, rising on the outside of the sacred area. D is a ground plan of the temple, as supposed, by Dr. Smith, to be its original state. E is a section of the work on the line A B of plan D. The present appearance of this monument (see view B, taken from the south-west) is that of a confused heap of erect and fallen stones. The original arrangement of these (see plan D, vew E, and elevation C) may, however, be readily understood; for by the position and situation of the yet standing and prostrate members, we are enabled to judge of the number and ftate of those which have been removed. The whole consisted of two circular and two other curved rows, or arrangements of stones, the forms and positions of which are laid down in the plan, elevation, and fection, D, E, and F. (See Plate Stonehenge.) Horizontal stones, or impostes, were laid all round, in a continued order, on the outer circle; and five similar impostes on ten uprights of the third row. According to the plan referred to, Dr. Smith represents two other smaller trilithons, as forming part of the third row. The whole is surrounded by a ditch and vallum of earth, connected with which are three other rows. The vallum does not exceed fifteen feet in height, and is exterior to the ditch. Through this line of circumvallation there appears to have been an grand entrance from the north-east side, and this is decidedly marked by two banks and ditches, called the Avenue. Approaching Stonehenge in this direction, the attention is first attracted by an immense uncultifed stone, called "The Friar's Heel," which is now in a leaning position, and measures about sixteen feet in height, c. a. Immediately within the vallum is another stone, lying on the ground, three sides of which bear the fame marks of tools as the large uprights, and was evidently once standing. In length it measures twenty-one feet two inches, of which three feet six inches appear to have been formerly under ground when it fould upright. Its distance from the fence last-mentioned is one hundred feet; and it is nearly the fame distance from the outside of the outermost circle of the monument. Each impost of this row has two mortises in it, to correspond with two tenons on the top of each vertical stone. The impostes were connected together in such a manner, as to form a continued series of architraves. The uprights in this circle differ from each other in their forms and sizes; but their general height is about fourteen feet, and the measure of their sides seven feet by three. The space between them also varies a little; that between the entrance-ffones (see Plan D, a) is five feet, being somewhat wider than in the others. The diameter of this circle is one hundred feet, and the number of upright stones it originally contained, thirty; of which seventeen are still standing, but there are no more than five impostes. (Plan A, g.) At the distance of eight feet three inches from this outer circle, is an interior row, which, Dr. Stukeley remarks, consisted in its original state of forty upright stones. Wood, in his account of Stonehenge, states their amount at twenty-nine only, and affirms that they were formerly covered with impostes; but Smith, in his "Choix Gaur," specifies thirty. The stones of this circle are much smaller, and more irregular in their shapes, than those of the outermost row, and also differ from them in species. The number standing is only eight, but there are the remains of twelve others lying on the ground. A few particulars reflecting this circle claim attention. Dr. Stukeley, in his ground plan of Stonehenge, has placed the two stones at the entrance, (Plan D, b, 6,) a little within the range of the others, and observes, "that the two stones of the principal entrance of this circle, correspondent to those of the outer circle, are broader and taller, and set at a greater distance from each other, being rather more than that of the principal entrance into the outer circle. It is evident, too, that they are set somewhat more inward than the rest: so as their outward face stands in the line that marks the inner circumference of the inner circle." A stone lying near the above, and apparently belonging to this circle, resembles the impost of a small trilithon, and most probably gave rise to the inference of Wood, that all the stones of the smaller circles had impostes. See Plan A, g.

Within the circles just described are arranged two inner rows of stones, one of which constitutes the grandest portion of Stonehenge. It was formed by five distinct trilithons, or two large upright stones, with a third laid over them as an impost. Dr. Smith conjectured that this arrangement consisted of seven pairs of uprights, with an impost to each pair; whilst Dr. Stukeley gave them the name of trilithons, or three stones. The largest trilithon was placed in the centre, opposite the entrance, and measured, when
STONEHENGE.

when standing, exclusive of the impost, twenty-one feet six inches in height (Plan D, d); those next to it, on each side, were about seventeen feet two inches (D, e, f) ; but the others were not more than sixteen feet three inches (D, s, f). Thus we perceive a progressive rile in the height of these trilithons. Besides, the stones are evidently more regular in their shapes, and more carefully formed, than those in the outer circle. At present, we find that only two of these trilithons are perfect (Plan A, z, and g). One of the uprights is standing at z; but leans inwards, and rests on 10. The next trilithon, s, fell down in the year 1787, and it is remarkable, that this is the only alteration recorded of Stonehenge. At s, one of the uprights is standing; but its corresponding stone and the impost have fallen, and are broken into several pieces.

The interior row of stones which next claims attention, consists, according to Stukeley, of nineteen uprights, without impost; but their original number is differently stated by other authors. These stones "incline to a pyramidal form." The most perfect among them, according to the measurement of Sir Richard Hoare, is seven feet and a half high, twenty-three inches wide at the base, and decreases to twelve inches at the top. Another is remarkable as having a regular groove from top to bottom, and as being "bevelled almost to an angle on the inner side." For what purpose the groove has been formed, it is impossible to conjecture; and it is equally difficult to say whether the hollow has been formed by nature or art. (D, z; and A, 10.)

The altar-stone, as it is usually called, lies flat on the ground, and occupies the cove, or adytum of the temple. Two other stones belonging to this monument remain to be noticed: they are situated close to and within the vault, one on the south-east side, and the other on the north-west side; the former measures nine feet in height, and has fallen from its base backwards on the vault; but the latter is not more than four feet high; and both are rude and unhewn. Two small hollows likewise appear adjoining the bank, which merit particular attention in a description of Stonehenge. Dr. Stukeley considers them to have been the sites of two altar stones, and the cavities round them are conjectured to have received the blood of victims. The fallacy of the doctor's opinions, however, on this subject, is sufficiently proved by the investigations of Sir Richard Hoare, who, upon digging into them, found one to contain a simple interment of bone.

The total number of stones of which Stonehenge was composed, according to Dr. Smith's plan and calculation, in its complete state, was one hundred and twenty-nine. Thus, the outer circle contained thirty, with thirty impost; the second, or inner circle, thirty; the third interior row, fourteen, and seven impost; and the fourth interior row thirteen; the remainder are the altar-stones, the three stones adjoining the agger, and the large stone in the avenue.

Natural Quality of the Stones.—Those of the outer circle, and third row, with the stone in the avenue, and those adjoining the vault, are, according to Dr. Townshend, in Tracts and Observations on Natural History, &c. all "of a pure, fine-grained, compact sand-stone, and only differ a little in their colour; some of them being white, and others inclining to yellow." These stones resemble precisely in their quality the grey-weathers, and numerous other detached masses which lie on the surface of the Downs, in the vicinity of Avebury and Marlborough. The second circle, and the interior row, consist of a "fine-grained grünstein," interpersed with black hornblende, felspar, quartz, and chlorite, excepting four in the circle; one of which is a fiddleous schist, another an argillaceous schist, and the others horn-fine, with small specks of felspar and pyrites. The slab, or altar-stone, is different from all these, being a kind of "grey cos, a very fine-grained calcareous sand-stone," which strikes fire with steel, and contains some minute fragments of silver mica. Many persons have absurdly supposed that these stones are artificial, and formed in moulds.

The mystery of Stonehenge, the legendary stories connected with it, and the natural and artificial features of the surrounding plain, are certainly calculated to make strong impressions on the mind of every spectator. The area of the temple, as may be readily supposed, has excited the attention of the curious in a high degree, and, consequently, has been examined with considerable care by different antiquaries. Stukeley, indeed, informs us, that a tablet of sin was found there in the reign of Henry VIII., and would wish it to be believed that it was a memorial of the founders, because the character engraved upon it were unintelligible to the most learned antiquaries of the age. It is much to be regretted that this relic is lost. Mr. Cunliff investigated this spot and the adjoining barrows with great care, but could only find a few fragments of Roman and British pottery, with some charred wood and animal bones; such as were dug up in the vicinity of the Roman British habitations on other parts of the plain.

Avenue and Curfus.—But though the area of this monument affords few materials of interest, the surrounding plain deserves particular attention. This is covered with a profusion of barrows, unparalleled in any spot of similar extent in England, and probably in the world. Many of these were opened by Sir Richard Hoare and his indefatigable coadjutor, Mr. Cunliff, and were found to contain, in some instances, cists filled with burnt bones, and in others entire skeletons, with various relics of British art. Some other objects here, however, beside the barrows, present themselves to our notice. The principal of these are the Avenue and the Curfus, the former of which has been previously noticed. It is a narrow strip of raised ground, bounded on each side by a flight bank of earth, and extending in a straight line from the entrance through the vault of Stonehenge on the north-east to the distance of five hundred and ninety-four yards, at which spot it divides into two branches, one of which continues southward, and is seen between two rows of barrows, while the other proceeds northward, and approaches within a few yards of the curfus. The left is a very curious and interesting appendage to Stonehenge, if such it can be properly considered, and certainly ranks among the most perfect vestiges of this fort that are to be found in our country. It is a flat tract of land, bounded by two parallel banks and ditches, and is situated about half a mile N.E. of the temple; it measures one mile five furlongs and one hundred and seventy-six yards in length, and one hundred and ten yards in breadth. Its direction is from east to west, and at the former extremity is a mound of earth, reminding a long barrow, which stretches entirely across it. The western extremity is deflected of any mound like that at the eastern end; but there are two barrows, irregularly placed within the area of the curfus, a part of which appears also to be cut off by a flight bank. The original purpose of this it is difficult to determine, for we can scarcely suppose that if (as would seem most probable from the existence of the mound) the chariots started from the east end, they would drive over this bank to the termination of the course at the west end. We should therefore be inclined to think it had been raised at a later period for some object different from racing, did we not perceive that another similar bank is thrown across a second and smaller curfus, which is situated at the distance of nearly a mile from the
larger one. From the near resemblance of the above work to the curiaus of the Romans, it seems reasonable to suppose, that if the earth-works were not formed by that people, they were made in imitation of them, and by a class of people familiar with their manners and customs. Having thus given a full, and, it is hoped, clear account of what Stonehenge has been and is, it will be necessary to review the writings of those antiquaries who have published their opinions on the subject. See HIPPENSTIN.

Writers on Stonehenge.—The earliest account of Stonehenge occurs in the writings of Nennius, who lived in the eighth century. He narrates the story of the massacre of four hundred and sixty Britons, at a conference between King Vortigern and Hengist, at or near the spot on which our monument is situated, and attributes its erection to the Britons, who thereby endeavored to perpetuate the memory of this tragic event. The historical Triads of the Welsh also refer its origin to the same cause, and relate that it was constructed by Merlin, at the desire of Aurelius Ambrosius, the successor of Vortigern, after he had punished the perfidy of Hengest. This likewise is the account of Walter de Mapes, a Welsh chronicler, who is very circumstantial in his narrative.

Jeffery of Monmouth is another monkish historian, who gives, with some flight variation, a similar account of the origin of Stonehenge. The same story is also noticed by some other authors about the same era, and particularly by Giraldus Cambrensis, who farther relates that, during his tour through Ireland, he "saw with his own eyes" an immense monument of stones on the plains of Kildare, or Killarana, corresponding in appearance and construction with that of Stonehenge. Henry of Huntingdon calls this structure one of the wonders of Britain; but disbelieving the story of Merlin, candidly confesses that no one can devise by what means, or for what purpose, such a work could have been erected. Camden, the great antiquary and chorographer, characterizes this monument as an "infana subfructio," or a wild structure. His description of it is so very erroneous and defective, that we doubt much if he ever saw the place. On the question of its origin and uses he forbears to give any opinion.

Such is the scanty information which certain old writers, commonly called historians, furnish relative to this curious monument of ancient times. Modern authors on the subject have thrown aside every item of historical information, and have raised their theories concerning it solely on speculative foundations. Of these theories, that of Inigo Jones first demands attention. His essay was undertaken at the desire of King James I., who commanded the "author to produce of his own practice in architecture, and experience in antiquities abroad, what possibly he could discover concerning this of Stonehenge." Jones did not, however, live to complete the proposed work; but his son-in-law, John Webb, finished and laid it before the public in one small folio volume, with a portrait of the author, and several plates, A.D. 1655. In this work he endeavours to shew that Stonehenge was a temple of the Romans, dedicated to Calus: but unfortunately for Jones's theory, he has committed palpable errors in the form and arrangement of the stones, and has thus rendered his descriptions and assertions untenable and untrue.

Jones's work was succeeded, in 1665, by an answer and dissertation from the pen of Dr. Charleton, who contends that Stonehenge was an erection of the Danes; but, unfortunately for his theory, the monument existed long previous to the settlement of any Danes in Britain. Nennius, who first notices it, wrote anterior to the year 800, at which period people had not entered Wiltsshire.

Dr. Charleton's dissertation introduced a voluminous essay in support of Jones, by his editor, Mr. Webb, in folio, 1665. This volume abounds with dulness, sophistry, misstatement, and proximity. It was followed by a volume from Aylett Sammes, who, after recapitulating the former suppositions respecting Stonehenge, remarks, "why may not these giants (alluding to the title of Choreas gigantum given to our monument) be the Phoenicians; and the art of erecting these stones, instead of the stones themselves, brought from the farthermost parts of Africa, the known habitations of the Phoenicians." This idea, however plausible it may seem, completely fails, from the want of evidence to prove the settlement of those people in England.

Bishop Gibson, in his edition of Camden's Britannia, 1694, after opposing the suppositions of Jones and Charleton, concludes with observing, that "one need make no scruple to affirm, that it (Stonehenge) is a British monument, since it does not appear that any other nation had so much footing in this kingdom, as to be authors of such a rude and yet magnificent pile." The learned prelate is followed in the same spirit by many succeeding writers, though they differ from each other in the period of its origin, and the purposes of its erection.

Dr. Stukeley, more fanciful than correct in his reasoning, published a folio volume in 1740 on the subject, containing several plates. In this volume he attributes the work to the Druids; but, instead of refting his theory upon solid Britten ground, he takes up a large portion of his essay with irrelevant dissertation and speculation. Wool, an architect of Bath, devoted much time to make plans of this structure, which he published with an essay, in 1745. His opinion is, that it was a temple, erected by the British Druids about a hundred years before the Christian era.

William Cooke, M.A. in a treatise entitled "An Enquiry into the Patriarchal and Druidical Religion, Temples, etc.," 1775, supposes Stonehenge to have been a place held face by the Druids, and appropriated to a meeting of great assemblies on civil or religious occasions; and adds, "the world does not afford a nobler spot. Its situation is upon a hill, in the midst of an extended plain in the southern part of the kingdom, covered with numerous herds and swarms of sheep, in which respect the employment and the plain itself are patriarchal; where the air is perfectly salubrious, and the yielding turf fine as the surface of a bowling-green."

Dr. Smith, whose work on Stonehenge, called "Choir Gaur," appeared in 1770, after giving an account of the theories of Jones and others, with copious extracts, and a minute decription of the monument itself, says that he considers it to have been of Druidical origin, and erected as well for the purpes of astronomie observation as of religious ceremonials.

King, in his "Monimenta Antiqua," conjectures that this monument was constructed in the very latest ages of Druidism, while that religion was struggling against the overwhelming tide of Christianitie. This gentleman, however, had such strong prejudices and antipathies against every thing pagan, that he could never mention this, or any other anti-christian temple, but in terms of reprobaation.

Mr. Davies, the learned author of "Celtic Researches," and of the "Mythology, &c. of the British Druids," enters more profoundly, perhaps, than any other author into the question in the latter work respecting the origin and appropriation of Stonehenge. He supposes that this structure, and Silbury-hill, (which has already been described under the articles Avebury and Barrow,) are two of the three works alluded
STONEHENGE.

Alluded to in a Welsh Triad, as constituting the greatest labours of the island of Britain, i.e. "lifting the stone of Ketti;" "building the work of Emrys;" and "piling the mound of the allembles." That Stonehenge is really a Druidical structure, the fame learned writer farther remarks, "is evident from the language in which it was described, and the great veneration in which it was held by the primitive bardics, those immediate descendants and avowed disciples of the British Druids. As the great sanctuary of the dominion, or temple of our heathen deities, so complex in its plan, and constructed upon such a multitude of astronomical calculations, we find it not exclusively dedicated to the Sun, the Moon, Saturn, or any other individual object of superstition; but it was a kind of Pantheon, in which all the Arkite and Sabian divinities of British theology were supposed to have been present; for we perceive Noe and Hu, the deified patriarch; Elyon and Rheiddin, the Sun; Elyoe, Ifis; Kad, Ceres, with the cell of her sacred fire; Llywyy, Proferpine; Gwydien, Hermes, Bud, Victory; and several others." As to the precise date of Stonehenge, Mr. D. remarks, that the Druids could account for such the Druids could account for many of the stones at Stonehenge, and remarks, that it was most likely of later origin than the introduction of the Helio-Arkite superstition, which is traditionally said to have been of foreign origin, and to have come into England by the way of Cornwall, and, therefore, probably from the tin-merchants. He also remarks, that "it was a monument of venerable antiquity in the days of Hengist; and that its peculiar sanctity influenced the election of the spot for the place of conference between the British and Saxon princes." P. 985, &c.

Mr. D. farther mentions a passage in the Greek historian Diodorus Siculus, describing a round temple dedicated to Apollo, which Mr. D. concludes to have been most likely our monument of Stonehenge. The substance of the Greekian author is: "Among the writers of antiquity, Hecateus and some others relate, that there is an island in the ocean, opposite to Celtic Gaul, and not inferior in size to Sicily, lying towards the north, and inhabited by Hyperborees, who are said because they live more remote from the north wind. The soil is excellent and fertile, and the harvest is made twice in the same year. Tradition says that Latona was born here, and hence Apollo is worshipped above any other deity; to him is also dedicated a remarkable temple of a round form, &c."

The Rev. James Ingram, in his "Inaugural Lecture on the Utility of the Saxon Literature," has suggested a new idea relative to Stonehenge: he considers it to have been defined as an heathen burial-place, and the curfew adjoining as the hippodrome upon which the gods of the deceased were run for at the time of the burial." This opinion is entitled to some credit and consideration, from the vast number of barrows which abound in this part of the plain.

The late Mr. Cunningham, in the "History of Ancient Wiltshire," folio, 1812, grounds a novel supposition on the difference in quality and size between the stones of the great circle and interior row, and those of the smaller ones: and thence he supposes, that Stonehenge was erected at different periods. He also supposes, that the larger stones, with their imposts, constituted the old, or original work; and that the smaller stones of the second circle, and those of the inner range, were raised at a later period, as they add nothing to the grandeur of the temple." To exemplify this opinion, Mr. D. remarks, that Richard Hoare has given a bird's-eye view of the structure, thus divested of the smaller stones. Unfortunately for the theorist, this system is not warranted by any example among the numerous Druidical circles of Great Britain; but, on the contrary, it will be more consistent with these, and with the practices of remote ages, to conclude, that the second circle of small, rough, unhewn stones, with another circle immediately within the ditch, and some other members, now destroyed, formed the original, primitive temple. Many arguments might be used to exemplify this opinion; and also to prove that the great circle of upright chiselled stones, with their imposts, and the third row of trilithons, were posterior to the former, raised by other clays of people, and executed at a time when their principles and arts had been considerably changed. Contemporary with which it is conjectured, that an avenue of stones was raised, extending from the temple towards the curfew to the north-east; and also that those places for races and for other sports were formed at a time when the inhabitants of Britain had intercourse with the Greeks, or Romans.

A learned and eloquent writer in the "Edinburgh Review," for April 1806, in noticing Barry's account of the "Orkney Islands," remarks, that "rone circles, besides being used as places of worship, and courts of justice, evidently served the purpose of rude astronomical observatories, since the sun appeared to stand still in them, at the times which were considered as the most sacred of the fun, moon, and stars; the feasts of the year; and even the hours of the day; and where they are tolerably entire, a flight degree of attention would enable any person to do so at this hour. The sun seems to have been a great object of veneration, as an emblem of the deity."

With the following extract from Sir Richard Hoare's "Ancient Wiltshire," we shall conclude our account of Stonehenge.

"It may be naturally expected, that, after quoting the various descriptions of others respecting Stonehenge, I should give some opinions of my own. This I shall do with diffidence, and lament that the history of this celebrated 'wonder of the world' will most probably ever remain unknown. I cannot for a moment hesitate in declaring it to be neither Roman, Saxon, nor Danish. We learn from the Holy Scriptures, that the earliest memorials were of stone; and we find to this day, single, double, and triple upright stones, as well as numerous circles disfigured about our dominions: we then find stone attempts at architecture in the cromlechs and kiltvans, both of which we see immense pieces of the fun, moon and stars; the feasts of the year; and even the hours of the day: and where they are tolerably entire, a flight degree of attention would enable any person to do so at this hour. The sun seems to have been a great object of veneration, as an emblem of the deity."

The Rev. James Ingram, in his "Inaugural Lecture on the Utility of the Saxon Literature," has suggested a new idea relative to Stonehenge: he considers it to have been defined as an heathen burial-place, and the curfew adjoining as the hippodrome upon which the gods of the deceased were run for at the time of the burial." This opinion is entitled to some credit and consideration, from the vast number of barrows which abound in this part of the plain.

"The most remarkable of these monuments, and such as must excite curiosity in the highest degree, is situated in the hamlet of Carnac, near Vannes and Auray, on the western coast of Bretagne, and in the department of Morbihan, in France. M. Cambray, in his 'Monumens Celtiques,' has given a very detailed and animated description of this interesting relic of antiquity. He tells us, that some detached stones on the hills and sand-banks announce the approach to this grand theatre, which consists of an immense number of rude tumuli or small barrows, standing in an upright position, on a sandy plain, near the sea-coast. They are ranged in eleven straight lines, which lines are separated from each other by a space of thirty or thirty-three feet, and the distance from one stone to another varies from twelve to fifteen feet. The height of these stones measures twenty-
twenty-two feet out of ground; the width varies; one of them is twenty-two feet high, twelve feet wide, and six feet thick; and many of them are movable; these stones present the most singular aspect; they stand alone on an extensive plain, attended only by the land that supports them, and the vault of heaven that surrounds them; not an inscription to explain, nor an analogy to inform; the men whom you call, the traveller whom you interrogate, gaze at it, and either turn away their head, or recount follies. They recall to our memory those times which neither our calculation nor our history can ever attain.

"I have before stated my opinion, that our earliest inhabitants were Celts, who naturally introduced with them their own buildings, customs, rites, and religious ceremonies; and to them I attribute the erection of Stonehenge, and the greater part of the sepulchral memorials that still continue to render its environs so truly interesting to the antiquary and historian."

"The general title of Druidical has been given to all these stone monuments, and some of my readers may be surprised that I have not adopted it. That the Druids existed in our island at a very early period, and officiated as priests, there can be no doubt; but, as the learned Mr. Bryant, in his Mythology, observes, 'under the fashions of their names, we shelter ourselves whenever we are ignorant and bewildered.' And Mr. Borlase, with equal justice, remarks, 'that the work of Stonehenge must have been of that a great and powerful nation, not of a limited community of priests; the grandeur of the design, the dintance of the materials, the tedium of the work, which all such massive works are necessarily attended, all shewed that such designs were the fruits of peace and religion.'"

Besides the works already referred to, the preceding account has been chiefly derived from the Topographical History, &c. of Wilts, in vol. xiv. of "The Beauties of England," by J. Britton, F.S.A. 1814. "The History of Ancient Wilts," folio, by Sir Richard Hoare, with numerous plates of Stonehenge, the barrows on Salisbury plain, and the discoveries made in opening them, is most curious and interesting; and truly honourable to the liberality and perseverance of the worthy baronet, who has so laudably employed his time. One of the plates in this volume is more peculiarly interesting, as displaying a plan of the chalice of the temple, the avenue, the situation, and extent of the great curvus; also a smaller curvus, with numerous ditches, barrows, and encampments, in the vicinity of Stonehenge. Comte Alexandre de la Borde, in an elegant work now publishing in Paris, entitled "Les Monuments de la France classé chronologiquement," &c. has given views and accounts of some curious Celtic monuments in that kingdom.

STONEHOUSE. See Plymouth Dock.

STONESHATTER LAND, in Agriculture, a term applied to that fort of land which is constituted of loose, reduced, mixed, stony materials, and which is of a light, dry quality, capable of being wrought at almost any time. It is often good turnip land with but little cultivation and nurture. See Soil.

STONI, in Ancient Geography, a people of the Alps, according to Strabo, who join to the Lepontii and Tridentini. According to Livy, they were subjugated by the confid Q. Marcus.

STONINGTON, in Geography, a port-town and port of America, in New London county, Connecticut, 14 miles E. by S. from New London city, separated from Rhode island by the E. line of the state, settled in 1658, and containing a church, a court, and a place of worship, and 3043 inhabitants, of whom nine are slaves.

STONEHUTT, North, a town of Connecticut, in New London county, containing 2524 inhabitants, of whom two are slaves.

STONE INLET, a channel on the coast of Carolina, S. of the channel of Charleston, at the N.E. corner of John's island, which is bounded by Stono river on the west. N. lat. 38° 41'. E. long. 80° 2'.

STONY CREEK, a small stream of Upper Canada, which runs into lake Erie, E. of Sagona creek, having a harbour for boats.

STONY HILL, situated in Baltimore county, Maryland, 5 or 6 miles N.W. of Whetstone Fort, at the mouth of Baltimore harbour, and two miles S.E. of Hook's Town.

STONY ISLAND, an island near the E. coast of Labrador. N. lat. 53° 4'. W. long. 55° 30'. - Alto, a small island in the Spanish Main. N. lat. 14° 20'. W. long. 82° 45'.

STONY MOUNTAINS, mountains in the N.W. part of North America, extending from S. to N. in a N.W. direction, from N. lat. 48° to 68°. The north part of this range is called the Mountains of Bright Stones.

STONY POINT, a small village in Orange county, New York, projecting from the W. bank of Hudson's river into Haverferray bay, about 40 miles N. of New York city. The population of Haverferray in 1810 was 1816, including 36 slaves.

STONY RIVER, a river of West Florida, which runs into the gulf of Mexico. N. lat. 29° 55'. W. long. 84° 13'. See also Roche.

STONY STRATFORD. See STRATFORD.

STONY LANDS, in Agriculture, such as are full of flints, pebbles, or small fragments of free-Rome. It is found that lands of this sort, in many places, yield good crops; and the general rule is, that in flint and cold lands, the stones should be as carefully picked out as possible, but in light and dry grounds they should be left. These lands should, however, have the large stones removed as soon as possible. See Clearing of Land.

In some parts of Suffolk, the flinty stones, in cafes where they have not been picked off the land, lie so thick as effectually to cover the ground; and it is said to be a curious and interesting to see how the vegetation flourishes and gets through such beds of flints. The common opinion there is, that if the farmers were to put themselves to the trouble and expense of picking them off the land, the soil would be made materially injured; and that some, indeed, who have tried this experiment, are thoroughly convinced of the loss thereby sustained, the land having never since produced such fine crops of corn as before; this, however, only applies, it is thought, to places where the stones are very numerous and closely belet upon the land. See Stone, in Agriculture.

STONYHARD, the name of a plant of the weed kind, common in arable lands, the corn gromwell.

STOOK, or Stook, the common name of a short or hat-toc of corn or grain set up in the field. See HATTOCK.

In some districts, a distinction is made in this mode of putting up corn in the field, the floka or flouk consisting of twelve sheaves, while the hattock has only ten.

STOOKING, or STOOKING, the operation of setting up the sheaves of grain into floka, flouks, or hattocks, in the field, to guard them from rain. It is sometimes written FOXING. It was formerly the practice to set one sheaf upper-right, with the ears uppermost; and round that to place a circle of many other sheaves, in the same direction, inclining on the first sheaf; then to lay an horizontal circle of sheaves, with all the ears in the centre, and cover those ears with a loaf.
STO

Boofe sheave or two. And thus placed, they are paid to be well protected from all wet. But a better mode is that which is practiced in Yorkshire, as described by the Rev. Mr. Comber; ten sheaves are disposed in two rows, each row leaning against the other; then two sheaves are opened at the ear-ends, and slipped on the top, so as to meet at the centre with their tails, and to slope downwards. In this mode the air has a free course, whether it bears against one or other end of the floof, or even against either side of it. Thus, two weighty sheaves afford a good cover, and continue to be blown away by any wind, if carefully laid on: at least not to be blown away but so as soon to be replaced. And the flooping position of the cap-sheaves neither exposes them to receive directly, nor to retain or transmit the rain to the corn below, but to throw it off, especially as the tails of the sheaves, in which the flour is thickest and strongest, receive the most rain, which can do them little or no harm, and especially if they be thrust closely together. See Harvesting and HATTOCK.

STOOL, Alvis, in Medicine. A thing is said to be voided by floof, when it is discharged by the anus, or fundament. In the Philosophical Transactions, we have instances of sick persons voiding facetious Roes, balls, &c. by floof. See Alvis and DEFECATION.

STOOLS, Bloody, in Medicine. The spirit of vitriol, mixed with the patient's drink, has often been found beneficial in cases of bloody floos. See Dysentery and FLUX.

STOOLS, Retention of the feces in infants. See INFANT.

STOOL, in Mining, is used when the miners leave digging deeper, and work in the ends forward. The end before them is called the flool.

STOOLS, in Ship-Building, pieces of plank bolted to the quarters, for the purpose of forming and erecting the quarter-galleries, and sometimes to the ship's sides abait the masts for the backslats. Also ornamented blocks of wood for the poops and top-lanthorns to stand on.

STOOL, Cucking. See CUCKING.

STOOL, in Agriculture, a term used provincially to signify, to ramify or tiller, as grain.

STOOLS, in Gardening, such headed-down young trees and shrubs in the nursery-ground, or other places as are appropriated for the production of an annual supply of lower shoots or branches near the ground, properly situated for layering. See LAYERING.

STOOLS, Hop, in Rural Economy, the small contrivances of this kind which are made use of in hop-gardens, in picking the produce from off the bines, in some districts. They are thought useless and improper in some hop plantations in different districts, and of course never employed; but in others they are still continued, and supposes to be of considerable utility and benefit in the execution of the above sort of work.

STOMING of Wine, a term used to signify the putting of bags of herbs or other ingredients into it to prevent fermentation.

STOOP, in Commerce, a liquid measure in Holland and Flanders. See Tab. XXXII. under MEASURES.

STOOP, in Rural Economy, a post fixed in the earth, as a gate-post, &c. and many other forts.

STOOPEN, in Falconry, is when a hawk, being upon her wings at the height of her pitch, bends down violently to take the fowl.

STOOR, in Rural Economy, a term signifying to rise up in clouds, as smoke, dust, fallen lime, and some other matters.

STOREN, in Geography, a town of Norway, in the province of Dronthem; 36 miles S.W. of Dronthen.

STOOTER, in Coinage, a small Dutch silver coin, valued at 34 flivers.

STOP, in the Manege, is a paufe, or discontinuation of going. In order to stop a horfe, the rider should, in the first place, quicken him a little, and at the instant when he begins to go faster than the usual cadence, or time of his pace, bring to the calves of his legs, to animate the horfe, and to make him bend and play his haunches; then flinging his shoulders backwards, hold the bridle more and more tight, till the floop is made; then vigorously extend the hams, and rest upon the flirrups, to make him form the times or motions of his floop, in fagcading with his haunches three or four times. You should not form the floops of your horfe short and precipitate, left you spoil his hams and mouth. After flooping, a horfe should be made to make two or three corvettes.

With a raw and young horfe very few floops should be made; and when they are made, they should be performed by degrees, very gently, and not all at once; because nothing so much strains and weakens the hocks of a stifl and awkward horfe as a fudden and rude floop. It is an universally agreed point, that nothing shews so much the vigour and obedience of a horfe, as his making a beautiful and firm flop at the end of a swift and violent career. The facility of stopping, however, depends upon the natural aptness and content of the horfe, and also upon his form and the proportions which the different parts of his body bear to each other. The merit of a flop muft, therefore, be estimated by the strength and temper of the horfe, by the flexibilities of his head and neck, and the condition of his mouth and haunches. If your horfe has not readily obeyed in making his flop, make him go backwards, by way of punishing his fault. If in flooping he tolles up his nofe, or forces the hand, keep your bridle-hand low and firm, and your reins quite equal; give him no liberty, prefs upon his neck with your right hand, till he has brought down his nofe, and then immediately give him all his bridle; this is the surest method to bring him into the hand. To compel a horfe to flop upon his haunches, nothing is so efficacious as a little flooping ground; nevertheless you must examine, previously to this kind of exercise, if his feet, reins, shoulders, and legs, are able to bear it; for otherwise your horfe would soon be spoiled. In this case the rider shou'd put the stirrups of his aids rather in his thighs and knees than in the flirrups. One of the most trying lessions to which a horfe can be put is to flop him, and make him go backwards up hill; and therefore, on these occasions, you must ease the fore-parts of the horfe as much as possible, and throw your whole weight upon the hinder. As there are some horfes which, from weaknesses in their make, can never be brought to form a juit and beautiful flop, there are others which are apt to flop too suddenly and short upon their shoulders, though otherwise too much raised before and too light. These employ all their powers in order to flop all at once; these horfes should never be made to go backward; but, on the contrary, should be flopped slowly and by degrees, that they may be embossed, but they should never be forced or kept in too great a degree of subjection. The lefion of making a horfe to flop upon his haunches is admirable, if it be practiced with horfes which have been supple and prepared; but it should never be used to colts or raw horfes, whose joints are fiff.

The most certain method, says Mr. Berenger, to unite and assemble together the strength of a horfe, in order to give him a good mouth, to fix and place his head, as well as to regulate his shoulders, to make him light in the hand, and capable of performing all sorts of airs, depends entirely upon the perfection and exactness of the flop. The qualities above
above enumerated are essential to the flrop, and the flrop must be considered as the effect, and not as the cause of these good qualities. Berenger’s Hist. and Art of Horsemanship, vol. 11, chap. 5.

The opposite term to flarp is parting. In former times, the flop of a horse was called parade. See NAIL.

STOP, Half a, is a flop not finished by a peyade; so that the horse, after fasclading three or four times upon the haunches, refumes and continues his gallop, without making peyades or corsets; which fee.

STOP, at Sea, a word used by him that holds the half-minute glass, in hearing the log; for immediately when the glass is out, he calls flop to them that let run the line. See STOPPING.

STOP, in the Practice of Rigging, is a temporary lashing. When used to stop worning, it is snaked. This is a name given to several turns of spun-yarn taken round the end of a rope, similar to a lashing, to fasten it to another rope. Also, a projection left on the upper part of top-gallant masts, etc., to prevent the rigging from fliding down.

STOP, Saturday. See Saturday.

STOP is a floating beam, used to stop and detain barges at the toll-houses, when necessary, and during the night.

STOP-Gates are similar to Safety-gates, but they require to be fitted up, instead of acting of themselves. Stop-Planks are planks put into a groove, and serving the same purpose with stop-gates.

STOPCOCKS, in Hydraulics, are appendages to pipes constructed for the conveyance of fluids, and these, as well as valves, differ in their form and construction according to their various situations and uses. Stopcocks usually consist of a cylindrical or conical part, perforated in a particular direction, and capable of being turned in a socket formed in the pipe, so as to open or shut the passage of the fluid, and sometimes to form a communication with either of two or more vessels at pleasure. A valve is employed where the fluid is allowed to pass in one direction only, and not to return. See VALVE.

STOPPE, or STOP, in Mining. When a sumph or pit is sunk down in a lode, they break and work it away in stairs or steps, which method of working is called floping; and the height of step which each man breaks, is called a flop.

STOPPIN, a term in use at the military laboratory, derived from the French word stoppin, and signifying a wad, lump, clew, or bobbin of hemp, tow, rope-yarn, &c.

STOPPAROLA, in Ornithology, the name of a bird of the lark kind, described by Aldrovandus, and supposed by Mr. Ray to be the same with the pipollaia, or the toroia of the Venetians; but the muscicapa grifola of Linneus. See FLY-catcher.

STOPPEL, in Geography, a town of Flanders; 5 miles N.W. of Hulft.

STOPPERS, in a Ship, certain short pieces of rope, which are usually knotted at one or both ends, according to the purpose for which they are designed. They are either used to suspend any heavy body, or to retain a cable, hroudb, &c. in a fixed position. Thus, the anchors, when first hoisted up from the ground, are hung to the cat-head, by a stopper, called “anchor-stopper”, attached to the latter, which passing through the anchor-ring, is afterwards fastened to the timber-head; and the same rope serves to fasten it on the bow at sea; or to suspend it by the ring which is to be flunk from the ship to the bottom. The floppers of the cable have a large knot and a lannard at one end, and are fastened to a ring-bolt in the deck by the other. They are attached to the cable by the lannard, which is flanned securely round both by several turns passed behind the knot, or about the neck of the flopper; by which means the cable is restrained from running out of the ship, when the gades at anchor.

Those that are used to check the cable are called “bitt-floppers,” and the latter are denominated “deck-floppers.” “Dog-floppers” are used as additional securities when the ship is rising in heavy gales, or bringing up a ship with much stern-way, to prevent the cable from slapping at the bitts, and to safe the deck-floppers. “Wing-floppers” are used for the same purpose as dog-floppers.

The flippers of the hrouds, called “hroud-floppers,” have a knot and a lannard at each end. They are only used when the hrouds are cut adier in battle, or disabled by capricious weather; at which time they are lashed in the same manner as those of the cables, to the separated parts of the hroud, which are thereby reunited, so as to be fit for immediate service. This, however, is only a temporary expedient.

“Fore-tack” and “sheet-floppers” are used for securing the tacks and sheets, till bayed. Falconer.

STOPPER-BOLTS, in Ship-Building, large ring-bolts driven through the deck and beams, before the main hatchway, for the floppers to be attached to. They are carefully clenched on iron plates beneath.

STOPPING, in Grammar. See Point and Punctuation.

STOPPING, among Horses, the practice of filling the hollow of a horse’s foot with poultice, cow-dung, or any other moist application. It has the effect of softening the sole, and, on some occasions, may be advantageous, though it is frequently misapplied, and of course does injury. It is not unfrequently employed for the feet of team-horses, especially those of the plough kind, as travelling so much amid the mould renders them hard, brittle, and unsteady.

STOPPING a Leak, at Sea. See STOP.

STOPPING a Ship. When a ship comes to an anchor, and the cable is veered out by degrees till the ship is found to ride well, and then flopped, it is called flopping the ship.

STOPPINGS-Up, in Ship-Building, the pommets, timber, &c. used to fill up the vacancy between the upper side of the bilgeways and the ship’s bottom, for supporting her when launching.

STOPS, in Grammar. See Point.

STOPS of an Organ. See Organ.

STOPS, or STOP, in Rural Economy, a term provincially applied to small well-buckets, and those of some other kinds.

STOR, in Geography, a lake of Sweden, in the province of Glefricia; 6 miles S.W. of Gefle. — Alto, a lake of Norway, in the province of Aggerhuus; 40 miles N.E. of Chrifinia. — Alto, a river of Mecklenburg, which runs from lake Schwernin to the Elde.

STORA, a town of Sweden, in the government of Wafa; 20 miles S.E. of Christiansted.

STORA. See SOGATA.

STORAX-TREE, in Botany. See STYRAX.

STORAX, Official, in the Materia Medica, is the resinous drug, obtained in perfection only from those trees that grow in Asiatic Turkey, which issues in a fluid flate from incisions made in the bark of the trunk, or branches, of the storax-tree. It is brought from Turkey, but is so adulterated, that it is very difficult to meet with any that is pure. It has a most pleasing fragrant odour, and is called STYRAX CALAMUS, because it is said to be transported in hallow cans; or, according to others, because it exuded from the tender twigs and young shoots of the tree, and costed...
them over, so as to resemble a reed or other hollow cylindric body drawn over the twigs. Two kinds of this resin have been commonly distinguished in the shops; viz., the pure and the common flora, the first, or pure, is usually obtained in irregular compact masses, free from impurities, of a yellowish or reddish-brown appearance, and interfered with with whitish tears, somewhat like gum ammoniac or benzoin; it is extremely fragrant, and upon the application of heat readily melts. This has been called “florax in the lump,” “red florax,” and the separate tears, “florax in the tear.” The common florax is found in large masses, very light, and bears no kind of external resemblance to the former florax, as it seems to be almost wholly composed of dirty sawdust, merely caked together by the resinous matter; and though much less esteemed than the pure kinds of florax, yet when freed from the woody part, it is said to produce more fragrance, and to be superior to the other kind. Rectified florax, the common menstruum of refining, readily dissolves the florax, which may be inspissated to a solid consistency in the manner directed for the “flyracis purificatio” in the London Pharmacopoeia, without fouling any considerable loss of its sensible qualities. Common florax, infused in water, imparts to the menstruum a yellow colour, some share of its smell, and a slight balsamic taste. It gives a considerable impregnation to water by diffillation, and strongly diffuses its fragrance when heated, though it scarcely yields any essential oil. The spirituous solution, gently distilled off from the filtered reddish liquor, brings with it very little of the fragrance of the florax; and the remaining infusion is more fragrant than the finest florax in the tear, which Dr. Lewis met with. The pure resin distilled without addition yields, along with an empiric aromatic oil, a portion of salve matter, similar to the flowers of benzoin; and Dr. Lewis says, that he has also sometimes extracted from it, a substance of the same nature by cogging in water.

Of some of the ancients, florax was a familiar remedy as a resolvent, and particularly used in catarrhal complaints, coughs, asthma, menstrual obstructions, &c.; and from its affinity to the balsams, it was also prescribed in ulcerations of the lungs, and other states of pulmonary consumption. And our Pharmacopoeia formerly directed the “pulvus e florace” (see Storax Filla); but this odoriferous drug has now no place in any of the official compouds; and though it be a medicine which might seem to promise some efficacy in nervous debilities, yet it is almost totally disregarded by modern practitioners. Lewis’s Med. Med. Woodville’s Med. Bot.

Storax, Liquid, is a resinous juice, obtained from a large tree, with leaves like those of the maple, called by Ray “flowers acris folio,” by Linnaeus liquidambar flavicrus, a native of Virginia and Mexico, and lately naturalized to our own climate. The juice called liquidambar, is said to exude from incisions made in the trunk of this tree, and the liquid florax to be obtained by boiling the bark or branches in water. See Liquidambar.

“Two sorts of liquid florax are distinguished by authors: one, the purer part of the resinous matter that rises to the surface in the liquid florax, separated from the florax, and of the presence of honey, tenacious like turpentine, of a reddish or ash-brown colour, moderately transparent, of an acid undulating taste, and a fragrant smell, resembling that of the solid florax, but somewhat disagreeable; the other, the more impure part, which remains on the strainer, untransparent, in smell and taste much weaker, and containing a considerable portion of the substance of the bark. That which is commonly met with in the shops under this name, is of a weak smell and a grey colour, and is supposed to be an artificial complexion. Liquid florax has been chiefly used in external applications. Among us, it is at present almost wholly in dilute. Lewis’s Med. Med.

Storax, White. See Balsamum Persicifolium, under Balsam.

STORCICA, in Geography, a town of Poland, in the part of Kiev; 24 miles S.S.W. of Biala. Storck, Anthony, in Geography, a medical professor of considerable note at Vienna, succeeded the celebrated Van Swieten in the office of president and director of the faculty of medicine in the university of that metropolis, and was also honoured with the appointment of principal consulting physician to the empress Maria Theresa. He distinguished himself chiefly by a long and aulicious course of experiments relative to the operation of various narcotic vegetables, and to the best mode of preparing and administering them. The vegetables of which he has treated in various tracts, are the hemlock, henbane, Atromonium, aconite, meadow-saffron, and pulsatilla nigricans: and although he was disposed to over-rate the efficacy of some of these substances, and has ascribed to them virtues which subsistent experience has not always confirmed, he had the merit of calling the attention of the medical world to a class of active remedies, which, under proper management, are productive of much benefit, and constitute a valuable addition to the Materia Medica. Between the years 1760 and 1771, his various tracts upon these subjects were printed at Vienna, and they have subsequently undergone several editions and translations in other countries. He was also author of a collection of cafes which occurred under his observation in the hospital at Vienna, entitled “Anna Medicus, quo factuntur Observationes circa Morbus acutos et chronicos,” 1759; of which he published an “Anna Secundum” in 1761. This work was afterwards continued by his successor, Dr. Colin. In 1775, he published a volume, entitled “Instituta Facultatis Medicarum Vindobonensiae.” Eloy Diet. Hist. de la Mé.

STORDALEN, in Geography, a town of Norway; 28 miles N.E. of Drontheim.

Store, a town of America, in North Carolina; 50 miles W. of Exeter.

Store, Bill of Stores. See Bill.

Store, Naval. See Naval.

Store-House, in Agriculture, that fort of house or building which is constructed for the purpose of storing up and preserving some sort of farm produce, which should be constructed suitably to the particular kinds of products they are to contain, and to the uses to which they are to be applied.

Houses of this kind are sometimes also employed for storing and laying up different sorts of small tools and implements, and many other things which are necessary in farming, in order to keep them safe and dry.

They are seldom used for any sort of grain, especially for any length of time, as that requires a particular sort of building. See Granary.

The store-houses of a fortress are constructed for the preservation of all kinds of artillery and ammunition; those of a dock-yard, or of a maritime town, for cables, anchors, timber, and other necessaries, to repair and furnish ships. And they are of different forms and sizes, according to the purposes for which they are intended.

Store-Room, in Rural Economy, a room or place in a house or other building, for storing up different sorts of farm articles. These rooms should be as dry as possible, and perfectly secure from vermin. An upper floor is the best.
bent for the first purpose; but for the latter, vaults or cellars under ground are the most suitable.

Store-Room, in a Ship, an apartment or place of reserve, of which there are several, to contain the provisions or stores of a ship, together with those of her officers, during a sea-voyage.

Store-Keeper, an officer in the royal dock-yards, who is invested with the charge of the principal naval stores; as the falls, anchors, cordage, &c.

Store-Master, in Agriculture, a term applied to that kind of farmer who is, in a great measure, in the live-flock kind of farming in some way or other, as either by means of sheep, neat cattle, or some other fort of domestic animals.

Store-Ship. See Store-SHIP.

STOREA, among the Romans, a kind of basket made of ropes or rushes, for gathering flowers or garden-fruit.

STOREA was likewise a kind of defence, made of large cables fastened into a sort of netting; which was so strong, that no weapon, though thrown out of an engine, could penetrate it.

STORGE, ἰερός, a Greek term, frequently used by naturalists to signify that parental instinct, or natural affection, which animals bear toward their young.

The storae is an admirable principle implanted by the all-wise Creator throughout the animal world, for the preservation of it; and is governed by such rules as make it best contribute thereto. By means of this, with what care and minuteness do animals nurture their young; and what dangers will they brave for their security; even the most timorous creatures, which at other times fly the face of men, dogs, &c. will, for the sake of their young, expose themselves. Thus hens, instead of flying from, will assault such as meddle with their brood; and partridges, before their young can fly, will frequently drop down before the dogs, first at leis, then at greater distances, to dodge and draw them off from pursuing their young.

With what concern do others lead about their young in places of safety; and some even admit them for their part into their beds. Thus the heron, which, as Tyron observes, has a curious bag on purpose for securing and carrying about her young. The same author adds, from Oppian, that the dog-fish, upon any storm or danger, receives her young into her belly, which comes out again when the fright is over. And it is said that the squatina and glaucus do the like.

With what tenderness do others seek and prepare the food for their young, teach them to suck, cherish, or lull them to rest, &c. like so many nurses, deputed by the Creator to take care of his creatures? and fill in proportion, as they grow up, and become fit to look to themselves, this storae abates; and at length, when no longer needed, becomes extinct. Mr. Ray observes, that young doves are fed with meat first eat by the dam, and sodden awhile in her prolube. And Clusius observes, that the old female Ethopian takes no food but from the male, after this manner.

The returns made by the young to the parent animal, when grown old, are not less considerate. Pliny says of rats, that they nourish their aged parents with eminent piety.

St. Ambrose, and after him Olaus Magnus, observe of the crane, that when the parents, through old age, are bereft of their feathers, and left half naked, their offspring stand around them, and cherish them with their own feathers; that they seek food for them; and when nature, as it often happens, repairs their decays, and restores them to strength again, they take them up, by turns, on their wings, and habituate their unpractised limbs to their ancient art of flying. See Instinct.

STORHAMNEN, in Geography, a small island on the W. side of the gulf of Bothnia. N. lat. 61° 32'; E. long. 17° 13'.

STORHOLMEN, a small island on the W. side of the gulf of Bothnia. N. lat. 62° 34'; E. long. 17° 42'.

STORING, Substances of the Corn, Fruit, and other Kinds, in Agriculture and Gardening; the means of advantageously and properly laying them up and securing them for future use.

In the storing of grain, as there is a constant decrease and loss in the weight of the corn from the moment of its being laid up, to that in which it is disposed of, (though this is considerably more at first than afterwards,) it is obviously a practice that should be carried to as little extent as possible in all cases. The common lois in this way has been found to be from one-seventh to one-tenth of the whole in different parts of corn, according to circumstances, and the length of time it has been stored up.

The storing of all articles of this kind should always be performed at dry times, and in dry well-aired places, and not laid in too large quantities together, but so as that they may be capable of being readily turned over, and have new surfaces frequently exposed to the action of the atmosphere. Corn is often not only injured, but rendered improper for storing up, by being suffered to remain too long on moist damp floors, in barns and other places.

The storing of fruits, vegetables, and roots, has been performed in various ways, which are well known already; but lately some better modes have been suggested for this purpose.

For apples and pears, it has been stated in the "Memoirs of the Caledonian Horticultural Society," that after they have been carefully gathered from the trees, and laid in heaps covered with clean cloths or mats for sweating, which is effected in three or four days, they remaining for that length of time afterwards, they are to be wiped separately with clean cloths; when some glazed earthen jars are to be provided with tops or covers, and likewise a quantity of pure pit-fand, which is quite free from any mixture. This is to be thoroughly dried upon a flue. Then put a layer of this sand an inch thick on the bottoms of the jars; above this a layer of fruit, a quarter of an inch free of each other; covering the whole with sand to the depth of an inch; then a second course of fruit is to be laid in, and again covered with an inch of the sand, proceeding in the same way until the whole be finished and completed. An inch and a half in depth of sand may be laid over the last or uppermost layer of fruit; when the jars are to be closed and placed in some dry situation, as cool as possible, but entirely out of the way of frost.

The usual time at which each kind of such fruits should be ready and fit for the table being known, the jars containing such fruit may, it is said, be examined, by turning out the sand and fruit together cautiously into a sieve. The ripe fruit may then be laid upon the shelves of the fruit-room for use, and the unripe be carefully replaced in the jars as before; but with fresh dry sand.

Some kinds of apples managed in this way, will, it is said, keep a great while, as till July; and pears until April, and in some parts till June. It is not improbable but that many other sorts of fruit might be stored and preserved in somewhat the same way.

Vegetables of the cauliflower kind have been stored and kept well through a great part of the winter, it is said, in the same work, by putting them, when in full head,
on a dry day, into pits about eighteen inches in depth, and much the same breadth, in a perfectly dry foil, with the stalks and leaves to them, the latter being carefully doubled over and lapped round the heads, instead of hanging them up in sheds or other places, as is the usual practice in preserving them. In performing the work, it is begun at one end of the pits, laying the heads in with the root-stalks uppermost, so that the former may incline downwards, the roots of the one layer covering the tops or heads of the other, until the whole is completed. The pits are then to be closely covered up with the earth into a sort of ridge, and beaten quite smooth with the back of the spade, in order that the rain-water may be fully thrown off. Fine cauliflowers have been thus stored and kept for the occasional supply of the table until the middle of the following January.

For storing and preserving different kinds of roots for common summer use, until the coming in or return of the natural crops, the following method has likewise been proposed. As the ice in ice-houses has commonly furnished for food, as four, five, or more, by the beginning of the spring, it is proposed to deposit in the rooms or vacancies so left empty, the roots that are to be preserved. As soon as any openings in the places have been well stuffed with straw, and the surfaces of the ice covered with the sort of material, cafe-boxes, dry ware, caffs, baskets, or any other such vessels, are to be placed upon it, which are then to be filled with the roots, such as turnips, carrots, beets, celery, potatoes in particular, and some others.

In cities where there are not ice-houses, vegetation may be greatly retarded, and the roots preserved by storing them in deep vaulted cellars, caves, coal-pits, mines, or in any place heated deep in the earth.

Potatoes have also been well floored and preserved, it is said, by earthing them in small parcels, as about two balls each, heaped up, and covered in the usual way with straw and earth; which are turned over into other pits in the early spring, first rubbing off all the sprouts or shoots, and having the roots well watered in small quantities as they are put into the other pits, the whole earthy covering being also well watered and beaten together at the time with the back part of the spade. This covering is to be made to the thickness of about two feet. The same practice or process is to be repeated every time the potatoes are turned over, which should be about once in three weeks, as the state of the weather may be. And where the pits or heaps are not in the shade, it is sometimes proper, when the season is very hot, to cover them with mats supported on sticks, so as to permit a free current of air between the mats and the heaps.

In this way, it is stated that these roots have been preserved quite plump and entire in the earth until the end of September, or till the succeeding crop becomes perfectly ripe, so as to be used without loss, as it must always be the case where the roots are largely employed before they are in a state of mature growth. It is asserted, too, that in this manner potatoes are even capable of recovering in plumpness and tattle, where they have been suffered, by improper exposure to air or heat, to become deficient in these qualities.

**STORK, Ciconia, in Ornithology, a family of the Ardea or Heron class. See Heron. Naturalists have been much puzzled in assigning the winter abode of storks. Many authors have supposed that they go to the Nile at this feast in quest of food; to which purpose Dr. Shaw observes, that in the middle of April he saw three flights of these birds, each of which took up more than three hours in passing by him, extending itself more than half a mile in breadth. These, he says, were then leaving Egypt, where the canals and the ponds that are annually left by the Nile were become dry, and directing themselves towards the north-east. He adds, that they return again a little after the autumnal equinox, when the waters of the Nile returning within the banks, leave the country in a fit state to supply them with nourishment. But M. Klein counters the opinion, that storks visit Egypt in the winter in search of food; observing, that if this were the case, they would not go in the winter, and remain until April, but in the summer; for the inundation of the Nile begins towards the end of April, and about the month of September the waters diminish, and about the 7th or 8th of October quite retire into their channel, so that in the winter this river is extremely small; and he apprehends that they take up their winter-quarters under water.

It is observed of the storks, says Dr. Shaw, that for the space of about a fortnight before they pass from one country into another, they constantly resort together from all the circumjacent parts in a certain plain, and there forming themselves daily into a dou-wanne (according to the phrase of the people), are paid to determine the exact time of their departure, and the places of their future abodes. See Jer. chap. viii. ver. 7.

The stork is held in the highest esteem and veneration among the Mahometans, with whom it is no less sacred than the ibis was among the Egyptians; and no less profane would that person be deemed, who attempted to kill or molest it. The regard paid to these birds, Dr. Shaw says, may probably have arisen, not so much from the service they perform to a moiff fenny country, in clearing it of useless reptiles and insects, as from the solemn festivities they are observed to make as often as they rest upon the ground, or return to their nests. Shaw’s Travels, p. 428, fol.

**STORKAGAT, in Geography, a town of Sweden, in Weit Bothnia; 25 miles S. of Pitea.**

**STORKÖ, a small island on the E. side of the gulf of Bothnia. N. lat. 63° 52'. E. long. 23° 59'.—Albo, an island in the Baltic, near the S. coast of Sweden. N. lat. 56° 5'. E. long. 15° 34'.**

**STORKOW, a town of Brandenburg, in the Ucker Mark; 26 miles W.S.W. of Francfort on the Oder. N. lat. 52° 15'. E. long. 14° 55'.**

**STORKYRO, a town of Sweden, in the government of Vasa; 17 miles E. of Vasa.**

**STORM, in the Military Art. See Assault.**

**Storm, in Rural Economy, a term signifying a fall of snow, hail, &c. which is injurious either to animals or plants.**

In some districts, storms of these kinds are very prevalent, and highly hurtful in different ways. In the sheep farms in the northern parts of the island, storms are often extremely hurtful and destructive to the sheep. They are the most fatal to these animals, it is said, when the frosts is keen, the wind strong, and the snow light and mobile; as then the defenceless flock move before the blast, into some hollow part or place, where they find a little relief from the piercing storm, but are covered up deep with drifted snow, and when long confined underneath it, many of them perishing, and those which survive are often much reduced in condition, and sometimes have lost part of their wool. And though this place of retreat be near a rivulet, as often happens, and a sudden thaw come on, the melted snow brings down a torrent of water on them, and they all perish.
Smooth green hills, that are destitute of rocks, woods, or other shelter, are, it is thought, the moat in danger for the sheep on them, from the drifting snow. The sheep, in these cases, are to be collected, and kept moving, in order to prevent their being benumbed with the cold, and overblown by the drifting snow. Stone fields are also useful; but the true and effectual shelters are, it is said, plantations of forest trees, to which the sheep naturally fly on the approach of storm. See SHORE.

Storm Bay, in Geography, a bay on the south coast of New Holland, between South Cape and Tasman's Head.

Storm Cape, is the northern limit of the mouth of Bay Verte, and forms the south-east corner of the province of New Brunswick.

Storm-Finch, or Storm-Finch, in Ornithology. See Procellaria Pelagica.

STORMAR, or Stormaria, in Geography, a district of the duchy of Holstein, of which Hamburg is the capital. The Stor, whence it derives its name, confined this district on the north, and separated it from Ditmaria: the Sula, Trave, and Billa, determined the rest of its extent. It was formerly almost one slimy marsh. The land and low situation of Stormaria and Ditmaria exactly corresponds with the Roman account of the Saxons living in inaccessible marshes. Stormaria is somewhat quadrangular, and its sides may be estimated at 33 miles. Adam Bremen derives the name from Stor, a metaphor expressive of the feddins of its inhabitants; but Stor, the river, and Mark, the inhabitants in marshes, seem to compose a juter etymology. Adam distinguishes the Stormarii by the epithet *nobiles*, Their banner, in ancient times, was a white swan with a golden collar. Hamburg, their metropolis, had been, before the eleventh century, *viris et armis potens*; but in Adam's time it was *in solitudinem redacta.* Stormaria was one of the three districts which, in the eleventh century, divided Norderlinga, or Eld-Saxsen; Ditmaria and Holstia being the two other districts. These were the countries in which our Roman ancestors resided, and in which they spread terror throughout Europe, when their attention became directed to maritime depredations.

STORMONT, a district of Scotland, in Perthshire, on the left side of the Tay. Dunkeld is the chief town.

STORMONT, a county of Upper Canada, bounded east by the county of Glengary, south by the river St. Lawrence, the west boundary of the township of Oinabrack, and west by the late townships of Williamburgh, running N. 24° 11' W., until it intersects the Ottawa or Grand river; thence descending that river, until it meets the north-west boundary of the county of Glengary. The county of Stormont comprehends all the islands in the river St. Lawrence near it, and the greater part of the country lies fronting the St. Lawrence.

STORINA, in Ancient Geography, a town of India, on the other side of the Ganges, belonging to the people called Tanganis, according to Ptolemy.

STORINARA, La, in Geography, a town of Cappadocia; 9 miles N.E. of Ancyli.

STORNAWAY, a parochial town on the eastern side of the island of Lewis, and isle of Rona, Scotland. It contains a good and well-frequented harbour. The parish is of great extent, and stretches about ten miles north-east, along the north side of an arm of the sea, called the Broad Bay. In this, ships of large burthen have good anchorages, and can ride with safety, as no heavy sea can come into it. The town of Stornaway is situated at the extremity of loch Stornaway; and, from a small origin, has of late attained considerable size and opulence, by the patriotic exertions of Lord Seaforth. The principal employment of the inhabitants of Stornaway is the prosecution of the white and herring fisheries. It is a port of the customs, and has a post-office, and regular packet, which calls weekly with the mail and passengers. The houses of the town are generally well built, and, in 1811, amounted to 698, with 3500 inhabitants. Here are a neat and commodious custom-house, a town-house, assembly-room, and a church, also two free schools, and one instituted and patronized by lady Seaforth, for the introduction and promotion of the spinning of yarn in the island of Lewis. In Stornaway is also situated Seaforth Lodge, the residence of lord Seaforth, baron Mackenzie of Kinital, and lord lieutenant of the shire.—Carlisle’s Dictionary of Scotland, vol. ii. Beauties of Scotland, vol. v.

STORO, a small island on the east side of the gulf of Bothnia. N. lat. 63° 24'. E. long. 22° 3'.

STOROHAMN, a small island on the west side of the gulf of Bothnia. N. lat. 60° 17'. E. long. 17° 53'.

STOROZEVIOI, a cape on the north coast of Russia, in the straits of Vaigatchko. N. lat. 60° 24'. E. long. 86°.

STORSIO, a large lake of Sweden, in the province of Jamland; containing several islands, on one of which is the town of Frolon, and on the other town of Norderfl. It has a communication with many other lakes and rivers, and by means of these with the gulf of Bothnia. N. lat. 63° 10'. E. long. 14° 10'.

STORSKAR, two small islands on the east side of the gulf of Bothnia. N. lat. 63° 33'. E. long. 20° 43'.

STORT, a river of England, which passes by Bishop's Stortford, &c. and runs into the Lea, 2 miles N.E. of Hoddesdon.

STORTA, LA, a town of the Patrimonio, near the ruins of the ancient Veii; 6 miles N.W. of Rome.

STORTFORD, Bishop's. See Bishop's Stortford.

STORPYNE, the name of an instrument used by the ancients for drawing blood from the nose; but we are not perfectly informed of its shape or structure.

STOSSEN, in Geography, a town of Saxon, in Thuringia; 6 miles S.E. of Naumburg.

STOT, in Rural Economy, a provincial term applied to a heather, or young growing bullock.

STOTFIELD HEAD, in Geography, a cape of Scotland, on the coast of Murray. N. lat. 57° 42'. W. long. 3° 10'.

STOTTER SEE, a lake of Bavaria, in the bishopric of Augsburg; 10 miles N.N.W. of Fufellen.

STOTTLEDORF, a town of Austria; 6 miles S. of Sonneberg.

STOVE, in Building, a hot-house or room. The term stove is also used more restrictively for a place in which fire is made, and by means of which heat is communicated to a room or building. See CHIMNEY.

Stoves should, in propriety, be distinguished from fireplaces, from the fire being inclosed within the stove, and giving out its heat through the substance of the materials of which the stove is composed, to the air in the apartment; and in many stoves there are ingenious contrivances, to make a great quantity of air pass in contact with the heated surface of the stove, and be thus heated before passing off into the apartment. Fireplaces, on the contrary, have the fire as open and as much exposed as possible, sufficiently with the carrying off of the smoke, in order that it may throw out radiant heat into the apartment. This distinction is not sufficiently attended to in common language.
STOVE.

In modern fire-places, every care is taken that the air of the room may be heated; but it does not appear, from the construction of their fire-hearth, that our forefathers had any idea of warming the air of a room to fit in. All they proposed was to have a place to make a fire in, by the radiating heat of which they could warm themselves when cold.

The ancients are supposed to have used stoves, in which the fire was not seen; but on inquiring into the progress of the art of warming apartments economically, few traces remain of the manner in which the ancients warmed their habitations. It is imagined they lighted the fire in a large tube in the middle of a room, of which the roof was open, and that the other apartments were warmed by portable braziers. In Seneca's time, they began to construct tubes in the walls, to convey the heat into the upper apartments; the fire-places being full placed below. It appears, however, that this was the origin of stoves for smoking, and even of stoves; the situation and proportions of which have successively undergone an infinity of changes, according to the localities, the wants of the inhabitants, or the style of the decorations.

The ancients had the custom of heating apartments by fires placed under archs or vaults; but this was confined to palaces, and other edifices, where magnificence was augmented by prodigality; and the apartments have been discovered in ancient ruins. Dr. Franklin pointed out this as their definition. In digging, some years ago, for foundations in the city of Autun, one of these ovens was discovered under a mosaic pavement, with chimneys at each extremity.

The northern Chinese have a method of warming their ground-floor, which resembles the ancient plan just mentioned. The floors are made of tiles a foot square, and two inches thick; their corners being supported by bricks set on end, that are a foot long, and four inches square; the tiles, too, joined into each other, by ridges and hollows along their sides. This forms a hollow under the whole floor, which on one side of the house has an opening into the air, where a fire is made; and it has a funnel rising from the other side to carry off the smoke. The fuel is a sulphurous pit-coal, the smell of which in the room is thus avoided, while the floor, and of course the room, are well warmed. But as the under-side of the floor must grow foul with foot, (and a thick coat of foot prevents much of the direct application of the hot air to the tiles,) Dr. Franklin suggests that burning the smoke, by obliging it to descend through the red coals, would, in this construction, be very advantageous; as more heat would be given by the flame than by the smoke, and the floor, thereby being kept free from foot, would be more heated with less fire. A different kind of stove used in China, and called Zang, is briefly described under that article.

Francis Kellar of Frankfort, whose work, entitled "Eargove-bois," &c. (The wood-faver, &c.), appeared, in French, in 1619, is the eldest writer who defers to be quoted, having proposed any useful laws on the subject of stoves. He formed eight chambers, one above another, through which the smoke was to pass before it entered the chimney. He also brought air directly from without into the ash-pan, to feed the fire; and there was another aperture to draw air from the apartment for the same purpose.

Savoy, in his "Architecture Francaise des Batimens particuliers," i.e. Architecture of private Houses, printed in 1625, gave some advice relative to the best method of contructing chimneys, but with scarcely any other object than to prevent their smoking.

M. Daleme, in 1686, suggested the first idea of a stove without smoke, which he called furus acupina. Here the smoke is forced to descend into the fire-place, where it is consumed. Dr. Franklin, who afterwards executed a very complete stove on that principle, still spoke of it, in 1773, as a mere curiosity or philopohical experiment, as it required too much attention to be managed by common servants.

This machine consists of a tube of iron-plate, such as is used for the flue of a German stove. This tube was bent at right angles, and the part which was horizontal was about two feet in length, and joined to the rest of the tube, which ascended vertically. At the opposite end of the horizontal tube the furnace was made: it consisted of a cylindrical tube of plate-iron erected upon the horizontal tube near the end, and provided with a gratings, upon which the fuel was placed; and the grate prevented the fuel falling down into the horizontal tube. To light this stove, some clear burning charcoal was put into the large short tube or furnace, and supported on the grate. As soon as the tubes grew warm, the air within them would ascend in the perpendicular tube or chimney, and go out at the top of it: fresh air must enter into the horizontal tube through the furnace. In this course it must descend through the burning fuel, and becoming heated by the burning coals, through which it has passed, would rise more forcibly in the longer tube, in proportion to its degree of heat, or rapid, according to the situation and length of that tube. Such a machine is a kind of inverted siphon; and as the greater weight of water in the longer of the common siphon, in descending, is accompanied by an ascension of the same fluid in the shorter; so in this inverted siphon, the greater quantity of levity of air in the longer leg, in rising, is accompanied by the descent of air in the shorter. The things to be burnt being laid on the hot coals contained in the furnace, the smoke must descend through those coals, and be converted into flame, which, after destroying the offensive smell, comes out at the end of the longer tube, as mere heated transparent gas or vapour.

Whoever would repeat this experiment with success, must take care that the part of the short tube is quite full of burning coals, so that no part of the smoke may descend and pass by them, without going through them, and being converted into flame; and that the longer tube is so heated, that the current of ascending hot air will be established in it, before the things to be burnt are laid on the coals; otherwise there will be disappointment.

It does not appear, either in the Memoirs of the Academy of Sciences, or Philosophical Transactions of the English Royal Society, that any improvement was ever made of this ingenious experiment, by applying it to useful purposes; but there is a German book, entitled "Vulcanus Famulans," by Joh. George Leutmann, P.D., printed at Wurtzberg in 1723, which describes, among a great variety of other stoves for warming of rooms, one which seems to have been formed on the same principle. It was probably taken from the Chinese, although M. Daleme's experiment is not mentioned; for the construction is as nearly as possible the same, except in the proportion of parts; the furnace being made in the form of a basin or vase, having the grate in the bottom of it.

Gauger, author of "Le Mechanisme du Feu," &c., printed at Paris in 1709, was the perfom to whom we are indebted for the first and most complete system of experiments on the circulation of heat, by means of air-holes affording warm air; as also the manner of making one fire warm several rooms, and to send off the heat in elliptic curves.
curves. We there find a description of a chimney, with the back, the hearth, and the jamb, of hollow iron, to heat the air that is to enter the room. But it does not appear that this work produced much effect at the time; the most important truths lie concealed in books, till some preying interest awakens the attention of mankind to their utility.

Dr. Franklin, in 1745, published an account of the new fires of Pennsylvania; the advantages of which he compares with those of the fires of Germany and Holland, and the chimney of Gauger. A description and drawing of this stove are given in our article Fire-Place.

In 1785, Dr. Franklin published the description of another stove, which has the flame reversed; that is, it paffes downwards through the fuel. The appearance of this stove is that of a vase of cast-iron, with its pedestal; and this is mounted upon the top or lid of an air-box, standing upon the hearth of the fire-place, and built close in a niche in the stone-work; but the vase being wholly detached from the back of the niche, has a very neat appearance. The top of the vase turns back upon a hinge, so as to open like a lid, to put in the fuel; and the opening is covered by a brafs frame, which allows the air to enter. The bottom of the vase has in it an opening, of about two inches diameter, which leads through the stem or foot of the vase into a hollow iron box, forming the pedestal. At the bottom of this pedestal is a grating in the lid or top of the air-box, upon which the vase stands. The air-box is divided by four partitions, between which the flame paffes and repaffes horizontally in a waving direction, until it escapes into the chimney. Thus the flame and smoke, immediately after it has descended through the grate in the top of the air-box, paffes backwards towards the chimney between the two middle partitions; but as it cannot enter into the chimney at that part, it turns round the ends of these partitions, and returns in two currents towards the front of the box; then returns again round the end of other partitions, and goes back into the chimney, which is behind, or rather at the sides of the niche, in which the vase stands. The front plate of the air-box is made to slide in a groove, in two pieces, which meet together in the front like folding-doors; and these pieces being folded back, expose the spaces between the partitions, which, as before mentioned, act as winding flues for the smoke to circulate in, and give out its heat through the metal of the air-box. In the space between the two middle partitions, and into which the smoke first descends, a drawer is fitted to receive the ashes or cinders, which may fall through the grate in the top of the air-box; and it can be readily withdrawn, to clear it out.

There is likewise a small grate at the lower part of the space, upon which the fuel contained in the vase will rest. When this fuel is lighted, the flame and smoke will draw downward, and, descending through the grate, will pass through the hole in the bottom of the vase into the hollow pedestal, and through the grate in the top of the air-box: it then paffes horizontally in the space between the two middle partitions of the air-box, and proceeds in the same direction towards the back of the chimney; there dividing, one turns to the right and paffes to the right end of the middle partition; then coming forwards, it turns round the near end of the outside partition; then moving backwards, it arrives at the opening into the bottom of one of the upright corner funnels behind the niche, through which it ascends into the chimney, thus heating that half of the box and that side of the niche. The other part of the divided flame paffes to the left, round the far end of the middle partition, round the near end of the outside partition, and so into and up the other corner funnel; thus heating the other half of the box, and the other side of the niche. The vase itself, and the box, will also be very hot; and the air surrounding them being heated, and rising, as it cannot get into the chimney, it spreads in the room; colder air succeeding, is warmed in its turn, rises, and spreads, till by the continual circulation the whole is warmed.

If there is occasion to make the fire when the chimney does not draw, it must not be begun in the vase, but in one or more of the passages of the lower air-box; first withdrawing the sliding front of the air-box, and covering the mouth of the vase. After the chimney has drawn some time with the fire thus low, and begins to be a little warm, those passages may be closed, and another fire kindled in the hollow pedestal, leaving its sliding shutter a little open; and when it is found that the chimney, being warmed, draws forcibly, that passage may be shut, and the vase opened, to make the fire there, as above directed. The chimney, well warmed by the first day's fire, will continue to draw constantly all winter, if the fire is made daily.

In the management of this stove, there are certain precautions to be observed, at first with attention, till they become habitual. To avoid the inconvenience of smoke, the grate must be cleared before beginning to light a fire. If it is found clogged with cinders and ashes, the grate must be lifted up with the tongs, to let them fall upon the grate in the top of the air-box; the ashes will go through it into the drawer, and the cinders may be raked off through a sliding door in the pedestal, and returned into the vase, when they are to be burnt. Care must be taken that all the sliding-plates are in their places, and closely shut, that no air may enter the stove but through the round opening at the top of the vase; and to avoid the inconvenience of dust from the ashes, let the ash-drawer be taken out of the room to be emptied. The passages should be cleaned or raked out, when the draught of the air is strong inwards; and the ashes must be put carefully into the ash-box, whilst it remains in its place.

If it is required to prevent the fire burning in the absence of the proprietor, it may be done by removing the brafs frame from the top of the vase, and covering the passage or opening into the top of the vase with a round tin-plate, which will prevent the entry of more air than barely sufficient to keep a few of the coals alive. When the fire is wanted, though some hours afterwards, by taking off the tin-plate, and admitting the air, the fire will soon be recovered.

The effect of this machine, well managed, is to burn not only the coals, but all the smoke of them; so that while the fire is burning, if the top of the chimney is observed, no smoke will be seen rising, nor any thing but clear warm air, which, as usual, makes the bodies feel through it appear waving.

But it must not be imagined from this, that it can be a cure for bad or smoky chimneys, much less that, as it burns the smoke, it may be used in a room that has no chimney. It is only by the help of a good chimney, and the higher the better, that it produces its effect at all; and though a plate of plate-iron sufficiently high might be made in a very lofty room, the management would prevent all disagreeable vapour would be too nice for common practice, and small errors would have unpleasing consequences.

It is certain that clean iron yields no offensive smell, when heated; whatever smell of that kind is perceived where there are iron stoves, proceeds, therefore, from some foulens burning or fuming on their surface; they should, therefore, never be left upon, or greased, nor should any dust
STOVE.

Dust be suffered to lie upon them. But as the greatest care will not always prevent these things, it is well once a week to wash the stove with soap-lees and a brush, rinsing it with clean water.

The advantages of this revered flame in stoves are very considerable. The chimney does not grow foul, nor ever need sweeping; for as no smoke enters it, so no foot can form in it.

The air heated over common fires instantly quits the room, and goes up the chimney with the smoke; but, in the stove, it is obliged to descend in flame, and pass through the long winding horizontal passages, communicating its heat to a body of iron-plate, which, having thus time to receive the heat, communicates the same to the air of the room, and thereby warms it to a greater degree.

The whole of the fuel is consumed by being turned into flame, and the benefit of its heat is obtained; whereas, in common chimneys, a great part goes away in smoke, which may be seen as it rises, but it affords no rays of warmth. Some idea may be formed of the quantity of fuel thus wasted in smoke, by reflecting on the mass of foot that a few weeks' firing will lodge against the fides of the chimney; and yet this is formed only of those particles of the column of smoke which happen to touch the fides in its ascent. How much more must have passed off in the air? and we know that this foot is full fuel, for it will burn and flame as such; and, when hard caked together, is indeed very like and almost as solid as the coal from which it proceeds. The destruction of fuel goes on nearly in the same quantity in smoke as in flame, but there is no comparison in the difference of heat given. When fresh coals are first put on a fire, a considerable body of smoke arises. This smoke is, for a long time, too cold to take flame; but if a burning candle is plunged into it, the candle, instead of inflaming the smoke, will instantly be extinguishe. Smoke must have a degree of heat to be inflammable. As soon as it has acquired that degree, the approach of a candle will inflame the whole body, and the difference of the heat which it gives will be very sensible. A still easier experiment may be made with a candle itself. Hold your hand near the fide of its flame, and observe the heat it gives: then blow it out, the hand remaining in the same place, and observe what heat may be given by the smoke that rises from the still burning wick; you will find it very little: yet that smoke has in it the fulness of much flame and, if it be produced to you, if you hold another candle above it so as to kindle it. Now the smoke from the fresh coals, laid on this stove, instead of ascending and leaving the fire, while too cold to burn, being obliged to descend through the burning coals, receives among them that degree of heat which converts it into flame, and the heat of that flame is communicated to the air of the room, as above explained.

The flame from the fresh coals laid on in this stove, descending through the coals already ignited, preserves them long from consuming, and continues them in the state of red coals, as long as the flame continues that surrounds them, by which means the bars, crouching from the fides, are of much longer duration than in any other, and fewer coals are therefore necessary for the day. This is a very material advantage indeed. That flame should be a kind of pickle to preserve burning coals from consuming, may seem a paradox to many, and very unlikely to be true, as the doctor tells us it appeared to himself the first time he observed the fact: he therefore relates the circumstances, and mentions an easy experiment, by which his reader may be in possession of every thing necessary to the understanding of it.

In the first trial he made of this kind of stove, which was constructed of thin iron plate, he had, instead of the vase, a kind of inverted pyramid, like a mill-hopper; and fearing at first that the small grate contained in it might be clogged by cinders, and the passage of the flame sometimes obstructed, he ordered a little door near the grate, by which he could occasionally clear it; though after the stove was made, and before he had tried it, he began to think this precaution superfluous, from an imagination that the flame, being contracted in the narrow part where the grate was placed, would be more powerful in consuming what it should there meet with, and that any cinders between or near the bars would be presently destroyed and the passage opened. After the stove was fixed and in action, he had a pleasure now and then in opening that door a little, to see through the crevice how the flame descended among the red coals, and observing once a single coal lodged on the bars in the middle of the focus, he observed by a watch in what time it would be consumed: he looked at it long without perceiving it to be at all diminished, which surprised him greatly. At length it occurred to him, that he had seen the same thing a thousand times, in the conversion of the red coal formed in the snuff of a burning candle, which, while enveloped in flame, and thereby prevented from the contact of the passing air, is long continued, and consumed instead of diminishing, so that we are often obliged to remove it by the smoke, or else to blow the flame into the air, where it presently consumes to ashes. He then supposed, that to consume a body of air, passing air was necessary to receive and carry off the separated particles of the body: and that the air passing in the flame of the stove, and in the flame of a candle, being already saturated with such particles, could not receive more, and therefore left the coal undiminished as long as the outward air was prevented from coming to it by the surrounding flame, which kept in a situation somewhat like that of charcoal in a well-toted crucible, which, though long kept in a strong fire, comes out unconfumed.

This stove of Dr. Franklin is very ingenious, and has been much used in France, where the management of coal-fires is but little understood, and they are therefore induced to use stoves in preference to open fires, when they burn pitch-coals. Dr. Franklin completed the stove first described in 1771, and used it in London during three winters. While he was in France, he contrived another grate for burning pitch-coals, which has the same property of burning the smoke, and of the same time the fire is exposed in a grate. The grate is a short cylinder, with its axis placed horizontally, and the end turned towards the apartment; one of its circular ends being made with bars, and the other is a backplate: it is a foot (French) in diameter, and eight inches deep or long between the bars and the back; the fides and back are of plate-iron, the fides having holes of half an inch diameter, and three or four inches distant from each other, to let in air for enlivening the fire: the back is without holes, and the fides do not meet at either the top or bottom by eight inches; and this space is filled with grates at small bars, crooking from front to back, let in air below, and let out the smoke or flame above. The three middle bars of the front grate, that is, the circular end, are fixed; the upper and lower may be taken out and put in at pleasure, when hot, with a pair of pincers. The whole of this cylindrical grate turns upon pivots fixed in the opposite fides, across the centre of it: the pivots are supported by a crotchett, the stem of which is an inverted conical tube, five inches deep, which fits as many inches upon a pin, which is fixed upright in a cast-iron plate that lies upon the hearth. In the middle of the top and bottom grates are
STOVE.

are fixed small upright pieces, about an inch high, which, as the whole is turned on its pivots, float it when the grate is perpendicular. By this means the grate can be inverted by turning it over upon its pivots, but as that will prevent the back-plate to the apartment, it requires to be turned half round horizontally upon the conical pin to bring the front bars to the room.

In making the first fire in the morning with this grate, there is nothing particular to be observed; it is made as in other grates, the coals being put into the cylindrical grate above, after taking out the upper bar, which must be replaced when they are in.

The round figure of the front bars filled with fire, when thoroughly kindled, is agreeable: it represents the great giver of warmth to our system. As it burns down, it leaves a vacancy above, which must be filled with fresh coals, the upper bar is to be taken out, and fresh coals thrown in, the bar being afterwards replaced. The fresh coals, while the grate continues in the same position, will throw up, as usual, a body of thick smoke; but every one accustomed to coal-fires in common grates must have observed, that pieces of fresh coal stick in below among the red coals, have their smoke so heated, as that it becomes flame as fast as it is produced, which flame rises among the coals, and enlivens the appearance of the grate. Hence the smoke be the use of his swivel-grate: by a push with the tongs or poker, it can be turned over on its pivots till it is inverted, and the front bars face the back of the chimney; then turn it gently round on its vertical socket or axis, till it again faces the room, whereby all the fresh coals will be found under the live ones, and the greater part of the smoke arising from the fresh coals will, in its passage through the live ones, be heated so as to be converted into flame. By this means much more heat is obtained from them, and the red coals are longer preserved from consuming. This construction, though not so complete a consumer of all the smoke as the vase, is yet fitter for common use, and very advantageous; it gives also a full sight of the fire always, a pleasing object which we have not in the other. It may with a touch be turned more or less from any one of the company that desires to have less of its heat, or pretented full to one just come out of the cold; and when the front bars of the grate are supported in a horizontal position, a tea-kettle may be boiled on them.

Notwithstanding the acknowledged advantages of Dr. Franklin’s construction of a stove, the expense and trouble of it, and the difficulty of procuring workmen who understand the manner of executing it, have prevented the general use of his stoves. Mr. James Sharp, with a view of obviating these objections and difficulties, has proposed several improvements, for which he has obtained his majesty’s patent. According to the method which he proposes, they are easily accommodated to any rooms, where communication can be had with the external air; both to those which have, and those which have not chimneys; so that not only small rooms, but the largest halls, libraries, or churches, may be warmed in a more effectual manner than had ever been done before, and the greatest degree of heat produced from a given quantity of fuel. Mr. Sharp, by adding funnels to the top, renders these stoves fit for any chimney, and by lengthening the funnel, to any place without a chimney. By the hollow base with which his stoves are furnished, he is able to apply them with much greater effect to the external air, without any addition of brickwork; and by the alterations in the air-box, a much greater quantity of warm air is introduced than it was possible to introduce in their former state. If a stove of this kind is to be placed in a common fire-place, a hole must be made through the back of the chimney, or through the hearth, to communicate with the external air; and this hole should be made as large as possible, and in a defending position, so that the outward air may ascend towards the stove. The hollow base of the stove must be placed against this hole, so as to cover it completely; and the bottom of the base must be fitted so close to the earth, and pointed with lime or putty, that the air may not pass. Upon the stove there must be put a few feet of iron funnel to reach above the breadth of the chimney; and the chimney inclosed by iron plates, so constructed and placed in a square or oblong iron frame, that they may be easily removed when the chimney wants sweeping. By this construction, the warm air, introduced by the stove, will be carried into the room, which would otherwise pass up the chimney, and be lost. But if the stove is to be fixed in a room where there is no chimney, it may be placed in any part of it, where communication may be had with the outward air; and nothing more is necessary than a sufficient length of funnel to carry it through the roof, or wall, or window, or into any other chimney that may be convenient. If the fire-place be too small for the stove, the chimney may be closed by the aforementioned frame and plates, and the stove stand before the fire-place, and the smoke be turned off, by the help of a circular elbow, into the chimney above the mantel-piece. Many of these stoves, it is said, have been lately put up, in order to cure smoky chimneys, and have always succeeded. For farther particulars, see Sharp’s Account of the Air-Stove Grates, &c.

The inhabitants of the northern parts of Europe have long been accustomed to the use of stoves in which the fire is shut up, and gives out its heat to a draught or current of air, which is made to pass through proper openings in the stove, and when sufficiently warmed, enters into the apartment. The smoke arising from the fuel is made to pass through a circuitous passage of flues, by which means the greatest part of the heat is absorbed. Stoves on this principle are known in England, but are very seldom used, except for warming of halls, staircases, and passages, in grand houses, as the English are not contented to feel the air warm, unless they see the fire. In Russia, Sweden, and other northern countries, they are indispensably necessary, as without them, it would be impossible to keep the rooms tolerably warm. A common fire-place has too large an opening, and smoke be not taken up by the wood, &c. the heat it produces is hardly sensible, because it follows the current of the air, and is carried off by the smoke. The stoves, on the contrary, retain the heat a much longer time; and as their external parts, and also their flues, are very thin, they communicate their heat very readily, so that with a small quantity of wood, they warm an apartment much more than the fire of a common fire-place would do, with six times the quantity. For it was not sufficient that the inhabitants of these severe climates should discover the most ingeneous means of keeping up in their houses a comfortable degree of heat, it was also necessary that this should be done with the least possible expense of fuel.

The stoves which they employ perfectly fulfill the above-mentioned intentions; they are also susceptible of every kind of ornament. The more surface we give to a stove constructed in this manner, the more the heat is increased, consequently we must not be surprised to find that this kind of stove sometimes occupies the whole height of an apartment, its width and depth being proportioned to its height.

The construction of these stoves is simple; they consist of four,
STOVE.

four, five, or more small chambers, built one above another: the lower one is for the fire which burns in it, and the smoke rising from it enters into the chamber immediately above, then into the third, and from that to the fourth. The passageways through which the smoke enters into one chamber from that beneath, are, in all cases, made at the corner of the chamber, opposite to the passage at which the smoke will pass out from the same chamber to the next above it. By this means the smoke is obliged to pass through the whole of the chamber, and has the greatest chance of transmitting its heat. A fire lighted in one of these boxes early in the morning, and with a small quantity of fuel, will retain a strong heat during the whole day. The door of the fire-place is only opened to put in wood, and remains afterwards constantly shut. The wood lies upon a grate, consequently it is not buried in and stifled by the ashes. The ash-hole is spacious, and one or two feet in height, according to the capacity of the stove. Two doors are placed at the extremities of the ash-hole, and the current of air is very considerable, by which the smoke is carried up with great force, and the wood burns very briskly.

Stoves of this kind may be advantageously placed in halls, at the bottom of staircases, and in the anti-chambers of great houses: they may also, by proportioning their size to that of the rooms for which they are intended, be made use of in the housetops of private persons. To this it may perhaps be objected, that the heat produced from these stoves is unwholesome, because they deprive the air of its moisture; and that the air, by being made too dry, loses its elasticity, in consequence of which, respiration becomes difficult and laborious. These objections would appear of greater weight, if we had not the example of the Kuffians, the Swedes, the Danes, the Germans, and in short all the inhabitants of the north of Europe, to show that those who are habituated to such stoves, do not find them unwholesome. If others should be sensible of inconveniences from the dryness of the air in the apartment, it may be easily removed by the very simple expedient of placing upon the stove a vessel of glass or earthen-ware, which has a large surface, and is very shallow: this being filled with water, will indefinably evaporate, and restore to the air the moisture of which the heat of the stove has deprived it: the air will then recover its elasticity. If orange-trees are exposed to the heat of such a stove, and the fire is not properly regulated, the plants grow yellow and lose their leaves, especially if the air is not changed, which in winter is not very conveniently done; but if a vessel of water be placed upon the stove, the evaporation of the water will preserve the trees.

In a memoir published by M. Guyton in the Annales de Chimie, he has explained the construction of the stoves employed in Sweden, and recommends the adoption of one constructed on the same principle for general use in France.

The memoire is translated in the Repertory of Arts, 1st Series, vol. xvi. The construction of the stove which is there recommended may be improved, to adapt it to our use in England, where pit-coal is used: but the following principles, which the author lays down, are very useful as guides in making all kinds of stoves for warming apartments.

1. Heat is produced only in proportion to the volume of air confused by the fuel.

2. The quantity of heat produced is greatest, (the quantity and quality of the fuel being the same,) when the combustion is complete.

3. The combustion is the more complete, in proportion as the fulineous part is longer retained in channels where it may undergo a second combustion.

4. The only useful heat is that sent out into, and retained in the space intended to be heated. The temperature of that space will be higher in proportion, as the current which must be renewed from without to support the combustion, is less enabled to take up its passage the heat produced.

Hence the following inferences evidently arise:

1. The fire-place ought to be insulated from all bodies that are rapid conductors of heat. All the heat that goes out of the apartment is usefully lost, unless intentionally directed into another apartment.

2. Heat being produced only by combustion, and combustion being sustained only by a current of air, the current should be brought in by channels, where the needful rapidity may be preferred without being too distant from the space to be warmed, so that the heat it there departs, may be gradually accumulated in the whole of the insulated furnace, in order afterwards to flow out of it slowly, according to the laws of the equilibrium of that fluid.

3. The wood being far consumed as to give no more smoke, it is advantageous to close the mouth of these channels, in order to retain there the heat that would otherwise be carried off through the upper flue, by the continuance of a current of fresh air, necessarily of a low temperature.

4. Lastly, it follows from these maxims, that all things being equal, a higher temperature will be obtained, and supported during a much longer time, by forming, in the internal parts of the stove, or under the hearth of a chimney, and in their vicinity, tubes in which the air coming from without may be warmed before it enters the apartment, to serve the purpose of combustion, or replace that which has been consumed. These have been called bouche de chaleur (mouths or apertures of heat); because, instead of contemplating their principal use and intention, it is commonly imagined that they are only made in order to give by their issue a more rapid current to the heat produced. Nor is this idea absolutely devoid of foundation, since the air that issues from them has only changed its temperature, by carrying off a portion of the heat that would have remained in the interior. Thence, however, who would propose the mouth to the most important object, which is the retaining of the heat as long as possible, do not consider that they may be closed, and all communication with the external air cut off by a simple slide, and, therefore, it is easy to derive from them every possible advantage without any inconvenience. And we may add, that in small apartments, or such as are accurately closed, they are often indispensably requisite, if we could avoid being exposed to currents of cold air. Dr. Franklin very justly quotes a Chinesse proverb to this effect: "Shun a current of air, it's a narrow passage as you would the point of an arrow."

The Swedish or Russian stoves, which have chambers for the reception of the flame and smoke, are little known in this country: but stoves which are in common use in the halls and vestibules of our great houses are French stoves. They differ from the others in having a very great length of small flues or winding passages, through which the smoke passes, and communicates its heat to the air, which circulates in similar passages, until it becomes warmed, and makes its exit through the mouths into the apartment. This method is not so simple as the small chambers or apartments of the Russian stoves, nor is it so good in the long run; because the passages are very liable to become clogged with soot:
and even before they are so clogged as to intercept the passage of the smoke, the transmission of the heat is much impaired, because the interior surfaces of the flues becoming coated with soot, do not conduct the heat so rapidly, and in consequence, a great part will still pass out into the chimney. Also, these flues with small passages require a stronger draught in the chimney, to make the air pass through the passages, than when chambers are used.

The Holland stove, which has a flue proceeding from the top, the fire-place and ash-pit being closed by small iron doors opening into the room, comes next to be considered. It is frequently made of iron-plate, and is most commonly called a German flue. Its conveniences are, that it makes a room warm all over, for the chimney being wholly closed, except the flue of the flue, very little air is required to supply that, and therefore not much rushes in at crevices, or at the door when it is opened. Little fuel serves, the heat being nearly all fared; for it radiates almost equally from the four sides, and the bottom and top, into the room, and preferably warms the air around it, which being rarefied rises to the ceiling, and its place is supplied by the lower air of the room, which flows gradually towards the flue, and is therefore warmed and rises in its turn, so that there is a continual circulation, till all the air in the room is warmed. The air, too, is gradually changed by the flue-doors being in the room, through which part of it is continually paffing, and that makes these flues more wholesome, or at least more pleasant, than the German flues, next to be spoken of. But they have the inconvenience that there is no fight of the fire, which is in itself a pleasant thing, nor can any other use be conveniently made of the fire but that of warming the room.

When the room is warm, people not seeing the fire are apt to forget supplying it with fuel till it is almost out, then growing cold, a great deal of wood is put in, which soon makes it too hot. The changes of air are not carried on quick enough, so that if any smoke or ill smell happen in the room, it remains a long time before it is discharged. For these reasons, the Holland flues have not been much introduced among the English (who love the sight of the fire), used in workshops, where people are obliged to sit near the windows for light, and in such places they have been found of great use.

The real German flue is made like a box, one side wanting, and that side is built against the wall of the room. It is composed of five iron-plates screwed together, and fixed so as that the fuel can be put into it from another room, or from the outside of the house. It is a kind of oven reversed, its mouth being without and body within the room that is to be warmed by it. This invention certainly warms a room very speedily and thoroughly with little fuel: no quantity of cold air comes in at any crevice, because there is no discharge of air which it might supply, there being no passage into the flue from the room. These are its conveniences: its inconveniences are, that people have not so much fight or use of the fire as in the Holland flues, and are moreover obliged to breathe the same unchanged air continually, mixed with the breath and respiration from one another's bodies, which is very disagreeable to those who have not accustomed to it.

This may be remedied by making a small aperture into the flue, with a register to draw off the air. This kind of flue is still less in use in England than that which we have before described, and which is generally called the German flue, although it is used by the Dutch instead of the Germans.

Mr. Strutt, in their extensive cotton-mills at Belper, in Derbyshire, have employed a kind of flue which is found to answer extremely well; it consists of what is called a cockle, that is, a square chest or vessel of iron-plated, riveted together in the manner of a boiler, and let in a furnace, so that a fire can be made within itself upon a grate, and the smoke will pass off through a small passage into the flue which conducts to the chimney, the passage of which is regulated by a sliding damper. The cockle is of considerable dimensions, as much as four feet square and five feet in height, and the fire is made at the bottom of it, upon a grate of about fourteen inches by eighteen, so that the fire does not any where touch the inside of the cockle, but the heat rising up therein gives a considerable and equal heat, without rendering it so hot as to burn the air which it is intended to warm, for if that is once done the air will be rendered unpleasant.

The cockle is inclosed in a casing of brick-work, which is of the same shape as the cockle, and leaves a space all round between a few inches. This space of brick-work is again surrounded by walls of brick-work, leaving a space of about eighteen inches all round; and these walls are carried up, to form the chimney or funnel to convey the warmed air up to the several apartments of the mill. This chimney is divided, by thin brick partitions, into as many different flues as there are floors to be warmed; and a small opening is made, with a register, from each flue into the apartment it is intended to supply. This opening is made close to the floor; and in order to make a change of the air, ventilators are placed high up in the apartment, so as to be near the cockle.

This division of the chimney into several different flues is intended to equalize the supply of air to the several apartments, and by this means the upper apartments are equally well supplied with warm air as those below.

In order to make the air pass in contact with the surface of the heated cockle, a horizontal partition is built in the space between the chimney and the brick-casing of the cockle. The level of this partition is at about one half the height of the cockle, and its effect is to divide the brick-casing of the cockle into two halves, one above the partition and the other below. The cold air is freely admitted into the lower part of the chimney beneath the partition, but cannot escape into the chimney above it, without entering into the space between the cockle and its brick-casing, through a number of small openings made in it beneath the horizontal partition; and in thus passing in contact with the surface of the cockle the air becomes heated, and passes out again, through openings in the brick-casing, into the chimney above the partition. In order to make the cold air strike more forcibly against the heated surface of the cockle, a small iron tube is fitted through each of the openings in the lower part of the casing, and the ends of these tubes approach very near to the surface of the cockle. Mr. Strutt has introduced this kind of flue into the new Infirmary at Derby, and in several other similar institutions it has been adopted with great success.

In 1799, Mr. James Burns of Glasgow took out a patent for an improved flue, or fire-grate, to burn with an open fire: his flue has a very elegant appearance, and several advantages. The object of the improvement was to prevent the heat generated by combustion, and thrown out into the apartment by radiation, from being unnecessarily wasted by the draught of air for the support of the fire, as is usual in flues or grates of the common construction; where all the air that goes to maintain the combustion is furnished from the warm air in the room, the waste of which is supplied by the exterior cold air, which comes pouring into the room at the bottoms
STOVE.

bottoms of the doors, or by the sides of the windows, and thereby undone a great part of the effect that otherwise would be produced by the fire. To accomplish this intention, the air that maintains the fire in the improved stoves is brought through a tube, which is called the air-tube, from the outside of the house, and may be made to pass between two of the joists, (where the floors and ceilings are close enough to allow this,) so as to be brought to the bottom bars of the grate, without having any communication with the interior air of the room; while, at the same time, the grate and parts connected with it are so constructed, that when the fire is not wished to be supplied with cold air from the outside of the house, the passage may be shut more or less perfectly by means of a valve, a small door, a cock, or any similar contrivance. When convenience does not admit of the air-tube being carried to the outside of the house, it may be carried to a cellar, larder, or store-room, and the flame end will be gained, with this further advantage, that such cellar, or other apartment, will be always well ventilated, and prevented from acquiring or retaining any unhealthy or disagreeable smell.

The principle is to supply the fire with air from without the room or apartment, so as to prevent the warm air of the room from being drawn to the fire-place and hurrying up the chimney, while, at the same time, all the advantages of open grates may be enjoyed.

The form of Mr. Burns' stove is that of a vafe or urn placed in the chimney-place, which is made circular, to form a niche for its reception. The urn is open at top, and the sides are formed of open work or grating, with a grated bottom, forming a sufficient space to contain the fire; but the pedestal and lower part of the vafe are made close, to prevent the entrance of air to the fire, except that which passes up from the air-tube through the hollow pedetal; and within this pedetal is an air-valve, which opens and shuts by a register, to regulate the entrance of the current from the open air. In the pedetal of the vafe is a drawer, to receive the ashes. The niche or chimney in which the vafe is placed, has the usual opening at the top, to cause a draft to the face of the furnace. The air for the support of the fire enters from the external air, through the tube or air-pipe before described, and passes into the hollow pedetal of the vafe; and having passed through the hollow neck or stem of the vafe, it finds no difficulty in passing up through the bottom of the grate, the back or side of the ash-drawer next which the aperture is being made low, to allow it to flow in freely. The grate and its internal cavity may be of any convenient form, but circular or elliptical will answer best, especially when another improvement is applied. This is a glass door or iron-work fence or screen, to prevent those dreadful accidents which so frequently occur in ladies' or children's clothes being set on fire by sparks from the grate. Where this safe-guard fence or screen is wished to be applied, the jaspe of the chimney where the grate is to stand must be a semi-cylinder, or nearly so, with a lining or cover, made of metal, at such a distance from the semi-cylindrical wall or niche in which the vafe is placed, as to give sufficient room for allowing the safe-guard or fence to be slid round into it, when the fire is wished to be left open to introduce freer fuel, or when the drawer with the ashes is to be removed. The fence is a frame-work of metal, which, when filled up with glass, or with wire-work, forms a portion of a cylinder, answerable to the curvature of the space between the back of the chimney and the lining above-mentioned, made in one or two pieces, and moving in a circular groove in the hearth, which serves to conduct it into its place behind the grate, when the fire-place is wanted to be left open, as before-mentioned. The top of the front of the opening (the chimney-piece) projects in a circular form, or is furnished with an added projection, made of metal, and furnished with a circular groove on its under surface, of the same radius as the groove in the hearth, for the purpose of guiding the upper part of the frame of the guard. The glass with which the frame of the guard is filled may be stained or painted; complete safety is obtained, and, at the same time, the comfort arising from the view of a cheerful fire is not prevented by the interposition of any opaque body. But for nurseries or the like, where convenience and safety are more the objects than elegance or luxury, the frame-work may be filled up with wire-work.

Instead of such grooves at top and bottom for the fence to move in, the fence itself may be furnished with a groove at its top and one at its bottom, to receive any projecting piece of metal, or other substance of proper curvature; or its bottom groove may receive the upper edge of the fender, which, being made to a proper curve, and properly adjusted and kept in its place, will answer the same end. But whichever of these ways be followed, or whatever other method of construction (for it may easily be varied to answer circumstances), rollers or castors should be provided at the lower part of the fence, to make it move with greater ease, either to the front of the grate, or into the space between the back of the chimney and the lining above-mentioned.

Where either the glass or the wire-work frame, or both of them, are meant to be applied to figures or rectangular chimneys, without the trouble of giving them a semi-cylindrical form, the lining to receive the fence or fences may be introduced at the sides, or jambs, of such chimneys; or the fence may be made to slide, by means of pulleys, into the wall above the opening, or be slid sideways into the walls at the sides of the openings.

Besides the advantages already pointed out as connected with them, these stoves possess also the following; any room or apartment may be heated by their means with a much smaller quantity of fuel than by common open fires; at the same time, the advantage of seeing the fire is not lost, the whole being visible through the front of the grate, for these grates have side as well as bottom bars, which allow the radiant heat and light to be thrown out into the room, without any impediment; and, in fact, large rooms, halls, and the like, which by the usual methods can hardly be warmed, or made at all comfortable in cold weather, may, by means of these improvements, be heated as effectually as the smallest apartment; for when their full effect is wanted to be procured, it is only necessary to keep the fence in its rears, that even that portion of heat which would be kept back by the interposed glass or wire-work, may be thrown out into the room, and perform its office.

In 1804, Mr. Josiah Jowett of London obtained a patent for a very similar contrivance, which he called a fire-guard stove, which is intended to prevent accidents from sparks of fire flying out. The stove itself is an open fire, and is usually made of a cylindrical form, the axis of the cylinder being vertical. One half of the cylinder which faces the apartment is made with bars at the lower part, to contain the fire, and an opening over them to feed it. The back part of the cylinder is made of cast-iron plate; but, instead of the brick-work being built up close round the back, a small space is left to receive the guard. The weight of the stove or grate is supported upon a vertical iron bar, which is in the centre, or axis of the cylinder, which forms the stove, and the guard swings round upon this bar as a centre, and being a half-cylinder of wire-work, can be brought in front to insulate the
The fire-guard may be fixed to any stove which will admit of two centres or pivots being placed in a perpendicular line in the back of the stove, to support the fire-guard, and guide its motion; and the stove must admit of grooves on either side, for the guard to pass through, as the levers will direct. The principle of the action of the fire-guard, is that of being united to two centres or pivots, placed perpendicular one to the other; and it is connected to the two centres fixed to the stove by means of two lever-cranks, one end of which is fixed to the guard, and the other end of each to the centres or pivots, by which the guard swings in a rotary motion, passing through a groove formed in the stove on either side, to swing before the fire when required, and is brought into use by means of a handle or knob, fastened to the front edge of the frame of the guard for that purpose; or, instead of drawing it out with the hand, as before described, it may be brought into use by means of a spring fastened to the crank, and pressing against the cheek or back of the stove, to throw the guard forward. The same effect may be produced by means of a balance fastened to any part of the fire-guard, and working with a line or chain over pulleys fixed to the stove, or by means of the combined force of the spring and balance.

Mr. Allan Pollock took out a patent, in 1807, for a stove which is very similar to the Swedish stoves, having chambers through which the smoke is successively conveyed, and gives out its heat to the air of the apartment in which it is placed; in addition to this, the stove is made to give a constant current of warm air; for this purpose, the cold air is made to enter and circulate through winding passages, situated in the back of the fire-grate, or space in which the fire burns, and the frame passage is continued, by an iron tube, through the smoke-chambers up to an air-chamber situated in the top, from which it passes into the apartment. These stoves are made of cast-iron; but, to prevent the air receiving any taint from passing in contact with the hot iron, Mr. Pollock supplies a small addition to the smoke-moulds, in which the pipes are to be cast, which composition will become vitrified by the heat of the melted iron, when the frame is fused into the mould, and will form a glassy or vitrified lining to the tubes, and prevent the actual contact of the air with the iron. These stoves answer very well.

A very important improvement is those fire-places for burning of coal, which are generally called register-stoves, has been lately made by Mr. John Cutler of London, for which he had a patent in 1815. The stoves constructed by him are nearly such as are known by the name of register-stoves, being made of cast-iron plate to incline the fire-place at the back and sides, but open in front to the apartment; leaving only a passage for the smoke through a regifter, at the upper part of the inclosed space. Mr. Cutler's improvement consists in applying to such grates or stoves a chamber, or magazine, situated beneath the grate (or the space inclosed by grating) in which the fire is to burn. This chamber is to contain a magazine of fuel sufficient to supply the combustion for a whole day, or other required space of time; the bottom plate of the chamber is moveable; and by means of a wheel and axles, the fuel contained in the magazine can be elevated, so as to introduce a portion of the fuel into the grate at the lower part, or from beneath; and thus, from time to time, replace the fuel which is consumed, without the trouble of occasionally throwing on coals.

In order to make the fire burn, the flue or entrance to the chimney must be of such a construction, as will produce the most efficient draught or current of air to pass through and across the top of the fire. This improvement of introducing a supply of fuel into the grate from beneath, causes the fire to burn clear and with little smoke; because the smoke, or gas, which issues from the newly introduced fuel, when it is first heated, must of necessity ascend through the hot ashes of the fire, and be wholly consumed. Another improvement is to reduce the fire, or extinguish it, when it is left for the night. This is done by lowering down the whole of the fire from the grate into the chamber, or magazine, beneath the grate: the supply of air is thus interrupted, and the fire is completely inclosed in a deep chest, so that it is impossible sparks can fly out, and the fire soon becomes extinguished. The advantages of these improvements are by no means trifling. By burning the smoke, the whole effect of the fuel consumed is produced, and were this invention universally introduced into London, that pernicious foetid atmosphere in which it is hidden would be to improved, as to be equally pure with that of Paris, or other continental cities, where wood alone is used for fuel.

The burning of the smoke renders the sweeping of the chimneys unnecessary, and the danger of fire from the foot contained in the flue is avoided: also chimneys which throw out smoke into the room will, in almost all cases, be cured by this improvement, because the quantity of air or gas which must pass through the chimney is so small. To avoid the trouble of throwing on coal, and to have at all times a bright and cheerful fire, are matters of convenience, but are not wholly to be overlooked; and, lastly, to have the means of extinguishing the fire, when it is left for the night, is a most important improvement; when it is considered that, amongst the fires which happen every year in London, how many break out in the hours when the fires are left, and a great proportion are doubtless occasioned by fires left unextinguished.

The machinery for raising up the moveable bottom of Mr. Cutler's stove is very simple. The magazine-chamber is composed of iron plates joined together, and the moveable bottom is fitted to it, so as to leave as small a space round the edges as possible. A bar is fixed across beneath the bottom plate, and the ends of this bar pass through slits, or narrow openings, in the side plates of the chamber. To the extremities of the bar the ends of two chains are attached, and the upper ends of these chains are made to wind upon the ends of a horizontal axle, which extends over the top of the stove, so as to be within the chimney, and out of sight. The axle is turned round by a face or crown-wheel, fixed upon the extremity of it, and the teeth thereof are engaged by the teeth of a small pinion, the axis of which comes through the iron work of the stove; and the end has a small square hole in it, to receive a square or key upon a small winch handle. By means of this handle, the iron axle is turned round, and winds up the chains, so as to elevate the bottom plate of the magazine, and thereby raise up a portion of fresh fuel into the lower part of the grate, where it is burned, as before mentioned; and the smoke which first issues from the coal rises through the fire, and is thereby consumed.

Mr. Cutler has made a great number of these stoves, which are found to answer very well; they have all the same properties as Dr. Franklin's cylindrical grate, but in a greater degree; and the fire can be supplied with fresh coals at the lower part, without the trouble of inverting the grate.

Stoves, American, are contrivances for warming of rooms.
by a continual introduction and exchange of dry fresh air. These stove are elevated American, because the first patterns in cast-iron upon this principle were the invention of Dr. Franklin, who then resided in Philadelphia. See Fire-Places.

Stoves, Chinese. See Kang.

Stoves, Dutch and German. See Fire-Places.

Stoves, in Gardening, a sort of garden-building or erection, coming down, brick and won in the north, as well as partly in the east, and roofed wholly with glazed flues to the south; being furnished internally with a pit, or long, wide, deep cavity, for a hot-bath or beds, and with flues round the inside of the walls for fire-heat: the whole calculated to produce a certain temperature at all seasons, adapted to the culture of the tenderest exotic plants, as well as for forcing various kinds, both hardy and tender, into flower and fruit, &c. at an early season; and which was so named before the use of bark-beds, from being worked only by means of fire-heat.

By their means the gardener is enabled to forward many hardy plants to early perfection, such as various sorts of curious flowers, fruits, fallad-herbs, dwarf kidney-beans, strawberries, &c.; and likewise many sorts of seeds, cuttings, and layers of exotics are made to grow freely in the bark-bed of the stove, that without such aid would not grow at all in this country.

There are different sorts of stoves used occasionally for different purposes: as the bark-beds, for common use, which has both a bark-bed and flues; the dry-beds, for particular succulent plants, &c.; which is furnished only with flues for fire-heat, having no bark-bed; the forcing-beds, which is employed purposely for forcing hardy fruits, flowers, &c. into early perfection, being constructed both with bark-bed and flues, or only with flues. By the uniform, moderate, moist, growing heat in the first fort of stove, many kinds of such plants as have been mentioned are brought forward and preferred, and in which some require the bark-bed, others succeed in any part of the house; and still others, as the succulents, require the driest situation near the flues. Many of the more tender herbaceous and shrubby plants, (such as fuchsia) are plunged in the bark-bed, though the greater part of the herbaceous and woody sorts succeed well enough in any part. The bark-bed is principally allotted for the pine-apples; and most of the smaller succulents, particularly may be flattened mostly over the top of the flues upon shelves, out of the way of moisture, as being naturally very replete with humidity; and the hardy plants designed for forcing, such as strawberries, kidney-beans, and various sorts of flowers, &c. that are potted, may be placed upon shelves, or on the parapet wall of the bark-bed; but the nearer the glass the better, particularly strawberries: but good early kidney-beans may be raised in almost any part of the stove. When any sort of flowers are to be forwarded, such as roses, pinks, &c. or any bulbous flowers, as early as possible, they may be plunged in the bark-bed, and some be placed upon shelves, &c. to succeed them. This sort of stove is sometimes called the moist stove.

The second sort of stove, from its affording a dry heat, is intended principally for the culture of very succulent tender exotics of parched soils, that require to be kept always dry. Where there are large collections of this sort of plants, it is very useful to deposit the most succulent of them in separate stoves, for fear of the others, which perish more freely, occupying a damp air in winter, which may be imbibed by the succulents, and injure them, as being impatient of much moisture, particularly in that season. In this kind of stove, moveable flans or shelves are erected above one another, on which to place the pots of plants, such as the tenderer sorts of aloes, cereus, euphorbiuns, melon-thistle, and other very tender succulent plants, &c.; but most of them may be cultivated in a common stove, with proper care.

The third sort of stove is sometimes used principally for flowers, as is common about London, to force large quantities of early roses, pinks, and numerous other flowers for any curious tender annual flowers, such as bellflowers, &c. and for fruits both for forcing flowers and fruits, and several sorts of small plants, as strawberries, kidney-beans, &c.: so that they confite of two kinds, which are a bark forcing-stove, furnished with a bark-bed and flues; and a fire forcing-stove, having only flues for fire, without any bark-bed: the former of which is constructed like a common bark-stove, being furnished with a pit for a bark-bed to receive the pots of particular sorts of plants intended for forcing, in order to forward them as being possible; and with flues for fire-heat occasionally, and sometimes it is formed capacious enough to admit of a border of earth behind the bark-bed, next the back wall, serving for fruit-trees to be planted in the full ground, such as cherries, peaches, apricots, &c. for early forcing. The bark-bed is for receiving various sorts of plants in pots in winter, for forcing to maturity of growth or production in that season, or early in the spring, as pots of roces, pinks, dwarf tulips, hyacinths, narcissiules, honeyfuckles, hypercums, and many other flower-plants of small or moderate growth, both of the shrubby and herbaceous kinds; also any curious tender annual flowers, such as bellflowers, &c. may be forwarded in it; likewise pots of strawberries, dwarf cherries, and other small fruits, plunged either in the bark-bed, or placed anywhere towards the glassies; also pots or boxes of kidney-beans, fallading, &c.

But besides these large stoves, it is necessary to have what are called succession stoves, and small pits for striking, forwarding, and nurting the plants in, while they are in their infant state of growth, especially where the collections of them are large, in order to prevent the large stoves from being usefully filled with plants of productive nature, and for the purpose of greater convenience. The pits serving to strike the plants in, and the succession stoves for placing and continuing them in afterwards, until they become ready and fit for fruiting or setting into the large stoves.

Stoves are constructed in various ways, and of many different sizes and forms, so as to suit the forts of culture and management that are to be carried on in them; but the most generally useful dimensions for them are probably those of from about ten to twelve, or fifteen feet in height behind, with any fittable length, and eight, ten, twelve, or more in width, having from two or three to five or six feet of height in the front. Very lofty or capacious stoves are but rarely wanted.

The most economical form of stove, Mr. Loudon supposes, is that of a parallelogram, placed from east to west, of glass on the south side, roof, and ends; and masonry toward the north: but that the most elegant and eligible for the plants, is one placed north and south, and of glass on all sides; however, unless an inner roofing be used in this case, glass on all sides is precarious, especially in the northern parts of the island. Stoves of the dry kind are kept at a temperature, in general, between fifty-five and seventy degrees of Fahrenheit's scale, and moit stoves between sixty-five and ninety degrees of the same thermometer. Where the plants are grown in pots, and plunged in earth.
earth or bark; the pits should be made of considerable depth, to admit of the materials, as in the usual culture of the pine; but pits filled with earth, and managed in the manner proposed by the above writer for growing this sort of plants, is so decidedly preferable, both in respect to beauty and economy, that few, who well understand the plan and think for themselves, will reject it for flower-plants, though they should even think it unfit for raising or growing those of the pine kind. See Bromelia.

The different modes of constructing houses of this kind are now so well understood, that they need not be noticed in this place, especially as they have, in some measure, been pointed out under the culture of the feveral plants which are raised or managed in them, and under some other heads. Before, most of the late improvements in the flowers of them, which are the most material parts, will be seen below.

Theucculceon stones and pits are probably the belt and most conveniently arranged and formed, either in connection with or contiguous to the large flowers, so as to admit of the plants being readily removed into them. They may be made of different sizes, in proportion to those of the flowers, and be provided with flaring glases in different ways, according to circumstances, but mostly in the manner of the principal flowers, especially in the former.

The flower-plants which are raised in flower-plants should be of any large dimensions, but have axes somewhat proportionate to those of the flower-plants, having flowers and glases, for the most part, only upon the top parts of them.

The fewon to begin forcing in these flowers is principally from about the latter end of December to the end of January, according as the flowers, fruits, &c. may be wanted: the plants and trees intended for forcing in pots should have been potted either a year before, or in the preceding spring or autumn, and in winter sheltered from severe frost till the forcing time: it is necessary for the shrubs and tree-kins in particular, as if planted or potted the preceding year, or before, and they are well rooted and firmly established in the earth, it is of essential advantage; being all previously raised in the open ground, till advanced to proper growth for flowering and fruiting; and the fruit-trees at the same time, trained in the requisite order: those intended for planting in the internal border of earth behind, should be planted fully therein early in autumn, without being potted; some of which, such as peaches, nectarines, apricots, &c. being trained as wall-trees, others as low standards, particularly cherries; and vines, planted also against the front without, have the stems trained in through small holes, and conducted up under the flaring glases: but such plants as are to be raised from seed, should not generally be sown till the time the pots are placed in the flower for forcing. When the plants, seeds, &c. have been properly arranged in these flowers, they are soon set in motion by the bark-bed heat, and afterwards by making moderate fires on cold nights, and on days occasionally, in very severe weather, to support a constant proper warmth to continue the plants always in moderate growth; by which means, various flowers and fruits may be obtained two or three months before their natural season in the open air.

But those of the latter kind, or such flowers as are worked by fire-best only, are mostly used for forcing fruit-trees, having the whole or most part of the bottom space within formed of good rich earth, full two feet deep, in order to plant the fruit-trees entirely in the ground to remain; an alley or walk being either formed next the back wall, or carried along the middle, allowing a raised border along the back part for the reception of the chooser fruits to be trained as wall-trees; and the main middle space for small stands of moderate growth: in these, the belt forts of apricots, peaches, nectarines, cherries, plums, vines, and figs; likewise any small fruit-plants, as gooseberries, currants, raspberries; also tufts of strawberries, which should all be first trained in the open ground to a bearing state; may be introduced: the peaches, nectarines, apricots, and figs, should be planted principally toward the back wall, and trained to a trellis, as wall-trees: the cherries as standards, both small-headed, moderate, full standards, half standards, and dwarfs, disposed in the middle space, the tallest behind, and the lowest forward; with pots of strawberries and low flowers upon shelves near the glases; and the vines either within, towards the front, or wholly without, close against the front wall; and the flemas, or a strong shoot of each plant, drawn in through a small hole made for each, either in the wall, or in the timber of the front ejections; and the branches within trained up to the inside of the flaring glases upon trellis-work: in the vines planted on the outside, it is necessary to guard the stems in winter, especially some time previous to and during the forcing leason, with hay-bands wrapped closely round them, also to lay some dry mulch over the roots, to protect the whole as well as possible, that the progress of the sap may not be much retarded by the external cold, and to promote its flowering more freely for the advantage of the internal growth of the vines, &c.

When the lozenge to begin forcing or making the forces in these flowers is January, or early in February, continuing it moderately every night and morning, during the cold weather in winter and spring, to forward the different fruits to as early perfection as possible.

Great improvements have lately been made in the construction of houses of this as well as other similar kinds in which fire-heat is required; and better and more effectual modes of applying it in these and other cafes and uses suggested. In a communication from C. Lorimer, esq. to the Caledonian Horticultural Society, can-dues are strongly advised in the construction of such forts of houses. The flowers of this kind there employed, were, it is said, from twenty-five to twenty-six inches long, of a conical or taper shape, from thirteen to thirteen and a half inches in diameter at the large end, and from eleven to eleven and a half inches at the small end, measured from the inside. In laying them for a flue, the small end is inflected into the large one an inch or an inch and a half, and the joinings closed and made secure with lime-plaster. At first, fire-clay was employed for this purpose, but it cracked and fell off, and let the smoke get into the house; however, since the lime-plaster has been used, the flue has been perfectly tight, and the house free from smoke. It is thought, that perhaps it might be an improvement, if the cans were made of a cylindrical or drum shape, all the length of the same diameter, so that the ends would exactly fit one another, with about the half of the thicknesses of them taken off on the outsides, for three-fourths of an inch from each, in order to hold the plaster. This would make the flue, it is supposed, look much neater and better on the outside, as the swelling at the joinings from the flue would thereby be greatly reduced; and when the flue was cleaned, the foot would be more readily and with greater facility got out, as it would be quite smooth in the inside from end to end.

It may be urged as an objection, it is said, that the houses may not have so much steam from the can-flues as from those of the old construction, but this, it is asserted, will not be found to be the case. As full as much steam has been raised by sprinkling the cans by means of a fine-rose watering-
ing-pan or pot, after they have been sufficiently heated, as could ever be done by the flues of the former construction.

In one instance, though the cans had been made of common clay, they spread the heat very well, and notwithstanding the flue once took fire; only the can next the furnace became cracked, but those made of fire-clay are thought to be safer, the strongest fire that has been applied not having in the least injured them.

In consequence of the cans not being half an inch thick, it is said, that they transmit the heat sooner, and in much greater proportion, than flues of the old construction, which are commonly three inches thick in the sides, and one in the tile-covering at the top.

In laying the can-flues, the ends of them should rest upon a brick set on edge, which keeps the under sides or parts of them five inches from the ground, and of course none of the heat is drawn off or lost in that way.

It may be objected also, that it is said, to the can-flues, that they will cool sooner than the brick and tile ones; but so long as any fire remains in the furnace, the can-flues will transmit the heat, which is not the case with the old form of flues, when the fire becomes weak.

The invention of these flues is said to belong to Mr. Burnet, of Viewfield, near Dunbar, in Scotland, who some time since built a house for forcing vines thirty-five feet in length by thirteen feet in width, measuring in the inside, with one furnace, which is found fully sufficient to keep up a proper temperature in the coldest weather. This plan of flue was had recourse to in it with complete success, as he has since had the largest crops of grapes that have been there known upon vines of such an age as lately, indeed, every part of the house, from the bottom to the top, has, it is said, been loaded with a profusion of fine clusters, so thick, that they appeared everywhere almost touching each other. It has been found, that after the eyes of the grape-vines in this house are all fairly broken in the spring, and the gardener is at liberty to increase the heat in the house, the thermometer at eight or nine o'clock in the evening, commonly stands at from seventy-two to seventy-five degrees. The fire is then mended for the night; and the succeeding morning, about six o'clock, the thermometer has kept up within two or at most three degrees of what it was the night before.

The furnace in the house is built on the plan of the late Mr. Nicol, with Rumford doors; and when the fire is mended for the night, the ash-pit door is shut quite close, which prevents the heat being too much increased, and occasions a very small consumption of fuel; yet from the cans being so thin a proper degree of heat is transmitted, so as to forward the growth of the vines almost invariably.

In two small houses of this fort for vines, which have one of Mr. Nicol's or Mr. Loudon's furnaces to each, one of which has the flue built with bricks, and tile covers in the old method; but in the other the flue was some time since taken down, and a can-flue put in its place, which is considered to be a real improvement. In the former of these houses, a fire was put on the 14th of February, while in the latter there was no fire until the 30th of March following, yet the house with the can-flues ripened the grapes sooner than the other which commenced the fire about six weeks earlier, and with a considerable saving in fuel. In other trials since the above the result has been the same.

And the can-flues have been found equally advantageous in producing large crops of grapes in other instances, and capable of being beneficially employed for different other forms of fruit-trees that are forced in houses of this kind.

The superiority in the use of these earthen-ware tubes, in the place of those which are formed by stones, bricks, or tiles, is, it is said, very great indeed. On the best authority, they are stated to have been attended with remarkable success. Great crops, not only on those forts of vines which are considered the best bearers, but on those which are less productive, such as the Frontiniac, have been afforded by means of them in many different climates and situations; in all of which, the grapes were not only fine, but as well-taisted as those in any foreign climate or country; and, it is thought, that they promise not only to be greatly successful in this fort of culture, but also in that of the peach and nectarine. In short, two very great advantages may, it is supposed, be derived from the use of these flues; first, that an equal degree of heat may be had from much less fuel; and, secondly, that the same degree of heat may be easily supported, with much greater uniformity, both during the day and night. In order to procure any heat in the air of forcing-houses, when the flues are built of brick or stone, a strong fire is required, which is very apt to give too much. But with the can-flues, a very little fire, burning very slowly, will give out a sufficient degree of heat. Upon the whole, therefore, there appears no doubt that the introduction of can-flues into the forcing culture in houses of this kind, may be considered as a very important improvement in the horticultural art.

The can-flues which are thus used are capable of being easily made by any potter; for which, however, fire-clay instead of common should be employed, as having some advantages, which have been already seen.

A more improved and economical mode of constructing houses of these forts, has also lately been suggested, and communicated to the same society, by Sir G. S. Mackenzie, as the result of careful experiment. Sir George having often been surprised at the cold of houses of this nature, the most moderate of which seemed to him to put the innocent luxuries afforded by them out of the reach of persons of moderate fortunes, he resolved to attempt to erect one that should combine the least possible expense, with the means of raising more fruit in a given space than was done by any of the plans which are in common use. This bold attempt, considering the small number of plans for the purposes which are in use, or which have been proposed at different times, may be suppos- ed to be more difficult, and possibly impracticable. It has, however, it is said, been accomplished, and attended with such success, that the inventor is inclined to flatter himself it will be the means of enabling many persons to enjoy the productions of such houses who never thought of possessing them, and of adding so much to the produce of market-gardens, as to increase the quantity of the richer fruits brought to towns, and consequently to lower the prices, as this plan of training may be applied to such houses as have been already built.

The first matter that occurred to him as an object in which economy might be exercised, was the ends of such houses being constructed with glasses. He could see no reason or necessity for this; and it appeared plain, that a solid end of masonry, with a porch and double door, would be more effectual in preventing the escape of heated air, or the rushing in of cold, than a glass end and a glass door. The next object which he had in view in this intention, and for which he defined a remedy, was the frequent occurrence of breakage, during the movement of the furnace in giving air; and he conceived it possible to have them always fixed, and yet to have ample means of ventilating the house. It was likewise considered, that such expensive workmanship might thus be avoided. These are matters of some importance in the business; but the principal improvement is conceived to be, the method of training the plants in the house.
STOVE.

This and some other purpoises are effected in the following methods. The training is done by means of a frame-work, which is set up at the distances of six feet across the house, and the moving of the frames, the ventilation, and regulation of the heat, by the roof being covered with a composition, in which there are hatches fixed that may be opened by cords and pulleys, or by levers, and which shut by their own weight. The number of these hatches is, of course, to be regulated by the sizes of the houses, and the degree of ventilation which may be required. In the front, there are fah-frams made to slide part each other; so that in each division, about eight square feet may be opened. When the front is opened, and the hatches raised, a current of air instantly passes through, which may be regulated at pleasure; while all motion of the great front fasbes is avoided, and, of course, all risk of breakage from that cause prevented.

A trellis is formed on the crofs frame-work, on which the branches of the vines, peaches, nectarines, or other fruit-trees are trained. There are two trellises on each frame; and where vines are cultivated, they are planted two in each division, and one at every six feet on the back wall, in which such houses are fifteen feet high in that part, and two feet in height in the front part. Each vine in the division is trained to its respective trellis, and to half of the back wall of the building; the foil of the door; such flues being consequently not only much larger than is common even in these cases, but having the division-walls for supporting a pavement-floor over the flues, all made of open brick-work, the whole space, as above, was hereby converted into one large flue, or chamber for heated air, which being made to in Fus from the joints left in the stone-floor, circulates freely to every part of the house; so that with one common fire, the temperature of it, the area of which is 30 feet by 18, and 7 feet in height from the floor on which the flues rest, is kept inviolately from 700 to 900 of the Fahrenheit's scale, while the wet materials are hanging in it, and the shutters in the upper part are open. This effect, which is much greater than in other cases of smaller flues, is, it is said, entirely to be ascribed to the largeness of the flues. On these grounds it is conceived, that the simple application of such large flues as the circumstances of houses and other houses of that kind will admit, would not only be attended with great advantage of point of economy, as a very small fire would be sufficient to maintain the temperature usually required in such houses; and that, it is perhaps, in consequence, such flues properly constructed upon this principle are capable of being easily regulated, and will induce a much more uniform degree of heat. It would seem from the above trial, it is said, that the flues in general use are of too small dimensions; that there is not capacity in them for allowing the heated particles of air to expand; and that the heat passes through the narrow flues, and makes its escape with the smoke in a latent state, without being allowed to act upon a surface large enough to rob it of its caloric.

Upon this principle, large buildings and halls might, it is thought, be heated; and one fire might be made to heat a much greater range of vineyards, or other houses of the same kind, than is the practice at present. It would also be a great improvement in the construction of heated houses, and the inclining of gardens, where they are of the wall kind, to make the walls hollow, as well on account of such a mode of construction including a space for air, which is an excellent non-conductor, as of the facility with which the fire may be applied, by converting the whole, or the greatest part of the wall, into a flue or receptacle for heated air. When this is to be done, the fire-place should be kept as low as possible; and after answering its purpoise
the house, the flue might be made to communicate with
the hollow garden-wall, and the smoke made to escape
at a chimney situated, according to circumstances, at
a greater or less distance from the heated house. It is thought
that an apartment heated with flues of a large confruc-
tion, is less incident to sudden changes of temperature than
when the flues are small. The heat in large flues can be
regulated with much precision, and they are attended with
the advantage of seldom or never requiring to be cleaned.
In all chimneys for houses of this kind, an aperture should,
it is said, be made in the wall, with a close shutter, near the
top of such chimneys, where a lamp or lighted candle should
be introduced for an hour or two, immediately after the fire
is put on, in order to create a current, and thereby bring the
smoke to flue at the chimneys.

These constitute the most material hints and improvements
which have yet been thought of for bettering the construc-
tion of houfes of the stone and other similar kinds.

Stove Plants, in Gardening, such tender exotics from
the hot parts of the world as require the aid of the stove
in order to preserve them in this climate. They are very numerous,
so that our limits will not allow our reciting them.

Stove or Lump-Salt, in Rural Economy, a term applied
to that sort of salt which is prepared by a certain heat,
as about 225°, and afterwards dried in the flues employed
in works of that kind. See Salt.

Stoves, at Sea, are square boxes made of planks, and
lined with brick, for burning charcoal in, to dry the ad-
miral's victuals.

STOVEN, in Rural Economy, a word that signifies a
spailing flout from the floor of a fallen tree.

STOUNUCK, in Geography, a township of America,
in Cumberland county, New Jersey.

STOVER, in Agriculture, a general name for the dif-
ferent kinds of fodder arising from threified grain, whether
it be straw, chaff, or the short flaws, such as ears and
rough chaffy matter, separated by the rake or riddle from
the corn in chaff, after the straw has been removed by shak-
ing from the floor. But besides these sorts of short flary
materials, it also signifies, and is applied to, the pulls and
points which are broken off in the threfing of rape crops,
and which are eaten with great greediness as food by dif-
ferent sorts of live-rock; the pulls being often considered
as equal to hay, and the points equal to cut wheat-flour,
as fodder.

STOUTHAIN, in Geography, called by the Indians
Pokemitt, or Putipuog, i.e. taken from a spring that rifies
out of the earth, a township in Norfolk county, Massa-
husetts, incorporated in 1726, and containing 1600 acres of
land and 1134 inhabitants. It is bounded E. by Brantree,
W. by Sharon, and lies 15 miles southwardly of Bolton.
This township contains iron-ore of excellent quality, and a
rolling and flitting mill, which manufacture considerable
quantities of steel and iron. Charcoal, barks, and brooms,
in considerable quantities, are sent from hence to Bolton. In
the late war, a large quantity of excellent cannon wood was
made in this town, for the American army, from salt-petre,
the produce of the town in its vicinity.

STOVING, in Sail-making, is the heating of the bolt-
ropes, so as to make them pliable. They should be flored
in a stove by the heat of a flue, and not in a baker's oven or
a flue-tub; and tarred with the blue Stockholm tar. The
flexibility of them should be always considered in taking in
the flack, which must rest on the judgment of the sail-
maker.

STOUND, in Rural Economy, the name of a wooden
wedge to put small beer in.

Vol. XXXIV.
the residence of the bishops of Worcester. It was given to the diocese by Burdred, king of Mercia, and several of the bishops have strengthened and decorated it. In the reign of Charles I. it was taken and fold by the parliament, but after the restoration, it was re-edified by the succeeding bishops: it is a brick structure, with battlements, turrets, &c.—Beauties of England and Wales, vol. xv. Worcester, by Mr. Laird.

STOUSE Head, a cape on the east coast of the island of South Ronaldsay. N. lat. 58° 40'. W. long. 2° 47'.
